Solutions to every problem in Royden & Fitzpatrick’s *Real Analysis* (fourth edition, 2010) — 1062 problems across the book’s 22 chapters: Lebesgue measure and integration for functions of a single real variable, differentiation and integration, the L^p spaces, metric and topological spaces, Banach and Hilbert spaces, and measure and integration in full generality. The book is filed at Real Analysis (Royden & Fitzpatrick).

1.1 Problems 1.1–1.7

Problem 1.1. For $a \neq 0$ and $b \neq 0$, show that $(ab)^{-1} = a^{-1}b^{-1}$.

Solution. Throughout we use only the Field Axioms.

Step 0: $c \cdot 0 = 0$ for every real number c . Since 0 is the additive identity, $0 + 0 = 0$, and hence by the Distributive Property

$$c \cdot 0 = c(0 + 0) = c \cdot 0 + c \cdot 0.$$

Let d be an additive inverse of $c \cdot 0$. Adding d to both sides and using associativity of addition,

$$0 = c \cdot 0 + d = (c \cdot 0 + c \cdot 0) + d = c \cdot 0 + (c \cdot 0 + d) = c \cdot 0 + 0 = c \cdot 0.$$

Step 1: $ab \neq 0$, so that $(ab)^{-1}$ is defined. Suppose to the contrary that $ab = 0$. Since $a \neq 0$, the multiplicative inverse a^{-1} exists, and by associativity of multiplication together with Step 0,

$$b = 1 \cdot b = (a^{-1}a)b = a^{-1}(ab) = a^{-1} \cdot 0 = 0,$$

contradicting $b \neq 0$. Hence $ab \neq 0$, and the Multiplicative Inverse axiom provides $(ab)^{-1}$.

Step 2: Multiplicative inverses are unique. Suppose $x \neq 0$ and $xy = 1 = xz$. Then, using commutativity and associativity of multiplication,

$$y = 1 \cdot y = (zx)y = z(xy) = z \cdot 1 = z.$$

Thus a nonzero real number has exactly one real number whose product with it is 1; this is the uniqueness noted in the text just after the Field Axioms.

Step 3: The computation. Using commutativity and associativity of multiplication repeatedly,

$$(ab)(a^{-1}b^{-1}) = (ab)(b^{-1}a^{-1}) = a(b(b^{-1}a^{-1})) = a((bb^{-1})a^{-1}) = a(1 \cdot a^{-1}) = aa^{-1} = 1.$$

So $a^{-1}b^{-1}$ is a real number whose product with ab equals 1. Since $ab \neq 0$ by Step 1, the uniqueness established in Step 2 forces

$$(ab)^{-1} = a^{-1}b^{-1},$$

as claimed.

Problem 1.2. Verify the following:

- (i) For each real number $a \neq 0$, $a^2 > 0$. In particular, $1 > 0$ since $1 \neq 0$ and $1 = 1^2$.
- (ii) For each positive number a , its multiplicative inverse a^{-1} also is positive.
- (iii) If $a > b$, then

$$ac > bc \quad \text{if } c > 0 \quad \text{and} \quad ac < bc \quad \text{if } c < 0.$$

Solution. Recall the definitions in force: $\mathcal{P}$ denotes the set of positive numbers, subject to P1 (if $a, b \in \mathcal{P}$ then $ab \in \mathcal{P}$ and $a + b \in \mathcal{P}$) and P2 (for each real a exactly one of $a \in \mathcal{P}$, $-a \in \mathcal{P}$, $a = 0$ holds); and $a > b$ means $a - b \in \mathcal{P}$. In particular $a > 0$ means $a - 0 = a \in \mathcal{P}$, i.e. a is positive.

We first record two consequences of the Field Axioms. As in Problem 1, $c \cdot 0 = 0$ for every c . Next, for all a and b ,

$$ab + (-a)b = (a + (-a))b = 0 \cdot b = 0,$$

so $(-a)b$ is the additive inverse of ab ; since additive inverses are unique, $(-a)b = -(ab)$. Applying this twice,

$$(-a)(-b) = -(a(-b)) = -(-(ab)) = ab,$$

the last equality because ab is an additive inverse of $-(ab)$ and additive inverses are unique.

(i) Let $a \neq 0$. By P2, either $a \in \mathcal{P}$ or $-a \in \mathcal{P}$. In the first case $a^2 = a \cdot a \in \mathcal{P}$ by P1. In the second case, by the identity above and P1,

$$a^2 = a \cdot a = (-a)(-a) \in \mathcal{P}.$$

In either case $a^2 \in \mathcal{P}$, i.e. $a^2 > 0$. By the Nontriviality Assumption $1 \neq 0$, and $1 = 1 \cdot 1 = 1^2$ by the Multiplicative Identity axiom; hence $1 > 0$.

(ii) Let $a \in \mathcal{P}$. Then $a \neq 0$ by P2, so a^{-1} exists. Also $a^{-1} \neq 0$: otherwise $1 = aa^{-1} = a \cdot 0 = 0$, contradicting Nontriviality. By P2, either $a^{-1} \in \mathcal{P}$ or $-a^{-1} \in \mathcal{P}$. Suppose the latter. Then, by P1, $a \cdot (-a^{-1}) \in \mathcal{P}$. But

$$a \cdot (-a^{-1}) = -(aa^{-1}) = -1,$$

so $-1 \in \mathcal{P}$. This contradicts P2, since by part (i) we already have $1 \in \mathcal{P}$, and exactly one of $1 \in \mathcal{P}$, $-1 \in \mathcal{P}$, $1 = 0$ may hold. Therefore $a^{-1} \in \mathcal{P}$, i.e. $a^{-1} > 0$.

(iii) Assume $a > b$, that is, $a - b \in \mathcal{P}$. By the Distributive Property and the identity $(-b)c = -(bc)$,

$$(a - b)c = (a + (-b))c = ac + (-b)c = ac + (-(bc)) = ac - bc.$$

Suppose $c > 0$, so $c \in \mathcal{P}$. Then P1 gives $(a - b)c \in \mathcal{P}$, i.e. $ac - bc \in \mathcal{P}$, which by definition says $ac > bc$. Suppose instead $c < 0$, i.e. $0 > c$, which means $0 - c = -c \in \mathcal{P}$. Then P1 gives $(a - b)(-c) \in \mathcal{P}$. Now

$$(a - b)(-c) = -((a - b)c) = -(ac - bc) = bc - ac,$$

where the last equality holds because $bc + (-(ac))$ added to $ac + (-(bc))$ gives 0, and additive inverses are unique. Hence $bc - ac \in \mathcal{P}$, i.e. $bc > ac$, which is exactly $ac < bc$.

Problem 1.3. For a nonempty set of real numbers E , show that $\inf E = \sup E$ if and only if E consists of a single point.

Solution. Throughout, $\sup E$ and $\inf E$ are understood in the extended real numbers, as in the text: $\sup E = \infty$ if E is not bounded above and $\inf E = -\infty$ if E is not bounded below, so that every nonempty set of real numbers has both a supremum and an infimum.

First a remark on finiteness. Since $E \neq \emptyset$, choose $x_0 \in E$. Then $\inf E \leq x_0 \leq \sup E$, because an infimum is a lower bound and a supremum is an upper bound. Hence $\inf E < \infty$ and $\sup E > -\infty$. Consequently, if $\inf E = \sup E$, this common value c satisfies $c < \infty$ and $c > -\infty$, so c is a real number; in particular E is then bounded above and below, and the Completeness Axiom (together with Problem 6 for the infimum) guarantees that $\sup E$ and $\inf E$ are the least upper bound and the greatest lower bound of E .

Suppose $\inf E = \sup E$, and call the common (real) value c . Let $x \in E$ be arbitrary. Since $\sup E$ is an upper bound for E ,

$$x \leq \sup E = c,$$

and since $\inf E$ is a lower bound for E ,

$$x \geq \inf E = c.$$

Thus $x \leq c$ and $c \leq x$. If $x \neq c$, then by P2 exactly one of $x - c$ and $-(x - c) = c - x$ is positive; but $x \leq c$ gives $c - x \in \mathcal{P}$ or $x = c$, and $c \leq x$ gives $x - c \in \mathcal{P}$ or $x = c$, so $x \neq c$ would force both $c - x$ and $x - c$ to be positive, contradicting P2. Hence $x = c$. As $x \in E$ was arbitrary and $E \neq \emptyset$, we conclude $E = \{c\}$, a single point.

Conversely, suppose $E = \{x_0\}$ for some real number x_0 . Then x_0 is an upper bound for E (indeed $x_0 \leq x_0$), and if b is any upper bound for E then $b \geq x_0$ since $x_0 \in E$. So x_0 is the least upper bound: $\sup E = x_0$. Symmetrically, x_0 is a lower bound for E and every lower bound a satisfies $a \leq x_0$, so x_0 is the greatest lower bound: $\inf E = x_0$. Therefore

$$\inf E = x_0 = \sup E.$$

Problem 1.4. Let a and b be real numbers.

- (i) Show that if $ab = 0$, then $a = 0$ or $b = 0$.
- (ii) Verify that $a^2 - b^2 = (a - b)(a + b)$ and conclude from part (i) that if $a^2 = b^2$, then $a = b$ or $a = -b$.

- (iii) Let c be a positive real number. Define $E = \{x \in \mathbb{R} \mid x^2 < c\}$. Verify that E is nonempty and bounded above. Define $x_0 = \sup E$. Show that $x_0^2 = c$. Use part (ii) to show that there is a unique $x > 0$ for which $x^2 = c$. It is denoted by $\sqrt{c}$.

Solution. (i) Suppose $ab = 0$ and $a \neq 0$. Then a^{-1} exists, and since $a^{-1} \cdot 0 = 0$ (Step 0 of Problem 1),

$$b = 1 \cdot b = (a^{-1}a)b = a^{-1}(ab) = a^{-1} \cdot 0 = 0.$$

So either $a = 0$ or $b = 0$.

(ii) By the Distributive Property and commutativity of multiplication, and using $(-b)x = -(bx)$ from Problem 2,

$$(a - b)(a + b) = a(a + b) + (-b)(a + b) = (a^2 + ab) + (-(ba) - b^2) = a^2 + (ab - ab) - b^2 = a^2 - b^2.$$

Now assume $a^2 = b^2$. Then $a^2 - b^2 = 0$, so $(a - b)(a + b) = 0$, and part (i) gives $a - b = 0$ or $a + b = 0$. In the first case $a = b$; in the second, a is the additive inverse of b , i.e. $a = -b$.

(iii) Let $c > 0$ and $E = \{x \in \mathbb{R} \mid x^2 < c\}$.

E is nonempty: $0^2 = 0 < c$, so $0 \in E$.

E is bounded above by $1 + c$: note $1 > 0$ by Problem 2(i), and $(1 + c) - 1 = c$ is positive, so $1 + c > 1 > 0$. Let $x \in E$ and suppose $x > 1 + c$. Then $x > 1 > 0$, so x is positive. Multiplying the inequality $x > 1 + c$ by the positive number x gives $x^2 > (1 + c)x$, and multiplying the inequality $x > 1$ by the positive number $1 + c$ gives $(1 + c)x > (1 + c) \cdot 1$; both multiplications are legitimate by Problem 2(iii). Combining,

$$x^2 > (1 + c)x > (1 + c) \cdot 1 = 1 + c > c,$$

contradicting $x^2 < c$. So no $x \in E$ satisfies $x > 1 + c$, and hence, by P2 applied to $x - (1 + c)$, every $x \in E$ satisfies $x \leq 1 + c$.

By the Completeness Axiom, $x_0 = \sup E$ exists. We record two facts.

First, $x_0 > 0$. Put $t = c(1 + c)^{-1}$. Since $c > 0$ and $1 + c > 0$, Problem 2(ii) and P1 give $t > 0$. From $c < 1 + c$, multiplying by the positive number $(1 + c)^{-1}$ gives $t < 1$; from $1 \leq 1 + c$, multiplying by the positive number $c(1 + c)^{-1}$ gives $t \leq c$. Since $0 < t < 1$, multiplying $t < 1$ by $t > 0$ gives $t^2 < t \leq c$, so $t \in E$ and therefore $x_0 \geq t > 0$.

Second, a monotonicity lemma: if $0 < u < v$ then $u^2 < v^2$. Indeed, multiplying $u < v$ by $u > 0$ gives $u^2 < uv$, and multiplying $u < v$ by $v > 0$ gives $uv < v^2$; combine.

We now show $x_0^2 = c$ by excluding the other two alternatives of P2 applied to $x_0^2 - c$.

Suppose $x_0^2 < c$ and set $\epsilon = c - x_0^2 > 0$. Since $2x_0 + 1 > 0$, the number

$$h = \min \left\{ \frac{1}{2}, \epsilon(2(2x_0 + 1))^{-1} \right\}$$

is positive, and satisfies $h < 1$ and $h(2x_0 + 1) < \epsilon$. Because $0 < h < 1$ we have $h^2 < h$, hence

$$(x_0 + h)^2 = x_0^2 + 2x_0h + h^2 < x_0^2 + 2x_0h + h = x_0^2 + h(2x_0 + 1) < x_0^2 + \epsilon = c.$$

So $x_0 + h \in E$ while $x_0 + h > x_0 = \sup E$, contradicting that x_0 is an upper bound for E .

Suppose instead $x_0^2 > c$ and set $\epsilon = x_0^2 - c > 0$. Since $2x_0 > 0$, the number

$$k = \min \left\{ \frac{1}{2}x_0, \epsilon(2 \cdot 2x_0)^{-1} \right\}$$

is positive and satisfies $k < x_0$ and $2x_0k < \epsilon$. Then $x_0 - k > 0$ and, since $k^2 > 0$,

$$(x_0 - k)^2 = x_0^2 - 2x_0k + k^2 > x_0^2 - 2x_0k > x_0^2 - \epsilon = c.$$

We claim $x_0 - k$ is an upper bound for E . Let $x \in E$. If $x \leq 0$ then $x < x_0 - k$ since $x_0 - k > 0$. If $x > 0$ and $x \geq x_0 - k$, then either $x = x_0 - k$, whence $x^2 = (x_0 - k)^2 > c$, or $x > x_0 - k > 0$, whence the monotonicity lemma gives $x^2 > (x_0 - k)^2 > c$; both contradict $x^2 < c$. So $x < x_0 - k$ in every case,

and $x_0 - k$ is an upper bound for E strictly smaller than x_0 , contradicting that x_0 is the least upper bound.

By P2 the only remaining alternative is $x_0^2 - c = 0$, that is, $x_0^2 = c$, and $x_0 > 0$.

Finally, uniqueness. Suppose $x > 0$ and $x^2 = c = x_0^2$. By part (ii), $x = x_0$ or $x = -x_0$. Since $x_0 > 0$, P2 gives $-x_0 < 0$, so $x = -x_0$ is incompatible with $x > 0$. Hence $x = x_0$. Thus there is exactly one positive real number whose square is c ; it is denoted $\sqrt{c}$.

Problem 1.5. Let a , b , and c be real numbers such that $a \neq 0$ and consider the quadratic equation

$$ax^2 + bx + c = 0, \quad x \in \mathbb{R}.$$

- (i) Suppose $b^2 - 4ac > 0$. Use the Field Axioms and the preceding problem to complete the square and thereby show that this equation has exactly two solutions given by

$$x = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \quad \text{and} \quad x = \frac{-b - \sqrt{b^2 - 4ac}}{2a}.$$

- (ii) Now suppose $b^2 - 4ac < 0$. Show that the quadratic equation fails to have any solution.

Solution. Write $2 = 1 + 1$ and $4 = 2 \cdot 2$. By Problem 2(i), $1 > 0$, so P1 gives $2 > 0$ and $4 > 0$; in particular $2 \neq 0$ and $4 \neq 0$ by P2. Since also $a \neq 0$, Problem 4(i) shows $2a \neq 0$ and $4a \neq 0$, so $(2a)^{-1}$ and $(4a)^{-1}$ exist.

Completing the square. For every real x , the Field Axioms give

$$(2ax + b)^2 = 4a^2x^2 + 4abx + b^2 = 4a(ax^2 + bx + c) + (b^2 - 4ac).$$

Hence

$$4a(ax^2 + bx + c) = (2ax + b)^2 - (b^2 - 4ac).$$

Since $4a \neq 0$, we have $4a(ax^2 + bx + c) = 0$ if and only if $ax^2 + bx + c = 0$: one direction is $4a \cdot 0 = 0$, and the other is Problem 4(i). Therefore, for every real x ,

$$ax^2 + bx + c = 0 \iff (2ax + b)^2 = b^2 - 4ac.$$

Call this equivalence (*).

(i) Suppose $d := b^2 - 4ac > 0$. By Problem 4(iii) there is a unique real number $\sqrt{d} > 0$ with $(\sqrt{d})^2 = d$. By (*), x solves the quadratic equation if and only if $(2ax + b)^2 = (\sqrt{d})^2$, which by Problem 4(ii) happens if and only if

$$2ax + b = \sqrt{d} \quad \text{or} \quad 2ax + b = -\sqrt{d}.$$

Since $2a \neq 0$, the first alternative is equivalent to $2ax = -b + \sqrt{d}$, i.e.

$$x = (2a)^{-1}(-b + \sqrt{d}) = \frac{-b + \sqrt{b^2 - 4ac}}{2a},$$

and the second is equivalent, in the same way, to

$$x = (2a)^{-1}(-b - \sqrt{d}) = \frac{-b - \sqrt{b^2 - 4ac}}{2a}.$$

Every step above is an equivalence, so these two numbers are solutions and there are no others. They are distinct: if they were equal, multiplying by $2a$ would give $-b + \sqrt{d} = -b - \sqrt{d}$, hence $2\sqrt{d} = 0$, and since $2 \neq 0$ Problem 4(i) would force $\sqrt{d} = 0$, contradicting $\sqrt{d} > 0$. Thus the equation has exactly two solutions, as stated.

(ii) Suppose $b^2 - 4ac < 0$ and suppose, for contradiction, that some real x solves the equation. Put $y = 2ax + b$. By (*), $y^2 = b^2 - 4ac < 0$. But every square is nonnegative: if $y \neq 0$ then $y^2 > 0$ by Problem 2(i), and if $y = 0$ then $y^2 = 0$. In either case $y^2 \geq 0 > b^2 - 4ac$, and P2 forbids y^2 from being both equal to and greater than $b^2 - 4ac$. This contradiction shows the quadratic equation has no solution when $b^2 - 4ac < 0$.

Problem 1.6. Use the Completeness Axiom to show that every nonempty set of real numbers that is bounded below has an infimum and that

$$\inf E = -\sup\{-x \mid x \in E\}.$$

Solution. We first record the reflection lemma: for real numbers u and v ,

$$u \leq v \iff -v \leq -u.$$

Indeed, since $-(-v) = v$ (additive inverses are unique), we have $(-u) - (-v) = (-u) + v = v - u$. So $v - u$ is positive or zero exactly when $(-u) - (-v)$ is positive or zero, which is the assertion.

Let E be a nonempty set of real numbers that is bounded below, and set

$$-E = \{-x \mid x \in E\}.$$

Since $E \neq \emptyset$, also $-E \neq \emptyset$. Let m be a lower bound for E , so $m \leq x$ for all $x \in E$. By the reflection lemma, $-x \leq -m$ for all $x \in E$, i.e. $-m$ is an upper bound for $-E$. Thus $-E$ is a nonempty set of real numbers that is bounded above, and the Completeness Axiom provides its least upper bound

$$s = \sup\{-x \mid x \in E\}.$$

We claim $-s$ is the greatest lower bound of E .

$-s$ is a lower bound for E : let $x \in E$. Then $-x \in -E$, so $-x \leq s$, and the reflection lemma gives $-s \leq -(-x) = x$.

$-s$ is the greatest lower bound: let ℓ be any lower bound for E . Then $\ell \leq x$ for all $x \in E$, so by the reflection lemma $-x \leq -\ell$ for all $x \in E$, i.e. $-\ell$ is an upper bound for $-E$. Since s is the least upper bound of $-E$, we get $s \leq -\ell$, and the reflection lemma once more gives $\ell = -(-\ell) \leq -s$.

Hence among the lower bounds of E there is a largest, namely $-s$; that is, E has an infimum and

$$\inf E = -s = -\sup\{-x \mid x \in E\}.$$

Problem 1.7. For real numbers a and b , verify the following:

- (i) $|ab| = |a| |b|$.
- (ii) $|a + b| \leq |a| + |b|$.
- (iii) For $\epsilon > 0$,

$$|x - a| < \epsilon \quad \text{if and only if} \quad a - \epsilon < x < a + \epsilon.$$

Solution. Recall the definition: $|x| = x$ if $x \geq 0$ and $|x| = -x$ if $x < 0$. Two immediate consequences will be used repeatedly.

Fact A: $|x| \geq 0$, and $|x|$ equals x or $-x$. If $x \geq 0$ this is clear; if $x < 0$ then $-x > 0$ by P2 and $|x| = -x > 0$.

Fact B: $|-x| = |x|$. If $x > 0$ then $-x < 0$, so $|-x| = -(-x) = x = |x|$; if $x < 0$ then $-x > 0$, so $|-x| = -x = |x|$; and $|-0| = |0| = 0$.

Fact C: $-|x| \leq x \leq |x|$. If $x \geq 0$ then $|x| = x$, so $x \leq |x|$, while $-|x| = -x \leq 0 \leq x$. If $x < 0$ then $|x| = -x > 0 > x$, so $x < |x|$, while $-|x| = x$.

Fact D: inequalities add. If $u \leq v$ and $u' \leq v'$, then

$$(v + v') - (u + u') = (v - u) + (v' - u'),$$

and each of $v - u$, $v' - u'$ is positive or zero. If both are positive their sum is positive by P1; if exactly one is zero the sum equals the other, which is positive; if both are zero the sum is zero. In every case $(v + v') - (u + u')$ is positive or zero, i.e. $u + u' \leq v + v'$.

(i) We use $(-x)y = -(xy)$ and $(-x)(-y) = xy$, established in Problem 2.

If $a = 0$ or $b = 0$, then $ab = 0$ and both sides equal 0, since $|0| = 0$.

If $a > 0$ and $b > 0$, then $ab > 0$ by P1, so $|ab| = ab = |a| |b|$.

If $a > 0$ and $b < 0$, then $-b > 0$, so $a(-b) = -(ab) > 0$ by P1, hence $ab < 0$ by P2, and

$$|ab| = -(ab) = a(-b) = |a| |b|.$$

The case $a < 0$, $b > 0$ is identical with the roles of a and b exchanged.

If $a < 0$ and $b < 0$, then $-a > 0$ and $-b > 0$, so $ab = (-a)(-b) > 0$ by P1, and

$$|ab| = ab = (-a)(-b) = |a| |b|.$$

All cases are covered by P2, so $|ab| = |a| |b|$ always.

(ii) By Fact C, $a \leq |a|$ and $b \leq |b|$, so Fact D gives

$$a + b \leq |a| + |b|.$$

Again by Fact C, $-|a| \leq a$ and $-|b| \leq b$, so Fact D gives $(-|a|) + (-|b|) \leq a + b$. Now $(-|a|) + (-|b|) = -(|a| + |b|)$, since adding $|a| + |b|$ to $(-|a|) + (-|b|)$ yields 0 and additive inverses are unique. Hence $-(|a| + |b|) \leq a + b$, and applying the reflection lemma of Problem 6,

$$-(a + b) \leq |a| + |b|.$$

By Fact A, $|a + b|$ is either $a + b$ or $-(a + b)$, and both of these are at most $|a| + |b|$. Hence

$$|a + b| \leq |a| + |b|.$$

(iii) Let $\epsilon > 0$ and let x and a be real numbers.

Suppose $|x - a| < \epsilon$. By Fact C, $x - a \leq |x - a| < \epsilon$, so $x - a < \epsilon$ and therefore $x < a + \epsilon$. Also, by Fact C applied to $-(x - a)$ together with Fact B,

$$-(x - a) \leq |-(x - a)| = |x - a| < \epsilon,$$

so $a - x < \epsilon$, which gives $a - \epsilon < x$. Hence $a - \epsilon < x < a + \epsilon$.

Conversely, suppose $a - \epsilon < x < a + \epsilon$. From $x < a + \epsilon$ we get $x - a < \epsilon$, and from $a - \epsilon < x$ we get $-(x - a) = a - x < \epsilon$. By Fact A, $|x - a|$ equals either $x - a$ or $-(x - a)$, and each of these is less than ϵ ; hence $|x - a| < \epsilon$.

1.2 Problems 1.8–1.14

Problem 1.8. Use an induction argument to show that for each natural number n , the interval $(n, n + 1)$ fails to contain any natural number.

Solution. Recall that a set E of real numbers is inductive provided $1 \in E$ and $x \in E$ implies $x + 1 \in E$, and that $\mathbb{N}$ is defined to be the intersection of all inductive subsets of $\mathbb{R}$. Consequently, to prove that every natural number belongs to a set E it suffices to prove that E is inductive; this is exactly the content of the Principle of Mathematical Induction.

We first record two lemmas.

Lemma 1. Every natural number n satisfies $n \geq 1$.

Indeed, the set $\{x \in \mathbb{R} \mid x \geq 1\}$ is inductive: it contains 1, and if $x \geq 1$ then $x + 1 \geq 1 + 1 > 1$, since $1 > 0$. Hence $\mathbb{N}$ is contained in this set.

Lemma 2. If n is a natural number and $n \neq 1$, then $n - 1$ is a natural number.

Define

$$F = \{x \in \mathbb{R} \mid x = 1 \text{ or } x - 1 \in \mathbb{N}\}.$$

Then $1 \in F$. Suppose $x \in F$. If $x = 1$, then $(x + 1) - 1 = 1 \in \mathbb{N}$, so $x + 1 \in F$. If $x - 1 \in \mathbb{N}$, then, since $\mathbb{N}$ is inductive, $x = (x - 1) + 1 \in \mathbb{N}$, and therefore $(x + 1) - 1 = x \in \mathbb{N}$, so again $x + 1 \in F$. Thus F is inductive and hence $\mathbb{N} \subseteq F$, which is the assertion of the lemma. (This is the first assertion of Problem 9; its proof uses only the definition of $\mathbb{N}$ as an intersection of inductive sets, so there is no circularity.)

We now prove, by induction on n , the assertion

$$S(n) : (n, n+1) \cap \mathbb{N} = \emptyset.$$

The base case $S(1)$. Define

$$E = \{1\} \cup \{x \in \mathbb{R} \mid x \geq 2\}.$$

Then $1 \in E$. If $x \in E$ and $x = 1$, then $x+1 = 2 \geq 2$, so $x+1 \in E$; if $x \in E$ and $x \geq 2$, then $x+1 \geq 3 > 2$, so $x+1 \in E$. Hence E is inductive and therefore $\mathbb{N} \subseteq E$. Since no point of E lies strictly between 1 and 2, no natural number lies in $(1, 2)$. Thus $S(1)$ holds.

The induction step. Suppose $S(k)$ holds for the natural number k , that is, no natural number lies in $(k, k+1)$. We claim $S(k+1)$ holds. Suppose, to the contrary, that n is a natural number with

$$k+1 < n < k+2.$$

By Lemma 1, $k \geq 1$, so $n > k+1 \geq 2 > 1$ and in particular $n \neq 1$. By Lemma 2, $n-1$ is a natural number. Subtracting 1 from each term of the displayed inequality gives

$$k < n-1 < k+1,$$

so $n-1$ is a natural number lying in $(k, k+1)$. This contradicts $S(k)$. Hence no natural number lies in $(k+1, k+2)$, that is, $S(k+1)$ holds.

By the Principle of Mathematical Induction, $S(n)$ holds for every natural number n : for each natural number n the interval $(n, n+1)$ contains no natural number.

Problem 1.9. Use an induction argument to show that if $n > 1$ is a natural number, then $n-1$ also is a natural number. Then use another induction argument to show that if m and n are natural numbers with $n > m$, then $n-m$ is a natural number.

Solution. Throughout we use the definition of $\mathbb{N}$ as the intersection of all inductive subsets of $\mathbb{R}$; equivalently, we use the Principle of Mathematical Induction, which asserts that a set of real numbers which is inductive contains $\mathbb{N}$.

First assertion. Define

$$F = \{x \in \mathbb{R} \mid x = 1 \text{ or } x-1 \in \mathbb{N}\}.$$

We claim F is inductive. Certainly $1 \in F$. Let $x \in F$. There are two cases. If $x = 1$, then $(x+1)-1 = 1$, and $1 \in \mathbb{N}$, so $x+1 \in F$. If $x \neq 1$, then $x-1 \in \mathbb{N}$; since $\mathbb{N}$ is inductive, $x = (x-1) + 1$ belongs to $\mathbb{N}$, and therefore $(x+1)-1 = x \in \mathbb{N}$, so $x+1 \in F$. In either case $x+1 \in F$, so F is inductive.

Since F is inductive, $\mathbb{N} \subseteq F$. Now let n be a natural number with $n > 1$. Then $n \in F$ and $n \neq 1$, so by the definition of F we conclude that $n-1 \in \mathbb{N}$. This proves the first assertion.

Second assertion. For a natural number m , let $S(m)$ be the assertion

$$S(m) : \text{for every natural number } n \text{ with } n > m, \text{ the number } n-m \text{ is a natural number.}$$

The base case $S(1)$ is precisely the first assertion just proved.

The induction step. Suppose $S(m)$ holds for the natural number m . Let n be a natural number with $n > m+1$. Since $1 > 0$ we have $m+1 > m$, and hence $n > m$. By the induction hypothesis $S(m)$, the number $n-m$ is a natural number. Moreover, subtracting m from both sides of $n > m+1$ gives

$$n-m > 1.$$

Therefore $n-m$ is a natural number strictly greater than 1, so by the first assertion $(n-m)-1$ is a natural number. But

$$(n-m)-1 = n-(m+1),$$

so $n-(m+1)$ is a natural number. As n was an arbitrary natural number exceeding $m+1$, the assertion $S(m+1)$ holds.

By the Principle of Mathematical Induction, $S(m)$ holds for every natural number m . That is, if m and n are natural numbers with $n > m$, then $n-m$ is a natural number.

Problem 1.10. Show that for any integer n , there is exactly one integer in the interval $[n, n + 1)$.

Solution. Recall that the set $\mathbb{Z}$ of integers consists of the natural numbers, their negatives, and the number 0; thus

$$\mathbb{Z} = \mathbb{N} \cup \{0\} \cup (-\mathbb{N}), \quad -\mathbb{N} = \{-p \mid p \in \mathbb{N}\}.$$

As observed in the solution of Problem 8, every natural number is greater than or equal to 1, since $\{x \in \mathbb{R} \mid x \geq 1\}$ is inductive. Hence every member of $-\mathbb{N}$ is less than or equal to -1 , and in particular is negative. This yields the positivity observation: if k is an integer and $k > 0$, then k belongs to neither $\{0\}$ nor $-\mathbb{N}$, so k is a natural number and therefore $k \geq 1$.

We also need the following closure property.

Lemma A. $\mathbb{N}$ is closed under addition: if p and m are natural numbers, then $p + m$ is a natural number. Fix a natural number m and set $G = \{x \in \mathbb{R} \mid x + m \in \mathbb{N}\}$. Since $\mathbb{N}$ is inductive and $m \in \mathbb{N}$, we have $1 + m = m + 1 \in \mathbb{N}$, so $1 \in G$. If $x \in G$, then $x + m \in \mathbb{N}$, so $(x + 1) + m = (x + m) + 1 \in \mathbb{N}$ because $\mathbb{N}$ is inductive; hence $x + 1 \in G$. Thus G is inductive and therefore $\mathbb{N} \subseteq G$, which proves the lemma.

Lemma B (the difference lemma). If m and n are integers with $n > m$, then $n - m$ is a natural number. We consider cases according to the trichotomy for m .

Case $m \in \mathbb{N}$. If $n \in \mathbb{N}$, then $n - m \in \mathbb{N}$ by Problem 9. If $n = 0$ or $n \in -\mathbb{N}$, then $n \leq 0 < 1 \leq m$, contradicting $n > m$; so these subcases do not occur.

Case $m = 0$. Then $n > 0$, so by the positivity observation $n \in \mathbb{N}$, and $n - m = n \in \mathbb{N}$.

Case $m = -q$ with $q \in \mathbb{N}$. If $n \in \mathbb{N}$, then $n - m = n + q \in \mathbb{N}$ by Lemma A. If $n = 0$, then $n - m = q \in \mathbb{N}$. If $n = -p$ with $p \in \mathbb{N}$, then $-p > -q$ gives $q > p$, and $n - m = q - p \in \mathbb{N}$ by Problem 9.

The three cases are exhaustive, since $\mathbb{Z} = \mathbb{N} \cup \{0\} \cup (-\mathbb{N})$. In every case $n - m$ is a natural number, and Lemma B is proved. (It is used again in Problems 11 and 12.)

Now let n be an integer. Since $n \leq n$ and $n < n + 1$, the integer n itself lies in $[n, n + 1)$, so the interval contains at least one integer.

For uniqueness, suppose m is an integer with $m \in [n, n + 1)$ and $m \neq n$. Since $m \geq n$ and $m \neq n$, we have $m > n$. By the lemma, $m - n$ is a natural number, hence $m - n \geq 1$, that is, $m \geq n + 1$. This contradicts $m < n + 1$. Therefore n is the only integer in $[n, n + 1)$.

Problem 1.11. Show that any nonempty set of integers that is bounded above has a largest member.

Solution. Let E be a nonempty set of integers that is bounded above. Since E is a nonempty set of real numbers that is bounded above, the Completeness Axiom provides a supremum; define

$$c = \sup E.$$

Since $c - 1 < c$ and c is the least upper bound for E , the number $c - 1$ is not an upper bound for E . Hence there is a member m of E with

$$m > c - 1.$$

We claim m is the largest member of E . Suppose otherwise. Then there is a member n of E with $n > m$. Both m and n are integers, so by the difference lemma (Lemma B in the solution of Problem 10), $n - m$ is a natural number, and therefore $n - m \geq 1$, since every natural number is at least 1. Thus

$$n \geq m + 1 > (c - 1) + 1 = c,$$

so $n > c$. This contradicts the fact that c is an upper bound for E and $n \in E$.

Therefore no member of E exceeds m ; that is, m is a member of E with $n \leq m$ for all $n \in E$. Hence E has a largest member, namely m . (In fact $m = c = \sup E$, so the supremum of such a set is attained.)

Problem 1.12. Show that the irrational numbers are dense in $\mathbb{R}$.

Solution. Recall the definition: a set E of real numbers is dense in $\mathbb{R}$ provided that between any two real numbers there lies a member of E . So we must show that if a and b are real numbers with $a < b$, then there is an irrational number x with $a < x < b$.

We first record that $\mathbb{Q}$ is closed under subtraction; for this we need that $\mathbb{Z}$ is closed under subtraction and under multiplication.

Recall from the solution of Problem 10 that $\mathbb{N}$ is closed under addition (Lemma A there). It is also closed under multiplication: for a fixed natural number m the set $\{x \in \mathbb{R} \mid xm \in \mathbb{N}\}$ contains 1, since $1 \cdot m = m \in \mathbb{N}$, and if $xm \in \mathbb{N}$ then $(x+1)m = xm + m \in \mathbb{N}$ by additive closure; hence this set is inductive and contains $\mathbb{N}$.

Now let m and n be integers, so that each lies in $\mathbb{N} \cup \{0\} \cup (-\mathbb{N})$. For the product: if either factor is 0, then $mn = 0 \in \mathbb{Z}$; otherwise write $m = \epsilon p$ and $n = \delta q$ with $p, q \in \mathbb{N}$ and $\epsilon, \delta \in \{1, -1\}$, so that $mn = (\epsilon\delta)(pq)$, and $pq \in \mathbb{N}$ by multiplicative closure, whence $mn \in \mathbb{N} \cup (-\mathbb{N}) \subseteq \mathbb{Z}$. For the difference: if $n > m$, then $n - m \in \mathbb{N} \subseteq \mathbb{Z}$ by the difference lemma (Lemma B in the solution of Problem 10); if $n = m$, then $n - m = 0 \in \mathbb{Z}$; and if $n < m$, then $m - n \in \mathbb{N}$ by that same lemma, so $n - m = -(m - n) \in -\mathbb{N} \subseteq \mathbb{Z}$. Thus $\mathbb{Z}$ is closed under multiplication and subtraction.

Consequently $\mathbb{Q}$ is closed under subtraction. Indeed, let s and t be rational, say $s = a_1/a_2$ and $t = b_1/b_2$ with a_1, a_2, b_1, b_2 integers and $a_2 \neq 0, b_2 \neq 0$. Then

$$s - t = \frac{a_1b_2 - b_1a_2}{a_2b_2}.$$

By the closure properties just established, the numerator and the denominator are integers, and $a_2b_2 \neq 0$ by Problem 4(i). Hence $s - t$ is a quotient of integers with nonzero denominator, that is, $s - t$ is rational.

By Problem 4(iii) there is a unique positive real number whose square is 2; it is denoted by $\sqrt{2}$. As shown in the text of Section 1.2, using the prime factorization theorem, $\sqrt{2}$ is irrational.

Now let a and b be real numbers with $a < b$. Then

$$a - \sqrt{2} < b - \sqrt{2},$$

so by Theorem 2, which asserts that the rational numbers are dense in $\mathbb{R}$, there is a rational number r with

$$a - \sqrt{2} < r < b - \sqrt{2}.$$

Set $x = r + \sqrt{2}$. Adding $\sqrt{2}$ to each term of the last display gives

$$a < x < b.$$

Finally, x is irrational. For if x were rational, then, since r is rational and the rationals are closed under subtraction, the number

$$\sqrt{2} = x - r$$

would be rational, contradicting the irrationality of $\sqrt{2}$.

Thus between any two real numbers there lies an irrational number, that is, the irrational numbers are dense in $\mathbb{R}$.

Problem 1.13. Show that each real number is the supremum of a set of rational numbers and also the supremum of a set of irrational numbers.

Solution. Let x be a real number.

The rational case. Define

$$E = \{r \in \mathbb{Q} \mid r < x\},$$

a set of rational numbers. We check that E is nonempty and bounded above, and that $\sup E = x$.

E is nonempty: since $x - 1 < x$, Theorem 2 (the rational numbers are dense in $\mathbb{R}$) provides a rational number r with $x - 1 < r < x$; this r belongs to E .

E is bounded above by x , directly from its definition. Hence by the Completeness Axiom $c = \sup E$

exists, and since x is an upper bound for E while c is the least upper bound,

$$c \leq x.$$

Suppose $c < x$. By Theorem 2 there is a rational number r with $c < r < x$. Since r is rational and $r < x$, we have $r \in E$; but $r > c = \sup E$, contradicting the fact that c is an upper bound for E . Therefore $c = x$, that is,

$$x = \sup\{r \in \mathbb{Q} \mid r < x\},$$

and x is the supremum of a set of rational numbers.

The irrational case. The argument is identical, with Problem 12 in place of Theorem 2. Define

$$E' = \{t \in \mathbb{R} \mid t \text{ is irrational and } t < x\},$$

a set of irrational numbers.

E' is nonempty: by Problem 12 the irrational numbers are dense in $\mathbb{R}$, so, as $x - 1 < x$, there is an irrational t with $x - 1 < t < x$, and this t belongs to E' .

E' is bounded above by x , so by the Completeness Axiom $c' = \sup E'$ exists and $c' \leq x$.

If $c' < x$, then by Problem 12 there is an irrational number t with $c' < t < x$; then $t \in E'$ while $t > c' = \sup E'$, a contradiction. Hence $c' = x$, that is,

$$x = \sup\{t \mid t \text{ irrational, } t < x\},$$

and x is also the supremum of a set of irrational numbers.

Problem 1.14. Show that if $r > 0$, then, for each natural number n , $(1 + r)^n \geq 1 + n \cdot r$.

Solution. Fix a real number $r > 0$. For a real number x the natural powers are defined recursively by $x^1 = x$ and $x^{k+1} = x^k \cdot x$. For a natural number n let $S(n)$ be the assertion

$$S(n): \quad (1 + r)^n \geq 1 + n \cdot r.$$

We prove $S(n)$ for every natural number n by the Principle of Mathematical Induction.

The base case $S(1)$. By definition $(1 + r)^1 = 1 + r = 1 + 1 \cdot r$, so $S(1)$ holds, with equality.

The induction step. Suppose $S(k)$ holds for the natural number k , that is,

$$(1 + r)^k \geq 1 + k \cdot r.$$

Since $r > 0$ and $1 > 0$ we have $1 + r > 0$. Multiplication by the positive number $1 + r$ preserves the inequality: if $(1 + r)^k > 1 + kr$, then $(1 + r)^k(1 + r) > (1 + kr)(1 + r)$ by Problem 2(iii), while if $(1 + r)^k = 1 + kr$ the two products are equal. In either case

$$(1 + r)^{k+1} = (1 + r)^k(1 + r) \geq (1 + kr)(1 + r).$$

Expanding the right-hand side by the distributive law,

$$\begin{aligned} (1 + kr)(1 + r) &= 1 + r + kr + kr^2 \\ &= 1 + (k + 1)r + kr^2. \end{aligned}$$

Now k is a natural number, so $k \geq 1 > 0$, and $r \neq 0$ gives $r^2 > 0$ (Problem 2(i)); hence $kr^2 > 0$ and therefore

$$1 + (k + 1)r + kr^2 \geq 1 + (k + 1)r.$$

Combining the two displays,

$$(1 + r)^{k+1} \geq 1 + (k + 1)r,$$

which is the assertion $S(k + 1)$.

By the Principle of Mathematical Induction, $S(n)$ holds for every natural number n ; that is, $(1 + r)^n \geq 1 + n \cdot r$ for every natural number n whenever $r > 0$.

We remark that the same argument works for every real r with $r > -1$, since the only properties of r used were $1 + r > 0$ and $kr^2 \geq 0$; this more general form is Bernoulli's inequality.

1.3 Problems 1.15–1.21

Problem 1.15. Use induction arguments to prove that for every natural number n ,

(i)

$$\sum_{j=1}^n j^2 = \frac{n(n+1)(2n+1)}{6}.$$

(ii)

$$1^3 + 2^3 + \dots + n^3 = (1 + 2 + \dots + n)^2.$$

(iii)

$$1 + r + \dots + r^n = \frac{1 - r^{n+1}}{1 - r} \quad \text{if } r \neq 1.$$

Solution. Throughout we use the Principle of Mathematical Induction in the form stated in Section 1.2: if S is a set of natural numbers with $1 \in S$, and with the property that $n \in S$ implies $n + 1 \in S$, then S is all of $\mathbb{N}$. In each part let S be the set of natural numbers n for which the asserted identity holds; we verify that $1 \in S$ and that S is closed under successor.

(i) For $n = 1$ the left-hand side is $1^2 = 1$ and the right-hand side is $\frac{1 \cdot 2 \cdot 3}{6} = 1$, so $1 \in S$.

Suppose $n \in S$, that is, $\sum_{j=1}^n j^2 = \frac{n(n+1)(2n+1)}{6}$. Then

$$\begin{aligned} \sum_{j=1}^{n+1} j^2 &= \left(\sum_{j=1}^n j^2 \right) + (n+1)^2 = \frac{n(n+1)(2n+1)}{6} + (n+1)^2 \\ &= \frac{(n+1)[n(2n+1) + 6(n+1)]}{6} = \frac{(n+1)(2n^2 + 7n + 6)}{6} \\ &= \frac{(n+1)(n+2)(2n+3)}{6} = \frac{(n+1)((n+1)+1)(2(n+1)+1)}{6}, \end{aligned}$$

where the factorization $2n^2 + 7n + 6 = (n+2)(2n+3)$ is checked by expanding the right-hand product. Hence $n+1 \in S$, and by induction $S = \mathbb{N}$.

(ii) We first record the companion identity

$$1 + 2 + \dots + n = \frac{n(n+1)}{2} \quad \text{for all } n \in \mathbb{N},$$

which is itself proved by induction: it holds for $n = 1$ since $1 = \frac{1 \cdot 2}{2}$, and if it holds for n then

$$(1 + \dots + n) + (n+1) = \frac{n(n+1)}{2} + (n+1) = \frac{(n+1)(n+2)}{2},$$

which is the same formula with n replaced by $n+1$.

Now let S be the set of n for which $1^3 + \dots + n^3 = (1 + \dots + n)^2$. For $n = 1$ both sides equal 1, so $1 \in S$. Suppose $n \in S$. Using the induction hypothesis and then the companion identity,

$$\begin{aligned} 1^3 + \dots + n^3 + (n+1)^3 &= (1 + \dots + n)^2 + (n+1)^3 = \left(\frac{n(n+1)}{2} \right)^2 + (n+1)^3 \\ &= \frac{n^2(n+1)^2}{4} + (n+1)^3 = \frac{(n+1)^2[n^2 + 4(n+1)]}{4} \\ &= \frac{(n+1)^2(n+2)^2}{4} = \left(\frac{(n+1)((n+1)+1)}{2} \right)^2 \\ &= (1 + 2 + \dots + (n+1))^2. \end{aligned}$$

Thus $n+1 \in S$, and by induction the identity holds for every natural number n .

(iii) As printed the exponent is a misprint: with $1 - r^{n-1}$ in the numerator the identity already fails at $n = 1$, where the left-hand side is $1 + r$ while the right-hand side is $\frac{1-r^0}{1-r} = 0$. The intended (and correct) statement is

$$1 + r + \dots + r^n = \frac{1 - r^{n+1}}{1 - r} \quad \text{if } r \neq 1,$$

and this is what we prove. Equivalently, multiplying by the nonzero number $1 - r$, the assertion is that $(1 - r)(1 + r + \dots + r^n) = 1 - r^{n+1}$.

Fix a real number $r \neq 1$ and let S be the set of natural numbers n for which the displayed identity holds. For $n = 1$,

$$\frac{1 - r^2}{1 - r} = \frac{(1 - r)(1 + r)}{1 - r} = 1 + r,$$

so $1 \in S$. Suppose $n \in S$. Then

$$\begin{aligned} 1 + r + \dots + r^n + r^{n+1} &= \frac{1 - r^{n+1}}{1 - r} + r^{n+1} = \frac{1 - r^{n+1} + r^{n+1}(1 - r)}{1 - r} \\ &= \frac{1 - r^{n+1} + r^{n+1} - r^{n+2}}{1 - r} = \frac{1 - r^{n+2}}{1 - r}, \end{aligned}$$

which is the identity with n replaced by $n + 1$. Hence $n + 1 \in S$, and by induction $S = \mathbb{N}$. (The identity also holds for $n = 0$, where both sides equal 1.)

Problem 1.16. Show that the set $\mathbb{Z}$ of integers is countable.

Solution. By the definition in Section 1.3, a set is countably infinite provided it is equipotent to $\mathbb{N}$, and a set is countable provided it is either finite or countably infinite. So it suffices to exhibit a one-to-one mapping of $\mathbb{N}$ onto $\mathbb{Z}$.

We first record that each natural number n is either odd or even, and not both: that is, n can be written as $n = 2k - 1$ for a natural number k , or as $n = 2k$ for a natural number k , but not both. Existence follows by induction: $1 = 2 \cdot 1 - 1$ is odd; and if $n = 2k - 1$ then $n + 1 = 2k$ is even, while if $n = 2k$ then $n + 1 = 2(k + 1) - 1$ is odd. The two alternatives are mutually exclusive: if $2k - 1 = 2k'$ then $2(k - k') = 1$, so the integer $j = k - k'$ satisfies $j = 1/2$; but $0 < 1/2 < 1$, and by Problem 10 the only integer in the interval $[0, 1)$ is 0, so no integer equals $1/2$. Finally k is uniquely determined by n in either case, since $2k = 2k'$ forces $k = k'$.

Define $f: \mathbb{N} \rightarrow \mathbb{Z}$ by

$$f(n) = \begin{cases} \frac{n-1}{2}, & \text{if } n \text{ is odd,} \\ -\frac{n}{2}, & \text{if } n \text{ is even.} \end{cases}$$

This is well defined: if n is odd then $n - 1$ is even so $(n - 1)/2$ is a nonnegative integer, and if n is even then $n/2$ is a natural number so $-n/2$ is a negative integer. Thus f maps the odd natural numbers into $\{0, 1, 2, \dots\}$ and the even natural numbers into $\{-1, -2, \dots\}$. Explicitly, f enumerates $\mathbb{Z}$ as

$$0, -1, 1, -2, 2, -3, 3, \dots$$

The mapping f is one-to-one. Indeed, suppose $f(m) = f(n)$. If m and n are both odd, then $(m - 1)/2 = (n - 1)/2$, and multiplying by 2 and adding 1 gives $m = n$. If m and n are both even, then $-m/2 = -n/2$, so $m = n$. The remaining case cannot occur: if, say, m is odd and n is even, then $f(m) = (m - 1)/2 \geq 0$ while $f(n) = -n/2 \leq -1$, so $f(m) \neq f(n)$.

The mapping f is onto $\mathbb{Z}$. Let p be an integer. If $p \geq 0$, set $n = 2p + 1$. Then n is an odd natural number and $f(n) = \frac{(2p+1)-1}{2} = p$. If $p < 0$, set $n = -2p$. Then $-p$ is a natural number, so $n = 2(-p)$ is an even natural number, and $f(n) = -\frac{-2p}{2} = p$.

Therefore f is a one-to-one correspondence between $\mathbb{N}$ and $\mathbb{Z}$, so $\mathbb{Z}$ is equipotent to $\mathbb{N}$. Hence $\mathbb{Z}$ is countably infinite and, in particular, countable.

Problem 1.17. Show that a set A is countable if and only if there is a one-to-one mapping of A to $\mathbb{N}$.

Solution. Here “a one-to-one mapping of A to $\mathbb{N}$ ” means a one-to-one mapping of A into $\mathbb{N}$; it is not required to be onto.

First suppose A is countable; we produce a one-to-one mapping of A into $\mathbb{N}$. By definition A is either finite or countably infinite.

If A is countably infinite, then A is equipotent to $\mathbb{N}$, so there is a one-to-one mapping f of A onto $\mathbb{N}$; in particular f is a one-to-one mapping of A into $\mathbb{N}$.

If A is finite, then either $A = \emptyset$, in which case the empty mapping is (vacuously) a one-to-one mapping of A into $\mathbb{N}$, or else there is a natural number n and a one-to-one correspondence g between A and $\{1, \dots, n\}$. Let $\iota: \{1, \dots, n\} \rightarrow \mathbb{N}$ be the inclusion mapping, which is one-to-one. Then $\iota \circ g$ is a mapping of A into $\mathbb{N}$, and it is one-to-one: if $(\iota \circ g)(x) = (\iota \circ g)(x')$ then $g(x) = g(x')$ since ι is one-to-one, and hence $x = x'$ since g is one-to-one.

Conversely, suppose f is a one-to-one mapping of A into $\mathbb{N}$. Let

$$B = f(A) = \{f(x) \mid x \in A\} \subseteq \mathbb{N}.$$

Regard f as a mapping of A to B . So regarded it is onto, by the very definition of B , and it remains one-to-one. Hence f is a one-to-one correspondence between A and B , so A is equipotent to B .

Now B is a set of natural numbers, and by Theorem 3 every set of natural numbers is countable; thus B is countable. As observed immediately after the definition of countability in Section 1.3, if a set is equipotent to a countable set then it is countable. Since A is equipotent to the countable set B , we conclude that A is countable.

(For the reader who prefers to avoid the appeal to that observation: if B is finite, then B is empty, in which case A is empty and hence finite, or B is equipotent to some $\{1, \dots, n\}$, and composing the one-to-one correspondence $A \rightarrow B$ with the one-to-one correspondence $B \rightarrow \{1, \dots, n\}$ gives a one-to-one correspondence between A and $\{1, \dots, n\}$, by Problem 20; so A is finite. If B is countably infinite, the same composition argument, using a one-to-one correspondence $B \rightarrow \mathbb{N}$, shows A is equipotent to $\mathbb{N}$, so A is countably infinite. In either case A is countable.)

Problem 1.18. Use an induction argument to complete the proof of part (i) of Corollary 4. [Corollary 4 (i) asserts that for each natural number n , the Cartesian product $\mathbb{N} \times \dots \times \mathbb{N}$ (n times) is countably infinite; the proof in the text treats the case $n = 2$ and leaves the general case as an exercise in induction.]

Solution. Write $\mathbb{N}^n$ for the n -fold Cartesian product $\mathbb{N} \times \dots \times \mathbb{N}$, whose members are the ordered n -tuples $(k_1, \dots, k_n)$ of natural numbers. Two such n -tuples are equal exactly when their corresponding entries agree. We must show that $\mathbb{N}^n$ is countably infinite for every natural number n ; that is, it is countable and it is not finite.

Step 1: $\mathbb{N}^n$ is countable, by induction on n .

Let S be the set of natural numbers n for which $\mathbb{N}^n$ is countable.

For $n = 1$ we have $\mathbb{N}^1 = \mathbb{N}$, which is countable (the identity mapping is a one-to-one correspondence between $\mathbb{N}$ and $\mathbb{N}$). So $1 \in S$.

Suppose $n \in S$, so $\mathbb{N}^n$ is countable. By Problem 17 there is a one-to-one mapping

$$h: \mathbb{N}^n \rightarrow \mathbb{N}.$$

Let $g: \mathbb{N} \times \mathbb{N} \rightarrow \mathbb{N}$ be the mapping $g(m, n) = (m + n)^2 + n$ used in the proof of Corollary 4; it was shown there to be one-to-one. Define

$$G: \mathbb{N}^{n+1} \rightarrow \mathbb{N}, \quad G(k_1, \dots, k_n, k_{n+1}) = g(h(k_1, \dots, k_n), k_{n+1}).$$

This is well defined, since $h(k_1, \dots, k_n)$ and k_{n+1} are natural numbers.

We claim G is one-to-one. Suppose

$$G(k_1, \dots, k_{n+1}) = G(k'_1, \dots, k'_{n+1}).$$

Then $g(h(k_1, \dots, k_n), k_{n+1}) = g(h(k'_1, \dots, k'_n), k'_{n+1})$. Since g is one-to-one, the two arguments agree as ordered pairs, that is,

$$h(k_1, \dots, k_n) = h(k'_1, \dots, k'_n) \quad \text{and} \quad k_{n+1} = k'_{n+1}.$$

Since h is one-to-one, the first equality forces $(k_1, \dots, k_n) = (k'_1, \dots, k'_n)$, so $k_j = k'_j$ for $1 \leq j \leq n$; together with $k_{n+1} = k'_{n+1}$ this gives $(k_1, \dots, k_{n+1}) = (k'_1, \dots, k'_{n+1})$. Hence G is one-to-one.

So G is a one-to-one mapping of $\mathbb{N}^{n+1}$ into $\mathbb{N}$, and therefore, by Problem 17 again, $\mathbb{N}^{n+1}$ is countable. Thus $n+1 \in S$, and by the Principle of Mathematical Induction $S = \mathbb{N}$: the set $\mathbb{N}^n$ is countable for every natural number n .

Step 2: $\mathbb{N}^n$ is not finite.

We first record the following consequence of the pigeonhole principle.

Lemma. If there is a one-to-one mapping φ of $\mathbb{N}$ into a set A , then A is not finite.

Proof of the Lemma. Suppose, to get a contradiction, that A is finite. Since $\varphi(\mathbb{N})$ is a nonempty subset of A , A is nonempty, so there is a natural number p and a one-to-one correspondence ψ between A and $\{1, \dots, p\}$. The composition $\psi \circ \varphi$ is a one-to-one mapping of $\mathbb{N}$ into $\{1, \dots, p\}$ (a composition of one-to-one mappings is one-to-one, by Problem 20). Restrict it to the initial segment $\{1, \dots, p+1\}$: we obtain a one-to-one mapping of $\{1, \dots, p+1\}$ into $\{1, \dots, p\}$, hence a one-to-one correspondence between $\{1, \dots, p+1\}$ and its image C , a subset of $\{1, \dots, p\}$. By Theorem 3, and specifically by the argument given there for a subset of a finite set, C is equipotent to $\{1, \dots, q\}$ for some natural number $q \leq p$ (the set C is nonempty, since $p+1 \geq 1$). Since equipotence is transitive, $\{1, \dots, p+1\}$ is equipotent to $\{1, \dots, q\}$. Since $q \leq p < p+1$, Problem 9 tells us that $m = (p+1) - q$ is a natural number. Writing $p+1 = q+m$, this says that $\{1, \dots, q+m\}$ is equipotent to $\{1, \dots, q\}$, contradicting the pigeonhole principle. Hence A is not finite, and the Lemma is proved.

Now fix a natural number n and define $\varphi: \mathbb{N} \rightarrow \mathbb{N}^n$ by

$$\varphi(k) = (k, 1, 1, \dots, 1),$$

that is, first entry k and all remaining entries equal to 1. If $\varphi(k) = \varphi(k')$, then comparing first entries gives $k = k'$, so φ is one-to-one. By the Lemma, $\mathbb{N}^n$ is not finite.

Combining the two steps: $\mathbb{N}^n$ is countable and not finite, hence, by the definition of countability, $\mathbb{N}^n$ is countably infinite. This is part (i) of Corollary 4.

Problem 1.19. Prove Corollary 6 in the case of a finite family of countable sets. [Corollary 6 asserts that the union of a countable collection of countable sets is countable; the proof in the text treats the case in which the index set Λ is countably infinite and leaves the finite case as an exercise.]

Solution. Let Λ be a finite index set and for each $\lambda \in \Lambda$ let E_λ be a countable set. Put

$$E = \bigcup_{\lambda \in \Lambda} E_\lambda.$$

We must show E is countable.

If Λ is empty, then E is empty and hence finite, so it is countable. If E is empty, it is likewise countable. So assume $\Lambda \neq \emptyset$ and $E \neq \emptyset$. Since Λ is finite and nonempty, there is a natural number M and a one-to-one correspondence between $\{1, \dots, M\}$ and Λ ; relabelling, we may write

$$\Lambda = \{\lambda_1, \dots, \lambda_M\}, \quad E = \bigcup_{n=1}^M E_{\lambda_n}.$$

Now we argue exactly as in the text's proof of Corollary 6, with the initial segment $\{1, \dots, M\}$ in place of $\mathbb{N}$ as the index range.

Fix n with $1 \leq n \leq M$. If E_{λ_n} is finite and nonempty, choose a natural number $N(n)$ and a one-to-one mapping f_n of $\{1, \dots, N(n)\}$ onto E_{λ_n} ; such a choice is possible by the definition of a finite nonempty set. If E_{λ_n} is countably infinite, choose a one-to-one mapping f_n of $\mathbb{N}$ onto E_{λ_n} ; such a choice is possible by the definition of a countably infinite set. (These are the only two possibilities, since each E_{λ_n} is countable.) If E_{λ_n} is empty, no f_n is chosen. Define

$$E' = \{ (n, k) \in \mathbb{N} \times \mathbb{N} \mid 1 \leq n \leq M, E_{\lambda_n} \text{ is nonempty, and } 1 \leq k \leq N(n) \text{ if } E_{\lambda_n} \text{ is also finite} \}$$

and define

$$f: E' \rightarrow E, \quad f(n, k) = f_n(k).$$

The definition makes sense: for $(n, k) \in E'$ the set E_{λ_n} is nonempty and k lies in the domain of f_n , and $f_n(k) \in E_{\lambda_n} \subseteq E$.

The mapping f is onto E . Indeed, let $x \in E$. Then $x \in E_{\lambda_n}$ for some n with $1 \leq n \leq M$, and in particular E_{λ_n} is nonempty. Since f_n maps its domain onto E_{λ_n} , there is a k in the domain of f_n with $f_n(k) = x$; that k is a natural number with $1 \leq k \leq N(n)$ in the case E_{λ_n} is finite, and an arbitrary natural number in the case E_{λ_n} is countably infinite. In either case $(n, k) \in E'$ and $f(n, k) = x$.

Finally, E' is a subset of $\mathbb{N} \times \mathbb{N}$, which is countable by Corollary 4 (part (i) with $n = 2$), so E' is countable by Theorem 3. Moreover E' is nonempty, since E is nonempty and f maps E' onto E . Therefore E is a nonempty set that is the image of a function whose domain is a nonempty countable set, and Theorem 5 tells us that E is countable.

Remark. Equivalently one may argue by induction on M : the case $M = 1$ is trivial, and for the inductive step it suffices to know that the union of two countable sets A and B is countable. That special case follows from the argument above with $M = 2$, or directly: choose one-to-one mappings $g: A \rightarrow \mathbb{N}$ and $h: B \rightarrow \mathbb{N}$ as furnished by Problem 17, and define $\Phi: A \cup B \rightarrow \mathbb{N}$ by $\Phi(x) = 2g(x)$ if $x \in A$ and $\Phi(x) = 2h(x) - 1$ if $x \in B \sim A$. Then Φ is one-to-one, since Φ takes even values on A and odd values on $B \sim A$ and is one-to-one on each of these two sets, and so $A \cup B$ is countable by Problem 17.

Problem 1.20. Let both $f: A \rightarrow B$ and $g: B \rightarrow C$ be one-to-one and onto. Show that the composition $g \circ f: A \rightarrow C$ and the inverse $f^{-1}: B \rightarrow A$ are also one-to-one and onto.

Solution. (The target of the composition is misprinted in the statement: $g \circ f$ maps A to C , not to B . We prove the assertion for $g \circ f: A \rightarrow C$.)

First, the composition. By definition $g \circ f$ is the mapping of A to C given by

$$(g \circ f)(x) = g(f(x)) \quad \text{for } x \in A,$$

which makes sense because $f(x) \in B$ and g is defined on all of B .

$g \circ f$ is one-to-one. Let $x, x' \in A$ and suppose $(g \circ f)(x) = (g \circ f)(x')$, that is, $g(f(x)) = g(f(x'))$. Since $f(x)$ and $f(x')$ belong to B and g is one-to-one, we conclude that $f(x) = f(x')$. Since f is one-to-one, we conclude that $x = x'$.

$g \circ f$ is onto C . Let $z \in C$. Since g maps B onto C , there is a $y \in B$ with $g(y) = z$. Since f maps A onto B , there is an $x \in A$ with $f(x) = y$. Then

$$(g \circ f)(x) = g(f(x)) = g(y) = z.$$

Second, the inverse. We must first check that f^{-1} is a well-defined mapping of B to A . Let $y \in B$. Since f is onto, there is at least one $x \in A$ with $f(x) = y$; since f is one-to-one, there is at most one such x . Hence there is exactly one $x \in A$ with $f(x) = y$, and we may define $f^{-1}(y)$ to be that x . This gives a mapping $f^{-1}: B \rightarrow A$ characterized by the equivalence

$$f^{-1}(y) = x \iff f(x) = y \quad (x \in A, y \in B).$$

In particular $f^{-1}(f(x)) = x$ for all $x \in A$ and $f(f^{-1}(y)) = y$ for all $y \in B$.

f^{-1} is one-to-one. Let $y, y' \in B$ and suppose $f^{-1}(y) = f^{-1}(y')$; call this common value $x \in A$. By the characterizing equivalence, $f(x) = y$ and $f(x) = y'$. Since f is a mapping, it assigns to x a single value, so $y = f(x) = y'$.

f^{-1} is onto A . Let $x \in A$ and set $y = f(x) \in B$. By the characterizing equivalence, $f^{-1}(y) = x$. Thus every member of A is a value of f^{-1} .

Therefore $g \circ f: A \rightarrow C$ and $f^{-1}: B \rightarrow A$ are both one-to-one and onto, as asserted.

Remark. These two facts are exactly what is needed to see that equipotence is an equivalence relation among sets, as asserted in Section 1.3: reflexivity is witnessed by the identity mapping, symmetry by the inverse f^{-1} of a one-to-one correspondence f , and transitivity by the composition $g \circ f$ of one-to-one correspondences f and g .

Problem 1.21. Use an induction argument to establish the pigeonhole principle. [As stated in Section 1.3: for any natural numbers n and m , the set $\{1, \dots, n + m\}$ is not equipotent to the set $\{1, \dots, n\}$. The induction is with respect to n .]

Solution. For a natural number k we write, as in the text, $\{1, \dots, k\}$ for the initial segment $\{j \in \mathbb{N} \mid 1 \leq j \leq k\}$. Let

$$S = \{n \in \mathbb{N} \mid \text{for every } m \in \mathbb{N}, \{1, \dots, n + m\} \text{ is not equipotent to } \{1, \dots, n\}\}.$$

We show $1 \in S$ and that $n \in S$ implies $n + 1 \in S$; the Principle of Mathematical Induction then gives $S = \mathbb{N}$, which is the pigeonhole principle. Since equipotence is symmetric (Problem 20), it does not matter in which direction we look for a one-to-one correspondence.

Base case. Let m be a natural number and suppose, to get a contradiction, that f is a one-to-one mapping of $\{1, \dots, 1 + m\}$ onto $\{1\}$. Since $m \geq 1$, we have $1 + m \geq 2$, so 1 and 2 are two distinct members of $\{1, \dots, 1 + m\}$. But $f(1)$ and $f(2)$ both lie in the one-element set $\{1\}$, so $f(1) = 1 = f(2)$, contradicting the assumption that f is one-to-one. Hence no such f exists, and $1 \in S$.

Inductive step. Suppose $n \in S$. Let m be a natural number and suppose, to get a contradiction, that there is a one-to-one mapping f of $\{1, \dots, (n + 1) + m\}$ onto $\{1, \dots, n + 1\}$. Write

$$q = (n + 1) + m = (n + m) + 1,$$

so that the domain of f is $\{1, \dots, q\}$ and $\{1, \dots, q\} \sim \{q\} = \{1, \dots, n + m\}$.

We first arrange that the largest element of the domain is sent to the largest element of the range. Since f is onto, there is a $p \in \{1, \dots, q\}$ with $f(p) = n + 1$. Let τ be the transposition of $\{1, \dots, q\}$ that interchanges p and q and fixes every other element:

$$\tau(p) = q, \quad \tau(q) = p, \quad \tau(j) = j \quad \text{for } j \notin \{p, q\}.$$

(If $p = q$, then τ is the identity mapping.) One checks directly that $\tau \circ \tau$ is the identity mapping of $\{1, \dots, q\}$; consequently τ is one-to-one, since $\tau(i) = \tau(j)$ gives $i = \tau(\tau(i)) = \tau(\tau(j)) = j$, and τ is onto, since any j equals $\tau(\tau(j))$.

By Problem 20, the composition $h = f \circ \tau$ is a one-to-one mapping of $\{1, \dots, q\}$ onto $\{1, \dots, n + 1\}$, and

$$h(q) = f(\tau(q)) = f(p) = n + 1.$$

Now let h_0 be the restriction of h to $\{1, \dots, n + m\} = \{1, \dots, q\} \sim \{q\}$. We claim h_0 is a one-to-one mapping of $\{1, \dots, n + m\}$ onto $\{1, \dots, n\}$.

h_0 takes its values in $\{1, \dots, n\}$: if $1 \leq j \leq n + m$, then $j \neq q$, so $h(j) \neq h(q) = n + 1$ because h is one-to-one; since $h(j) \in \{1, \dots, n + 1\}$ and $h(j) \neq n + 1$, we get $h(j) \in \{1, \dots, n\}$.

h_0 is one-to-one: it is the restriction of the one-to-one mapping h to a subset of its domain.

h_0 is onto $\{1, \dots, n\}$: let $i \in \{1, \dots, n\}$. Since h is onto $\{1, \dots, n + 1\}$, there is a $j \in \{1, \dots, q\}$ with $h(j) = i$. As $i \leq n < n + 1 = h(q)$, we have $h(j) \neq h(q)$, hence $j \neq q$, hence $1 \leq j \leq n + m$ and $h_0(j) = i$.

Thus $\{1, \dots, n + m\}$ is equipotent to $\{1, \dots, n\}$, with m a natural number. This contradicts the assumption $n \in S$.

Therefore no such f exists for any natural number m , that is, $\{1, \dots, (n+1) + m\}$ is not equipotent to $\{1, \dots, n+1\}$ for any natural number m . Hence $n+1 \in S$.

By induction $S = \mathbb{N}$, and the pigeonhole principle is established: for all natural numbers n and m , the set $\{1, \dots, n+m\}$ is not equipotent to $\{1, \dots, n\}$.

Remark. Two standard consequences follow at once. If n and n' are natural numbers with $n \neq n'$, then $\{1, \dots, n\}$ and $\{1, \dots, n'\}$ are not equipotent: for one of them, say $n < n'$, we may write $n' = n + m$ with $m = n' - n$, and m is a natural number by Problem 9; the principle then applies. Hence the natural number n attached to a nonempty finite set by the definition of finiteness is uniquely determined by the set.

1.4 Problems 1.22–1.28

Problem 1.22. Show that $2^{\mathbb{N}}$, the collection of all sets of natural numbers, is uncountable.

Solution. We first record an elementary observation that will be used repeatedly.

Observation. If E is a nonempty countable set, then there is a mapping of $\mathbb{N}$ onto E . Indeed, by the definition of countability E is either finite or countably infinite. If E is countably infinite there is a one-to-one correspondence h of $\mathbb{N}$ onto E , and h itself is such a mapping. If E is finite and nonempty there is a natural number n and a one-to-one correspondence h of $\{1, \dots, n\}$ onto E ; define $f: \mathbb{N} \rightarrow E$ by $f(k) = h(k)$ for $1 \leq k \leq n$ and $f(k) = h(1)$ for $k > n$. Then f maps $\mathbb{N}$ onto E .

Now suppose, by way of contradiction, that $2^{\mathbb{N}}$ is countable. The set $2^{\mathbb{N}}$ is nonempty, since the empty-set belongs to it. Hence, by the Observation, there is a mapping

$$f: \mathbb{N} \longrightarrow 2^{\mathbb{N}}$$

of $\mathbb{N}$ onto $2^{\mathbb{N}}$; that is, every set of natural numbers is of the form $f(n)$ for some natural number n .

Define

$$D = \{n \in \mathbb{N} : n \notin f(n)\}.$$

This is a well-defined set of natural numbers, so D belongs to $2^{\mathbb{N}}$. Since f is onto, there is a natural number m for which $D = f(m)$. We ask whether m belongs to D .

If $m \in D$, then by the definition of D we have $m \notin f(m) = D$, a contradiction. If $m \notin D$, then $m \notin f(m)$, and therefore, again by the definition of D , $m \in D$, once more a contradiction.

Both alternatives are impossible, so no mapping of $\mathbb{N}$ onto $2^{\mathbb{N}}$ exists. This contradicts the Observation, and therefore $2^{\mathbb{N}}$ is not countable, that is, $2^{\mathbb{N}}$ is uncountable.

Remark. The same argument shows, for an arbitrary set X , that there is no mapping of X onto 2^X ; in particular X and 2^X are never equipotent.

Problem 1.23. Show that the Cartesian product of a finite collection of countable sets is countable. Use the preceding problem to show that $\mathbb{N}^{\mathbb{N}}$, the collection of all mappings of $\mathbb{N}$ into $\mathbb{N}$, is not countable.

Solution. Part 1: finite Cartesian products of countable sets.

Let $A_1, \dots, A_n$ be countable sets; we show $A_1 \times \dots \times A_n$ is countable, arguing by induction on n .

For $n = 1$ there is nothing to prove. Consider $n = 2$, so let A and B be countable. If either A or B is empty, then $A \times B$ is empty and hence countable. So assume both are nonempty. By the Observation recorded in the solution of Problem 22, there are mappings f of $\mathbb{N}$ onto A and g of $\mathbb{N}$ onto B . Define

$$h: \mathbb{N} \times \mathbb{N} \longrightarrow A \times B, \quad h(m, k) = (f(m), g(k)).$$

If (a, b) belongs to $A \times B$, choose m with $f(m) = a$ and k with $g(k) = b$; then $h(m, k) = (a, b)$. Thus h maps $\mathbb{N} \times \mathbb{N}$ onto $A \times B$. By Corollary 4(i) the set $\mathbb{N} \times \mathbb{N}$ is countably infinite, in particular a nonempty countable set. Since $A \times B$ is nonempty and is the image of a function whose domain is a nonempty countable set, Theorem 5 tells us that $A \times B$ is countable.

Now assume the assertion holds for n , and let $A_1, \dots, A_{n+1}$ be countable. The mapping

$$((x_1, \dots, x_n), x_{n+1}) \mapsto (x_1, \dots, x_n, x_{n+1})$$

is a one-to-one correspondence between $(A_1 \times \dots \times A_n) \times A_{n+1}$ and $A_1 \times \dots \times A_{n+1}$. By the induction hypothesis $A_1 \times \dots \times A_n$ is countable, so by the case $n = 2$ the set $(A_1 \times \dots \times A_n) \times A_{n+1}$ is countable; since a set equipotent to a countable set is countable, so is $A_1 \times \dots \times A_{n+1}$. The induction is complete. Part 2: $\mathbb{N}^{\mathbb{N}}$ is uncountable.

For a set E of natural numbers define $\chi_E: \mathbb{N} \rightarrow \mathbb{N}$ by

$$\chi_E(n) = \begin{cases} 1, & n \in E, \\ 2, & n \notin E. \end{cases}$$

Then χ_E is a mapping of $\mathbb{N}$ into $\mathbb{N}$, so χ_E belongs to $\mathbb{N}^{\mathbb{N}}$, and the assignment $E \mapsto \chi_E$ is a mapping of $2^{\mathbb{N}}$ into $\mathbb{N}^{\mathbb{N}}$.

This assignment is one-to-one: if $E \neq F$ are sets of natural numbers, then there is a natural number n belonging to exactly one of them, say $n \in E$ and $n \notin F$; then $\chi_E(n) = 1 \neq 2 = \chi_F(n)$, so $\chi_E \neq \chi_F$. Consequently $2^{\mathbb{N}}$ is equipotent to the set

$$S = \{ \chi_E : E \in 2^{\mathbb{N}} \} \subseteq \mathbb{N}^{\mathbb{N}}.$$

Suppose $\mathbb{N}^{\mathbb{N}}$ were countable. Then, by Theorem 3, its subset S would be countable; and since $2^{\mathbb{N}}$ is equipotent to S , and a set equipotent to a countable set is countable, $2^{\mathbb{N}}$ would be countable. This contradicts the preceding problem. Therefore $\mathbb{N}^{\mathbb{N}}$ is not countable.

Problem 1.24. Show that a nondegenerate interval of real numbers fails to be finite.

Solution. Recall that an interval of real numbers is called degenerate provided it is empty or contains a single member. Thus a nondegenerate interval I contains two distinct points; choose $a, b \in I$ with $a < b$. Since I is an interval, every real number lying between two of its members belongs to I , so

$$[a, b] \subseteq I.$$

Step 1: I contains a subset equipotent to $\mathbb{N}$. For each natural number k put

$$x_k = a + \frac{b-a}{k}.$$

Since $b-a > 0$ and $0 < 1/k \leq 1$, we have $a < x_k \leq b$, so x_k belongs to $[a, b]$ and hence to I . Moreover $k \mapsto x_k$ is one-to-one: if $k \neq k'$ then $1/k \neq 1/k'$, and since $b-a \neq 0$ we get $x_k \neq x_{k'}$. Therefore

$$X = \{ x_k : k \in \mathbb{N} \}$$

is a subset of I that is equipotent to $\mathbb{N}$.

Step 2: a subset of a finite set is finite, and indeed corresponds to an initial segment. We use the following fact, which is exactly what the finite case of the proof of Theorem 3 establishes: if B is equipotent to $\{1, \dots, n\}$ and A is a nonempty subset of B , then there is a natural number N with $N \leq n$ and a one-to-one correspondence between $\{1, \dots, N\}$ and A .

Step 3: $\mathbb{N}$ is not finite. Suppose $\mathbb{N}$ were equipotent to $\{1, \dots, m\}$ for some natural number m , by way of a one-to-one correspondence ψ of $\mathbb{N}$ onto $\{1, \dots, m\}$. The set $\{1, \dots, m+1\}$ is a nonempty subset of $\mathbb{N}$, so its image $\psi(\{1, \dots, m+1\})$ is a nonempty subset of $\{1, \dots, m\}$ equipotent to $\{1, \dots, m+1\}$. By Step 2 there is a natural number $j \leq m$ with $\{1, \dots, j\}$ equipotent to $\psi(\{1, \dots, m+1\})$, and hence, by transitivity of equipotence, $\{1, \dots, j\}$ is equipotent to $\{1, \dots, m+1\}$. Writing $m+1 = j+p$ with $p = m+1-j \geq 1$ a natural number, this says that $\{1, \dots, j\}$ is equipotent to $\{1, \dots, j+p\}$, which contradicts the pigeonhole principle (Problem 21). Therefore $\mathbb{N}$ is not finite.

Step 4: conclusion. Suppose I were finite. Since I is nonempty, there is a natural number n and a one-to-one correspondence φ of I onto $\{1, \dots, n\}$. The set X of Step 1 is a nonempty subset of I , so

$\varphi(X)$ is a nonempty subset of $\{1, \dots, n\}$, and φ restricted to X is a one-to-one correspondence of X onto $\varphi(X)$. By Step 2 there is a natural number $N \leq n$ with $\{1, \dots, N\}$ equipotent to $\varphi(X)$. Since $\mathbb{N}$ is equipotent to X , X is equipotent to $\varphi(X)$, and $\varphi(X)$ is equipotent to $\{1, \dots, N\}$, transitivity of equipotence gives that $\mathbb{N}$ is equipotent to $\{1, \dots, N\}$, that is, $\mathbb{N}$ is finite. This contradicts Step 3. Therefore a nondegenerate interval of real numbers is not finite.

Problem 1.25. Show that any two nondegenerate intervals of real numbers are equipotent.

Solution. Equipotence is reflexive, symmetric and transitive (Problem 20), so it suffices to prove that every nondegenerate interval is equipotent to the single interval $(0, 1)$.

Lemma (absorbing a countable set). Let X be a set, let C be a countable subset of X , and suppose $X \sim C$ contains a countably infinite subset D . Then X and $X \sim C$ are equipotent.

Proof of Lemma. Here $X \sim C$ denotes the set of points of X that do not belong to C . Put $E = C \cup D$. By Corollary 6 the set E is countable. It is not finite: it contains D , and were E finite then, by Step 2 of Problem 24, D would be equipotent to an initial segment $\{1, \dots, N\}$, so that $\mathbb{N}$ would be finite, contradicting Step 3 of Problem 24. Hence E is countably infinite. Since $D \subseteq X \sim C$, the sets C and D are disjoint, so $E \sim C = D$. Let $\{e_k \mid k \in \mathbb{N}\}$ be an enumeration of E and $\{d_k \mid k \in \mathbb{N}\}$ an enumeration of D . Define

$$h: X \rightarrow X \sim C, \quad h(e_k) = d_k \quad (k \in \mathbb{N}), \quad h(x) = x \quad \text{for } x \in X \sim E.$$

This is well defined, since every point of X either belongs to E , and then equals exactly one e_k , or belongs to $X \sim E$; and its values lie in $D \cup (X \sim E) \subseteq X \sim C$. It is one-to-one: h is one-to-one on E because the d_k are distinct, it is one-to-one on $X \sim E$ because it is the identity there, and the two images D and $X \sim E$ are disjoint because $D \subseteq E$. It is onto $X \sim C$: its image is $D \cup (X \sim E) = (E \sim C) \cup (X \sim E) = X \sim C$. This proves the Lemma.

Step 1: every nondegenerate interval is equipotent to a nondegenerate open interval. Let I be a nondegenerate interval and let $\alpha = \inf I$ and $\beta = \sup I$ be its infimum and supremum in the extended real numbers. If $\alpha < z < \beta$, then z is not a lower bound for I , so there is $u \in I$ with $u < z$, and z is not an upper bound for I , so there is $v \in I$ with $z < v$; since I is an interval, $z \in I$. Hence, writing $J = (\alpha, \beta)$,

$$J \subseteq I \subseteq J \cup F, \quad F = \{\alpha, \beta\} \cap \mathbb{R},$$

so $I = J \cup C$ where $C = I \sim J$ is a subset of F and therefore has at most two elements. Since I is nondegenerate it contains two distinct points, so $\alpha < \beta$ and J is a nondegenerate open interval. Now apply the Lemma with $X = I$ and this finite (hence countable) set C : the set $X \sim C = J$ is a nondegenerate interval, so by Problem 24 it is not finite, and hence (as in Step 1 of Problem 24) it contains a countably infinite subset D . The Lemma then tells us that I is equipotent to $I \sim C = J$, that is, I is equipotent to the open interval $J = (\alpha, \beta)$.

Step 2: the interval $J = (\alpha, \beta)$ produced in Step 1 is equipotent to $(0, 1)$. Here $\alpha < \beta$ are extended real numbers, and we use the notation introduced in Section 1.2, namely $(a, \infty) = \{x \in \mathbb{R} \mid a < x\}$, $(-\infty, b) = \{x \in \mathbb{R} \mid x < b\}$ and $(-\infty, \infty) = \mathbb{R}$. Since $\alpha < \beta$, we have $\alpha \neq +\infty$ and $\beta \neq -\infty$; hence, according to whether each of α, β is real or infinite, J is of exactly one of the four forms (a, b) with $a < b$ real, (a, ∞) with a real, $(-\infty, b)$ with b real, or $\mathbb{R}$. We treat each in turn.

If $J = (a, b)$ with $a < b$ real, then $x \mapsto (x - a)/(b - a)$ is a one-to-one correspondence of (a, b) onto $(0, 1)$, with inverse $s \mapsto a + s(b - a)$.

If $J = (a, \infty)$, then $x \mapsto x - a$ is a one-to-one correspondence of (a, ∞) onto $(0, \infty)$, and

$$t \mapsto \frac{t}{1+t}$$

is a one-to-one correspondence of $(0, \infty)$ onto $(0, 1)$: it carries $(0, \infty)$ into $(0, 1)$ since $0 < t < 1 + t$, and $s \mapsto s/(1 - s)$ carries $(0, 1)$ into $(0, \infty)$ and is a two-sided inverse, because if $s = t/(1 + t)$ then $1 - s = 1/(1 + t)$ and so $s/(1 - s) = t$, while if $t = s/(1 - s)$ then $1 + t = 1/(1 - s)$ and so $t/(1 + t) = s$. If $J = (-\infty, b)$, then $x \mapsto b - x$ is a one-to-one correspondence of $(-\infty, b)$ onto $(0, \infty)$, and we conclude as in the previous case.

If $J = \mathbb{R}$, then

$$x \mapsto \frac{x}{1 + |x|}$$

is a one-to-one correspondence of $\mathbb{R}$ onto $(-1, 1)$: its values satisfy $|x|/(1 + |x|) < 1$, and $y \mapsto y/(1 - |y|)$ maps $(-1, 1)$ into $\mathbb{R}$ and is a two-sided inverse, since for $x \geq 0$ the value $y = x/(1 + x)$ lies in $[0, 1)$ and $y/(1 - y) = x$, while both maps are odd, so the case $x < 0$ follows by symmetry. Composing with the one-to-one correspondence $y \mapsto (y + 1)/2$ of $(-1, 1)$ onto $(0, 1)$ gives the assertion.

Conclusion. By Step 1 and Step 2, every nondegenerate interval of real numbers is equipotent to $(0, 1)$. By symmetry and transitivity of equipotence, any two nondegenerate intervals of real numbers are equipotent to each other.

Problem 1.26. Is the set $\mathbb{R} \times \mathbb{R}$ equipotent to $\mathbb{R}$?

Solution. Yes. We construct an explicit one-to-one correspondence, in five steps. Throughout we use two trivial remarks: equipotence is an equivalence relation (Problem 20), and if f is a one-to-one correspondence of X onto X' and g one of Y onto Y' , then $(x, y) \mapsto (f(x), g(y))$ is a one-to-one correspondence of $X \times Y$ onto $X' \times Y'$.

Let Σ denote the collection of all sequences $a = (a_n)_{n \geq 1}$ with each $a_n \in \{0, 1\}$ and with $a_n = 0$ for infinitely many indices n .

Step 1: the map $\sigma(a) = \sum_{n=1}^{\infty} a_n 2^{-n}$ is a one-to-one correspondence of Σ onto $[0, 1)$.

The series converges since it is dominated by $\sum 2^{-n} = 1$, and $\sigma(a) \geq 0$. If N is an index with $a_N = 0$, then $\sigma(a) \leq \sum_{n \neq N} 2^{-n} = 1 - 2^{-N} < 1$; such an N exists, so σ maps Σ into $[0, 1)$.

σ is one-to-one: let $a \neq b$ in Σ and let m be the least index with $a_m \neq b_m$, say $a_m = 1$ and $b_m = 0$. Since b has infinitely many zero terms, $\sum_{n > m} b_n 2^{-n} < \sum_{n > m} 2^{-n} = 2^{-m}$, and therefore

$$\sigma(a) - \sigma(b) = 2^{-m} + \sum_{n > m} (a_n - b_n) 2^{-n} \geq 2^{-m} - \sum_{n > m} b_n 2^{-n} > 0.$$

σ is onto $[0, 1)$: given $x \in [0, 1)$, define a_n recursively by declaring $a_n = 1$ if $\sum_{k=1}^{n-1} a_k 2^{-k} + 2^{-n} \leq x$ and $a_n = 0$ otherwise. Put $r_n = x - \sum_{k=1}^n a_k 2^{-k}$, with $r_0 = x$. We claim $0 \leq r_n < 2^{-n}$ for every $n \geq 0$. This holds for $n = 0$. Assume it for $n - 1$. The defining condition for a_n reads $r_{n-1} \geq 2^{-n}$. If it holds, then $a_n = 1$ and $r_n = r_{n-1} - 2^{-n}$, so $0 \leq r_n < 2^{-(n-1)} - 2^{-n} = 2^{-n}$. If it fails, then $a_n = 0$ and $r_n = r_{n-1} < 2^{-n}$, and $r_n \geq 0$. This proves the claim, and letting $n \rightarrow \infty$ gives $\sigma(a) = x$. Finally $a \in \Sigma$: if $a_n = 1$ for all $n > N$, then for $n > N$

$$r_n = r_N - (2^{-N} - 2^{-n}) = (r_N - 2^{-N}) + 2^{-n},$$

and $r_N - 2^{-N} < 0$; taking n large enough that $2^{-n} < 2^{-N} - r_N$ gives $r_n < 0$, a contradiction. So a has infinitely many zero terms.

Step 2: let B be the set of $a \in \Sigma$ having infinitely many terms equal to 1 as well. Then B is equipotent to $\mathbb{R}$.

The complement $\Sigma \sim B$ consists of the sequences in Σ with only finitely many terms equal to 1. For each natural number N there are exactly 2^N such sequences whose terms vanish from index $N + 1$ on, so $\Sigma \sim B$ is the union of a countable collection of finite sets and hence is countable by Corollary 6. Since σ is one-to-one, $C = \sigma(\Sigma \sim B)$ is a countable subset of $[0, 1)$ and $\sigma(B) = [0, 1) \sim C$. For each natural number m let $b^{(m)}$ be the sequence whose n -th term is 1 exactly when n is even and $n \geq 2m$; each $b^{(m)}$ has infinitely many ones and infinitely many zeros, so $b^{(m)} \in B$, and these sequences are distinct because $2m$ is the least index carrying a 1 in $b^{(m)}$. Hence $D = \{\sigma(b^{(m)}) \mid m \in \mathbb{N}\}$ is a countably infinite subset of $[0, 1) \sim C$. By the Lemma proved in Problem 25, applied with $X = [0, 1)$, the sets $[0, 1)$ and $[0, 1) \sim C = \sigma(B)$ are equipotent. Since σ restricted to B is a one-to-one correspondence of B onto $\sigma(B)$, the set B is equipotent to $[0, 1)$, which by Problem 25 is equipotent to $\mathbb{R}$.

Step 3: B is equipotent to $\mathbb{N}^{\mathbb{N}}$, the collection of all mappings of $\mathbb{N}$ into $\mathbb{N}$, which we regard as the collection of all sequences $(m_j)_{j \geq 1}$ of natural numbers.

Define $\Psi: \mathbb{N}^{\mathbb{N}} \rightarrow B$ as follows: $\Psi(m)$ is the sequence obtained by concatenating the blocks

$$\underbrace{0 \cdots 0}_{m_1-1}, \underbrace{1 \cdots 1}_{m_2}, \underbrace{0 \cdots 0}_{m_3}, \underbrace{1 \cdots 1}_{m_4}, \dots$$

that is, the first block consists of $m_1 - 1 \geq 0$ zeros and, for $j \geq 2$, the j -th block consists of $m_j \geq 1$ terms, all equal to 1 if j is even and all equal to 0 if j is odd. Since each block with $j \geq 2$ is nonempty, the concatenation is an infinite sequence of 0's and 1's; it has infinitely many ones (one from each even block) and infinitely many zeros (one from each odd block with $j \geq 3$). Hence $\Psi(m) \in B$.

Ψ is onto B and one-to-one because a sequence in B has a unique decomposition into maximal constant runs. We first describe a recovery recipe $\Phi: B \rightarrow \mathbb{N}^{\mathbb{N}}$. Let $a \in B$ and put $S = \{n \in \mathbb{N} \mid a_n \neq a_{n+1}\}$. If S were finite, a would be constant from some index on, contradicting the fact that both values occur infinitely often; so S is infinite and we may enumerate it increasingly as $s_1 < s_2 < \dots$. Put $s_0 = 0$ and $\ell_j = s_j - s_{j-1} \geq 1$. On each set of indices $\{s_{j-1} + 1, \dots, s_j\}$ the sequence a is constant, and its values on consecutive such sets differ; hence they alternate, starting with the value a_1 . If $a_1 = 0$, set $m_1 = \ell_1 + 1$ and $m_j = \ell_j$ for $j \geq 2$; if $a_1 = 1$, set $m_1 = 1$ and $m_{j+1} = \ell_j$ for $j \geq 1$. In either case (m_j) is a sequence of natural numbers; write $\Phi(a) = (m_j)$. Comparing blocks one at a time, $\Psi(\Phi(a)) = a$. Hence Ψ maps $\mathbb{N}^{\mathbb{N}}$ onto B .

It remains to check that $\Phi(\Psi(m)) = m$ for every $m \in \mathbb{N}^{\mathbb{N}}$, which gives that Ψ is one-to-one. Put $a = \Psi(m)$. Suppose first $m_1 \geq 2$. Then every block in the definition of $\Psi(m)$ is nonempty and consecutive blocks carry different values, so the maximal constant runs of a are precisely those blocks, in order, with lengths $m_1 - 1, m_2, m_3, \dots$; that is, $\ell_1 = m_1 - 1$ and $\ell_j = m_j$ for $j \geq 2$. Also $a_1 = 0$, so the recipe returns $\ell_1 + 1 = m_1$ and $\ell_j = m_j$ for $j \geq 2$, that is, $\Phi(a) = m$. Suppose instead $m_1 = 1$. Then the first block is empty, a begins with the second block and $a_1 = 1$, and the maximal constant runs of a have lengths $m_2, m_3, \dots$; that is, $\ell_j = m_{j+1}$ for $j \geq 1$. The recipe for the case $a_1 = 1$ returns first coordinate $1 = m_1$ and $(j+1)$ -st coordinate $\ell_j = m_{j+1}$, so again $\Phi(a) = m$.

Thus Ψ is a one-to-one correspondence of $\mathbb{N}^{\mathbb{N}}$ onto B .

Step 4: $\mathbb{N}^{\mathbb{N}} \times \mathbb{N}^{\mathbb{N}}$ is equipotent to $\mathbb{N}^{\mathbb{N}}$.

Given $u = (u_k)$ and $v = (v_k)$ in $\mathbb{N}^{\mathbb{N}}$, let $w = \Theta(u, v)$ be the interleaved sequence defined by $w_{2k-1} = u_k$ and $w_{2k} = v_k$ for $k \in \mathbb{N}$. Then Θ maps into $\mathbb{N}^{\mathbb{N}}$, and the assignment $w \mapsto ((w_{2k-1})_k, (w_{2k})_k)$ is a two-sided inverse. Hence Θ is a one-to-one correspondence.

Step 5: conclusion. Combining the steps,

$$\mathbb{R} \times \mathbb{R} \sim B \times B \sim \mathbb{N}^{\mathbb{N}} \times \mathbb{N}^{\mathbb{N}} \sim \mathbb{N}^{\mathbb{N}} \sim B \sim \mathbb{R},$$

where each $\sim$ denotes equipotence: the first by Step 2 and the product remark, the second by Step 3 and the product remark, the third by Step 4, the fourth by Step 3, the last by Step 2. By transitivity, $\mathbb{R} \times \mathbb{R}$ is equipotent to $\mathbb{R}$.

Problem 1.27. Is the set of rational numbers open or closed?

Solution. The set $\mathbb{Q}$ of rational numbers is neither open nor closed.

$\mathbb{Q}$ is not open. Let x be a rational number and let $r > 0$. The interval $(x - r, x + r)$ is a nondegenerate interval, and the irrational numbers are dense in $\mathbb{R}$ (Problem 12), so there is an irrational number y with $x - r < y < x + r$. Thus $(x - r, x + r)$ is not contained in $\mathbb{Q}$. Since this holds for every $r > 0$, and since $\mathbb{Q}$ contains a point (for instance 0), the defining property of openness fails at every point of $\mathbb{Q}$. Hence $\mathbb{Q}$ is not open.

$\mathbb{Q}$ is not closed. Let x be any real number and let I be an open interval containing x . Then I contains an interval of the form $(x - r, x + r)$ with $r > 0$, and by the density of the rational numbers, Theorem 2, there is a rational number q with $x - r < q < x + r$. Hence every open interval containing x contains a point of $\mathbb{Q}$, so x is a point of closure of $\mathbb{Q}$. Since x was arbitrary,

$$\overline{\mathbb{Q}} = \mathbb{R}.$$

But $\mathbb{R} \neq \mathbb{Q}$, since for instance $\sqrt{2}$ is irrational. Therefore $\mathbb{Q}$ does not contain all of its points of closure,

that is, $\mathbb{Q}$ is not closed.

Equivalently, one may argue the second assertion from the first through Proposition 11: were $\mathbb{Q}$ closed, its complement, the set of irrational numbers, would be open; but by the density of the rationals, Theorem 2, no interval $(x - r, x + r)$ about an irrational x consists entirely of irrationals.

Problem 1.28. What are the sets of real numbers that are both open and closed?

Solution. The only subsets of $\mathbb{R}$ that are both open and closed are the empty-set $\emptyset$ and $\mathbb{R}$ itself.

First, these two sets do have the property. By Proposition 8 both $\emptyset$ and $\mathbb{R}$ are open, and by Proposition 12 both are closed. (Alternatively: $\mathbb{R}$ is open and its complement $\emptyset$ is open, so by Proposition 11 the set $\mathbb{R}$ is closed, and symmetrically for $\emptyset$.)

Conversely, let E be a set of real numbers that is both open and closed, and suppose E is neither empty nor all of $\mathbb{R}$; we derive a contradiction.

Choose $x \in E$. Since E is open and nonempty, the construction in the proof of Proposition 9 applies: with

$$a_x = \inf\{z \mid (z, x) \subseteq E\}, \quad b_x = \sup\{y \mid (x, y) \subseteq E\}$$

taken in the extended real numbers, the interval $I_x = (a_x, b_x)$ contains x and, by assertion (2) in that proof,

$$I_x \subseteq E, \quad a_x \notin E, \quad b_x \notin E.$$

Since $E \neq \mathbb{R}$ and $I_x \subseteq E$, we have $I_x \neq \mathbb{R}$, so at least one of a_x, b_x is a real number. Suppose first that b_x is real. We claim b_x is a point of closure of E . Indeed, let I be an open interval containing b_x ; then I contains an interval $(b_x - r, b_x + r)$ for some $r > 0$. Since $a_x < x < b_x$, the number

$$t = \max\left\{x, b_x - \frac{r}{2}\right\}$$

satisfies $a_x < t < b_x$ and $b_x - r < t$, so t belongs both to $I_x \subseteq E$ and to $(b_x - r, b_x + r) \subseteq I$. Thus every open interval containing b_x contains a point of E , so b_x is a point of closure of E . Since E is closed, $E = \overline{E}$, and therefore $b_x \in E$. This contradicts $b_x \notin E$.

If instead $b_x = \infty$, then a_x must be a real number, and the symmetric argument applies: for any $r > 0$ the number $t = \min\{x, a_x + \frac{r}{2}\}$ satisfies $a_x < t < b_x$ and $t < a_x + r$, so every open interval containing a_x contains a point of $I_x \subseteq E$; hence a_x is a point of closure of E , so $a_x \in E$ because E is closed, contradicting $a_x \notin E$.

In either case we reach a contradiction. Therefore a set of real numbers that is both open and closed must be $\emptyset$ or $\mathbb{R}$.

1.5 Problems 1.29–1.35

Problem 1.29. Find two sets A and B such that $A \cap B = \emptyset$ and $\overline{A} \cap \overline{B} \neq \emptyset$.

Solution. Take

$$A = (0, 1), \quad B = (1, 2).$$

These are disjoint: a real number cannot satisfy both $x < 1$ and $x > 1$, so $A \cap B = \emptyset$.

Now compute the closures. I claim $\overline{A} = [0, 1]$. First, $[0, 1]$ is a closed set containing A : its complement $(-\infty, 0) \cup (1, \infty)$ is the union of two open intervals, hence open by Proposition 8, so $[0, 1]$ is closed by Proposition 11. Since $\overline{A}$ is the smallest closed set containing A (Proposition 10), $\overline{A} \subseteq [0, 1]$. Conversely, both 0 and 1 are points of closure of A : if I is an open interval containing 0, then I contains an interval $(-r, r)$ with $r > 0$, and by the Archimedean Property of $\mathbb{R}$ we may choose a natural number n with $1/n < \min\{r, 1\}$; then $1/n \in (0, 1) \cap I = A \cap I$. The same argument at the point 1, using the numbers $1 - 1/n$, shows that 1 is a point of closure of A . Since also $A \subseteq \overline{A}$, we get $[0, 1] = A \cup \{0, 1\} \subseteq \overline{A}$. Hence $\overline{A} = [0, 1]$, and by the identical argument (translate by 1) $\overline{B} = [1, 2]$.

Therefore

$$\overline{A} \cap \overline{B} = [0, 1] \cap [1, 2] = \{1\} \neq \emptyset.$$

A second, more extreme example: let $A = \mathbb{Q}$ and $B = \mathbb{R} \setminus \mathbb{Q}$ be the rationals and the irrationals. These are disjoint by definition. Fix a real number x and an open interval I containing x ; whatever the type of I , there is an $r > 0$ with $(x - r, x + r) \subseteq I$, so it suffices to produce points of A and of B in each bounded interval (a, b) with $a < b$. By Theorem 2 the rational numbers are dense in $\mathbb{R}$, so (a, b) contains a rational number; hence every real number is a point of closure of A and $\overline{A} = \mathbb{R}$. The interval (a, b) also contains an irrational number: by Theorem 2 pick rationals q and q' with $a < q < q' < b$, and set $z = q + (q' - q)/\sqrt{2}$. Since $0 < 1/\sqrt{2} < 1$ we have $q < z < q'$, so $z \in (a, b)$; and z is irrational, for if z were rational then $\sqrt{2} = (q' - q)/(z - q)$ would be a quotient of nonzero rationals and so rational, contradicting the irrationality of $\sqrt{2}$ established in Section 1.2. Hence $\overline{B} = \mathbb{R}$ as well, and $\overline{A} \cap \overline{B} = \mathbb{R} \neq \emptyset$, although $A \cap B = \emptyset$.

The examples show that the operation $E \mapsto \overline{E}$ does not preserve disjointness: closure can create new common points on the shared boundary of two disjoint sets.

Problem 1.30. A point x is called an **accumulation point** of a set E provided it is a point of closure of $E \setminus \{x\}$.

- (i) Show that the set E' of accumulation points of E is a closed set.
- (ii) Show that $\overline{E} = E \cup E'$.

Solution. Throughout, recall the definition: x is a point of closure of a set S provided every open interval that contains x also contains a point of S . Thus $x \in E'$ means: every open interval containing x contains a point of E different from x .

(i) E' is closed.

By definition a set is closed provided it contains all of its points of closure, so let x be a point of closure of E' ; we must show $x \in E'$. Let I be an open interval containing x . We must produce a point of $E \setminus \{x\}$ inside I .

Since x is a point of closure of E' , the interval I contains some point $y \in E'$.

Case 1: $y = x$. Then $x \in E'$ and there is nothing more to prove.

Case 2: $y \neq x$. The set $I \setminus \{x\}$ is open: indeed I is open and $\mathbb{R} \setminus \{x\}$ is open (its complement $\{x\}$ is closed, since any $z \neq x$ has the open interval $(z - |z - x|, z + |z - x|)$ about it missing x , so z is not a point of closure of $\{x\}$), and the intersection of two open sets is open by Proposition 8. Since $y \in I \setminus \{x\}$, there is an $r > 0$ with $J := (y - r, y + r) \subseteq I \setminus \{x\}$. Now $y \in E'$, so y is a point of closure of $E \setminus \{y\}$, and J is an open interval containing y ; hence J contains a point $z \in E \setminus \{y\}$. Then $z \in E$, $z \in J \subseteq I$, and $z \neq x$ because J misses x . So $z \in (E \setminus \{x\}) \cap I$.

In either case I contains a point of $E \setminus \{x\}$. As I was an arbitrary open interval containing x , we conclude x is a point of closure of $E \setminus \{x\}$, that is, $x \in E'$. Therefore E' contains all its points of closure and so is closed.

(ii) $\overline{E} = E \cup E'$.

($\supseteq$) We always have $E \subseteq \overline{E}$. And $E' \subseteq \overline{E}$: if $x \in E'$, then every open interval containing x contains a point of $E \setminus \{x\}$, and such a point lies in E ; hence x is a point of closure of E , i.e. $x \in \overline{E}$. Thus $E \cup E' \subseteq \overline{E}$.

($\subseteq$) Let $x \in \overline{E}$. If $x \in E$ then $x \in E \cup E'$ and we are done. So suppose $x \notin E$. Then $E \setminus \{x\} = E$. Since $x \in \overline{E}$, every open interval containing x contains a point of $E = E \setminus \{x\}$; hence x is a point of closure of $E \setminus \{x\}$, i.e. $x \in E'$. In either case $x \in E \cup E'$.

Therefore $\overline{E} = E \cup E'$.

Two remarks worth recording. First, part (i) is not a corollary of Proposition 10: that proposition says $\overline{E}$ is closed, and by part (ii) $\overline{E} = E \cup E'$, which carries no information about E' by itself. Indeed E' can be closed while E is not, and E' can be a proper subset of the closed set $\overline{E}$; the direct argument above is what is needed. Second, combining (i) and (ii): E is closed if and only if $E' \subseteq E$, since E is closed exactly when $E = \overline{E} = E \cup E'$, and that holds exactly when $E' \subseteq E$.

Problem 1.31. A point x is called an **isolated point** of a set E provided there is an $r > 0$ for which $(x - r, x + r) \cap E = \{x\}$. Show that if a set E consists of isolated points, then it is countable.

Solution. Assume every point of E is an isolated point of E . For each $x \in E$ fix a number $r_x > 0$ with

$$(x - r_x, x + r_x) \cap E = \{x\}.$$

By Theorem 2 the rational numbers are dense in $\mathbb{R}$, so we may choose rational numbers p_x and q_x with

$$x - r_x < p_x < x < q_x < x + r_x.$$

(Apply Theorem 2 once to the pair $x - r_x < x$ and once to the pair $x < x + r_x$.) Define a map

$$\varphi : E \longrightarrow \mathbb{Q} \times \mathbb{Q}, \quad \varphi(x) = (p_x, q_x).$$

φ is one-to-one. Suppose $x, y \in E$ and $\varphi(x) = \varphi(y)$, that is $p_x = p_y$ and $q_x = q_y$. Then

$$y \in (p_y, q_y) = (p_x, q_x) \subseteq (x - r_x, x + r_x),$$

and $y \in E$, so $y \in (x - r_x, x + r_x) \cap E = \{x\}$. Hence $y = x$. Thus φ is one-to-one.

$\mathbb{Q} \times \mathbb{Q}$ is countable. Write

$$\mathbb{Q} \times \mathbb{Q} = \bigcup_{q \in \mathbb{Q}} (\{q\} \times \mathbb{Q}).$$

Each set $\{q\} \times \mathbb{Q}$ is equipotent to $\mathbb{Q}$, hence countable by Corollary 4, and the index set $\mathbb{Q}$ is countable by Corollary 4 as well. So this is the union of a countable collection of countable sets, which is countable by Corollary 6.

Conclusion. Since φ is one-to-one, E is equipotent to the subset $\varphi(E)$ of the countable set $\mathbb{Q} \times \mathbb{Q}$. By Theorem 3 a subset of a countable set is countable, so $\varphi(E)$ is countable, and therefore E is countable. A second proof, avoiding $\mathbb{Q} \times \mathbb{Q}$. For each natural number n set

$$E_n = \left\{ x \in E : \left(x - \frac{1}{n}, x + \frac{1}{n} \right) \cap E = \{x\} \right\}.$$

Every $x \in E$ has some $r_x > 0$ as above, and by the Archimedean Property there is an n with $1/n < r_x$; then $(x - 1/n, x + 1/n) \cap E \subseteq (x - r_x, x + r_x) \cap E = \{x\}$ and this intersection contains x , so $x \in E_n$. Hence $E = \bigcup_{n=1}^{\infty} E_n$.

Fix n . Any two distinct points of E_n are at distance at least $1/n$: if $x, y \in E_n$ with $x \neq y$ and $|x - y| < 1/n$, then $y \in (x - 1/n, x + 1/n) \cap E = \{x\}$, so $y = x$, a contradiction. Consequently, for each natural number k the set $E_n \cap [-k, k]$ is finite. Indeed, partition $[-k, k]$ into the $2kn$ half-open intervals $[-k + \frac{j-1}{n}, -k + \frac{j}{n})$ for $j = 1, \dots, 2kn$, together with the single point $\{k\}$; two points lying in the same one of these $2kn + 1$ pieces are at distance strictly less than $1/n$, so by the pigeonhole principle $E_n \cap [-k, k]$ has at most $2kn + 1$ members.

Every real number lies in $[-k, k]$ for some natural number k , by the Archimedean Property applied to the pair 1 and $|x|$ when $x \neq 0$. Therefore $E_n = \bigcup_{k=1}^{\infty} (E_n \cap [-k, k])$ is a countable union of finite sets, hence countable by Corollary 6, and then $E = \bigcup_{n=1}^{\infty} E_n$ is a countable union of countable sets, hence countable by Corollary 6 again.

Problem 1.32. A point x is called an **interior point** of a set E if there is an $r > 0$ such that the open interval $(x - r, x + r)$ is contained in E . The set of interior points of E is called the **interior** of E , denoted by $\text{int } E$. Show that

- (i) E is open if and only if $E = \text{int } E$.
- (ii) E is dense if and only if $\text{int}(\mathbb{R} \setminus E) = \emptyset$.

Solution. Recall the two definitions in force. A set $\mathcal{O}$ of real numbers is open provided for each $x \in \mathcal{O}$ there is an $r > 0$ for which $(x - r, x + r)$ is contained in $\mathcal{O}$. A set E of real numbers is dense in $\mathbb{R}$ provided between any two real numbers there lies a member of E ; equivalently, every nonempty open interval (a, b) with $a < b$ contains a point of E .

First note the inclusion $\text{int } E \subseteq E$, valid for every set E : if $x \in \text{int } E$, choose $r > 0$ with $(x - r, x + r) \subseteq E$;

since $x \in (x - r, x + r)$, we get $x \in E$.

(i) Suppose E is open. Let $x \in E$. By the definition of openness there is an $r > 0$ with $(x - r, x + r) \subseteq E$, which is precisely the statement that x is an interior point of E . Hence $E \subseteq \text{int } E$, and combined with the inclusion above, $E = \text{int } E$.

Conversely suppose $E = \text{int } E$. Let $x \in E$. Then $x \in \text{int } E$, so there is an $r > 0$ with $(x - r, x + r) \subseteq E$. Since $x \in E$ was arbitrary, E is open.

(ii) Suppose first that E is dense in $\mathbb{R}$, and suppose, to get a contradiction, that $\text{int}(\mathbb{R} \sim E) \neq \emptyset$. Choose $x \in \text{int}(\mathbb{R} \sim E)$ and $r > 0$ with

$$(x - r, x + r) \subseteq \mathbb{R} \sim E, \quad \text{that is} \quad (x - r, x + r) \cap E = \emptyset.$$

But $x - r < x + r$, so by density there is a member of E lying between $x - r$ and $x + r$, i.e. a point of E in $(x - r, x + r)$. This contradicts the displayed line. Therefore $\text{int}(\mathbb{R} \sim E) = \emptyset$.

Conversely suppose $\text{int}(\mathbb{R} \sim E) = \emptyset$. Let $a < b$ be real numbers; we must find a member of E strictly between them. Suppose not, so that $(a, b) \cap E = \emptyset$, i.e. $(a, b) \subseteq \mathbb{R} \sim E$. Put

$$x = \frac{a + b}{2}, \quad r = \frac{b - a}{2} > 0.$$

Then $(x - r, x + r) = (a, b) \subseteq \mathbb{R} \sim E$, so x is an interior point of $\mathbb{R} \sim E$ and hence $\text{int}(\mathbb{R} \sim E) \neq \emptyset$, a contradiction. Therefore (a, b) contains a point of E for all $a < b$, i.e. E is dense in $\mathbb{R}$.

It is worth recording what falls out of the two parts. The set $\text{int } E$ is always open: it is exactly the union of all open intervals contained in E , and the union of any collection of open sets is open by Proposition 8. Moreover $\text{int } E$ is the largest open set contained in E , since any open $\mathcal{O} \subseteq E$ has every one of its points interior to E , so $\mathcal{O} = \text{int } \mathcal{O} \subseteq \text{int } E$ by part (i). Dually, part (ii) says E is dense exactly when $\mathbb{R} \sim E$ contains no nonempty open set.

Problem 1.33. Show that the Nested Set Theorem is false if F_1 is unbounded.

Solution. The Nested Set Theorem reads: let $\{F_n\}_{n=1}^\infty$ be a descending countable collection of nonempty closed sets of real numbers for which F_1 is bounded; then $\bigcap_{n=1}^\infty F_n \neq \emptyset$. We exhibit a descending countable collection of nonempty closed sets whose first member is unbounded and whose intersection is empty; this shows the boundedness hypothesis on F_1 cannot be dropped.

For each natural number n define

$$F_n = [n, \infty) = \{x \in \mathbb{R} : x \geq n\}.$$

Each F_n is nonempty, since $n \in F_n$.

Each F_n is closed. Its complement is $\mathbb{R} \sim F_n = (-\infty, n)$, which is an open interval and hence an open set. By Proposition 11, a set of real numbers is closed if and only if its complement in $\mathbb{R}$ is open, so F_n is closed.

The collection is descending: if $x \geq n + 1$ then $x \geq n$, so $F_{n+1} \subseteq F_n$ for every natural number n .

$F_1 = [1, \infty)$ is unbounded: it is not bounded above, for if b were an upper bound of F_1 then $b \geq 1 > 0$ and, by the Archimedean Property of $\mathbb{R}$ applied to the pair 1 and b , there is a natural number n with $n \cdot 1 > b$; but $n \in F_1$, so b is not an upper bound, a contradiction.

Finally the intersection is empty. Let x be any real number. If $x \leq 0$ then $x \notin F_1$. If $x > 0$, then by the Archimedean Property applied to the pair 1 and x there is a natural number n with $n > x$, and then $x \notin F_n$. In either case $x \notin \bigcap_{n=1}^\infty F_n$. Hence

$$\bigcap_{n=1}^\infty [n, \infty) = \emptyset.$$

So the conclusion of the Nested Set Theorem fails for this descending collection of nonempty closed sets, the only hypothesis violated being the boundedness of F_1 .

The failure is not an artifact of using unbounded sets at every stage: the proof of the Nested Set Theorem invokes the Heine-Borel Theorem for the closed set F_1 , and the Heine-Borel Theorem requires

the set to be both closed and bounded. Concretely, in the proof one covers F_1 by the ascending open sets $\mathcal{O}_n = \mathbb{R} \sim F_n$ and extracts a finite subcover; for $F_1 = [1, \infty)$ the open cover $\{(-\infty, n)\}_{n=1}^\infty$ of F_1 has no finite subcover, since a finite union of these is $(-\infty, N)$ for the largest index N present, and $N \in F_1 \sim (-\infty, N)$.

Problem 1.34. Show that the assertion of the Heine-Borel Theorem is equivalent to the Completeness Axiom for the real numbers. Show that the assertion of the Nested Set Theorem is equivalent to the Completeness Axiom for the real numbers.

Solution. Here is the precise setting. Let $\mathbb{R}$ denote a set satisfying the Field Axioms and the Positivity Axioms, so that all the algebra of Section 1.1 and the whole vocabulary of Section 1.4 – open interval, open set, closed set, point of closure, closure, cover, open cover, finite subcover, descending collection, bounded set – is available, together with Propositions 8, 10, 11 and 12, whose proofs use only the field and order axioms. Consider the following three assertions about such an $\mathbb{R}$.

(C) The Completeness Axiom. Every nonempty set of real numbers that is bounded above has a least upper bound.

(HB) The Heine-Borel assertion. If F is a closed and bounded set of real numbers, then every open cover of F has a finite subcover.

(NST) The Nested Set assertion. If $\{F_n\}_{n=1}^\infty$ is a descending countable collection of nonempty closed sets of real numbers for which F_1 is bounded, then $\bigcap_{n=1}^\infty F_n \neq \emptyset$.

We prove $(C) \Rightarrow (HB) \Rightarrow (C)$ and $(C) \Rightarrow (NST) \Rightarrow (C)$. The two forward implications are exactly the two theorems proved in the text: the proof of the Heine-Borel Theorem uses (C) once, to form $c = \sup E$ for the set E of numbers $x \in [a, b]$ such that $[a, x]$ can be covered by a finite number of the sets of the cover, and otherwise uses only the definitions of open set, closed set and cover together with Proposition 11; and the proof of the Nested Set Theorem uses (C) only through its appeal to the Heine-Borel Theorem, its remaining ingredients being Proposition 11 and De Morgan's Identities. So it remains to prove the two converses.

Part 1. (HB) implies (C).

Assume (HB). Let E be a nonempty set of real numbers that is bounded above, and suppose, to get a contradiction, that E has no least upper bound.

First, E has no largest member: a largest member of E would be an upper bound of E that is less than or equal to every other upper bound, hence a least upper bound. Consequently no member of E is an upper bound of E , for such a member would be a largest member.

Fix $a \in E$ and fix an upper bound b of E . Then $a \leq b$, and $a \neq b$ since b is an upper bound while a is not. So $a < b$, and $[a, b]$ is a nonempty bounded set. It is closed: its complement $(-\infty, a) \cup (b, \infty)$ is a union of open intervals, hence open by Proposition 8, so $[a, b]$ is closed by Proposition 11.

Now build an open cover of $[a, b]$. Let $x \in [a, b]$.

Case N (x is not an upper bound of E). Then there is an $e \in E$ with $e > x$. Set $\mathcal{O}_x = (-\infty, e)$. This is an open interval containing x , and no point of $\mathcal{O}_x$ is an upper bound of E , since every $z \in \mathcal{O}_x$ satisfies $z < e$ with $e \in E$.

Case U (x is an upper bound of E). Since E has no least upper bound, x is not the least upper bound, so there is an upper bound y of E with $y < x$. Set $\mathcal{O}_x = (y, \infty)$. This is an open interval containing x , and every point of $\mathcal{O}_x$ is an upper bound of E : if $z > y$ then for each $e \in E$ we have $e \leq y < z$.

The collection $\{\mathcal{O}_x\}_{x \in [a, b]}$ is an open cover of $[a, b]$. By (HB) there is a finite subcover $\mathcal{O}_{x_1}, \dots, \mathcal{O}_{x_m}$ of $[a, b]$. Call the index i of type N or of type U according to which case produced $\mathcal{O}_{x_i}$.

Suppose first that no index is of type U. Then every $\mathcal{O}_{x_i}$ is of the form $(-\infty, e_i)$ with $e_i \in E$. Let $e^* = \max\{e_1, \dots, e_m\}$, which exists because the list is finite and $\mathbb{R}$ is totally ordered; then $e^* \in E$ and $\bigcup_{i=1}^m \mathcal{O}_{x_i} = (-\infty, e^*)$. Since this covers $[a, b]$ and $b \in [a, b]$, we get $b < e^*$. But b is an upper bound of E and $e^* \in E$, so $e^* \leq b$. This is a contradiction.

So at least one index is of type U. Let $y_{j_1}, \dots, y_{j_k}$ be the numbers produced in Case U for those indices, and let $y^* = \min\{y_{j_1}, \dots, y_{j_k}\}$; each y_j is an upper bound of E , hence so is y^* . Define

$$c = \min\{y^*, b\}.$$

Then c is an upper bound of E : for each $e \in E$ we have $e \leq y^*$ and $e \leq b$, so $e \leq c$. Since $a \in E$ and c is an upper bound, $a \leq c$; and $c \leq b$ by construction. Hence $c \in [a, b]$, so c lies in some $\mathcal{O}_{x_i}$ of the finite subcover.

If that index i is of type N, then $\mathcal{O}_{x_i} = (-\infty, e_i)$ with $e_i \in E$, so $c < e_i$, contradicting the fact that c is an upper bound of E . Therefore i is of type U, so $\mathcal{O}_{x_i} = (y_j, \infty)$ for one of the numbers y_j above, whence $c > y_j \geq y^*$. But $c = \min\{y^*, b\} \leq y^*$. This is a contradiction.

Both cases being impossible, E must have a least upper bound. Thus (HB) implies (C).

Part 2. (NST) implies (C).

Assume (NST). We argue in two steps.

Step 1: (NST) implies the Archimedean Property, equivalently that $\mathbb{N}$ is not bounded above in $\mathbb{R}$. (The two are equivalent without completeness: if $\mathbb{N}$ is bounded above by M , then for the positive pair $a = 1, b = \max\{M, 1\}$ we have $n \cdot 1 \leq b$ for every natural number n , so the Archimedean Property fails; conversely if the Archimedean Property fails for the positive pair a, b , then $n \leq b/a$ for every natural number n and $\mathbb{N}$ is bounded above.)

Suppose, for a contradiction, that $\mathbb{N}$ is bounded above by some M ; note $M \geq 1$ since $1 \in \mathbb{N}$. For each natural number n put

$$T_n = \{m \in \mathbb{N} : m \geq n\}, \quad F_n = \overline{T_n}.$$

Then each F_n is nonempty (it contains n) and closed, by Proposition 10. The collection is descending: $T_{n+1} \subseteq T_n$ implies $\overline{T_{n+1}} \subseteq \overline{T_n}$, again by Proposition 10. Finally F_1 is bounded: $T_1 \subseteq [1, M]$, and $[1, M]$ is closed (its complement is open by Proposition 8, so Proposition 11 applies), so by the minimality clause of Proposition 10 we get $F_1 = \overline{T_1} \subseteq [1, M]$.

By (NST) there is a point $x \in \bigcap_{n=1}^{\infty} F_n$. Fix n . Since x is a point of closure of T_n and $(x - \frac{1}{2}, x + \frac{1}{2})$ is an open interval containing x , there is a natural number $m \geq n$ with $|x - m| < \frac{1}{2}$.

Apply this with $n = 1$ to obtain $m_1 \in \mathbb{N}$ with $|x - m_1| < \frac{1}{2}$. Apply it again with $n = m_1 + 1$ to obtain $m_2 \in \mathbb{N}$ with $m_2 \geq m_1 + 1$ and $|x - m_2| < \frac{1}{2}$. Then

$$1 \leq m_2 - m_1 = (m_2 - x) + (x - m_1) \leq |x - m_2| + |x - m_1| < \frac{1}{2} + \frac{1}{2} = 1,$$

which is absurd. Hence $\mathbb{N}$ is not bounded above, i.e. the Archimedean Property holds.

Step 2: (NST) together with the Archimedean Property implies (C).

Let E be nonempty and bounded above. If E has a largest member M_0 , then M_0 is an upper bound of E and every upper bound u of E satisfies $u \geq M_0$ because $M_0 \in E$; so M_0 is the least upper bound and we are done. So assume E has no largest member. Then no member of E is an upper bound of E , since a member of E that is an upper bound of E is a largest member of E .

Choose $a_1 \in E$ and an upper bound b_1 of E . Then $a_1 \leq b_1$, and $a_1 \neq b_1$ because b_1 is an upper bound of E while a_1 , being a member of E , is not; so $a_1 < b_1$, the number a_1 is not an upper bound of E , and b_1 is. Define a_n, b_n recursively by bisection: given $a_n < b_n$ with a_n not an upper bound of E and b_n an upper bound of E , let $m_n = (a_n + b_n)/2$ and set

$$\begin{aligned} a_{n+1} &= a_n, & b_{n+1} &= m_n & \text{if } m_n \text{ is an upper bound of } E, \\ a_{n+1} &= m_n, & b_{n+1} &= b_n & \text{if } m_n \text{ is not an upper bound of } E. \end{aligned}$$

In either case a_{n+1} is not an upper bound of E , b_{n+1} is an upper bound of E , $a_n \leq a_{n+1} < b_{n+1} \leq b_n$, and $b_{n+1} - a_{n+1} = (b_n - a_n)/2$. An induction gives

$$b_n - a_n = \frac{b_1 - a_1}{2^{n-1}} \quad \text{for every natural number } n.$$

Put $F_n = [a_n, b_n]$. Each F_n is nonempty and closed (complement open by Proposition 8, then Proposition 11), the collection is descending because $a_n \leq a_{n+1} < b_{n+1} \leq b_n$, and $F_1 = [a_1, b_1]$ is bounded. By (NST) there is a point

$$c \in \bigcap_{n=1}^{\infty} F_n, \quad \text{so} \quad a_n \leq c \leq b_n \text{ for every } n.$$

We record one consequence of the Archimedean Property: for every $\epsilon > 0$ there is an n with $b_n - a_n < \epsilon$. Indeed, choose a natural number n with $n\epsilon > b_1 - a_1$. An induction shows $2^{n-1} \geq n$ for every natural number n (it holds at $n = 1$, and if $2^{n-1} \geq n$ then $2^n \geq 2n \geq n + 1$). Hence

$$b_n - a_n = \frac{b_1 - a_1}{2^{n-1}} \leq \frac{b_1 - a_1}{n} < \epsilon.$$

c is an upper bound of E . Suppose not; then there is $e \in E$ with $e > c$. Put $\epsilon = e - c > 0$ and choose n with $b_n - a_n < \epsilon$. Since $a_n \leq c$,

$$b_n = a_n + (b_n - a_n) \leq c + (b_n - a_n) < c + \epsilon = e,$$

so $b_n < e$ with $e \in E$, contradicting that b_n is an upper bound of E .

c is the least upper bound of E . Let u be any upper bound of E and suppose $u < c$. Put $\delta = c - u > 0$ and choose n with $b_n - a_n < \delta$. Since $c \leq b_n$,

$$a_n = b_n - (b_n - a_n) \geq c - (b_n - a_n) > c - \delta = u.$$

So $a_n > u$. But a_n is not an upper bound of E , so there is an $e \in E$ with $e > a_n > u$, contradicting that u is an upper bound of E . Hence $u \geq c$ for every upper bound u .

Therefore c is the least upper bound of E , and (C) holds.

Conclusion. Assertions (C), (HB) and (NST) are equivalent over the Field and Positivity Axioms. In particular each of the Heine-Borel Theorem and the Nested Set Theorem is a faithful substitute for the Completeness Axiom: one may take either as the completeness postulate for $\mathbb{R}$ and recover the least upper bound property, and hence all of the analysis built on it. Note also that the equivalence gives (HB) $\Leftrightarrow$ (NST) directly.

Problem 1.35. Show that the collection of Borel sets is the smallest σ -algebra that contains the closed sets.

Solution. Write $\mathcal{B}$ for the collection of Borel sets, that is, by definition, the smallest σ -algebra of sets of real numbers that contains all of the open sets of real numbers. Let $\mathcal{F}$ denote the collection of all closed sets of real numbers, and let $\mathcal{C}$ denote the smallest σ -algebra of sets of real numbers that contains $\mathcal{F}$. Both $\mathcal{B}$ and $\mathcal{C}$ exist. Indeed, the collection $2^{\mathbb{R}}$ of all sets of real numbers is a σ -algebra containing every open set and every closed set, so in each case the family of σ -algebras being intersected is nonempty; Proposition 13 then tells us that the intersection of all σ -algebras of subsets of $\mathbb{R}$ containing a given collection is itself a σ -algebra containing that collection, and it is the smallest such in the sense that it is contained in every σ -algebra containing the collection.

We must show $\mathcal{B} = \mathcal{C}$. The whole argument rests on Proposition 11: a set of real numbers is open if and only if its complement in $\mathbb{R}$ is closed. Equivalently, E is closed if and only if $\mathbb{R} \sim E$ is open.

$\mathcal{C} \subseteq \mathcal{B}$. We check that $\mathcal{B}$ contains every closed set. Let F be a closed set of real numbers. By Proposition 11 the set $\mathbb{R} \sim F$ is open, so $\mathbb{R} \sim F \in \mathcal{B}$ because $\mathcal{B}$ contains all the open sets. A σ -algebra is closed with respect to the formation of complements, so

$$F = \mathbb{R} \sim (\mathbb{R} \sim F) \in \mathcal{B}.$$

Thus $\mathcal{B}$ is a σ -algebra of subsets of $\mathbb{R}$ containing $\mathcal{F}$. Since $\mathcal{C}$ is the smallest such σ -algebra, $\mathcal{C} \subseteq \mathcal{B}$.

$\mathcal{B} \subseteq \mathcal{C}$. We check that $\mathcal{C}$ contains every open set. Let $\mathcal{O}$ be an open set of real numbers. By Proposition 11 the set $\mathbb{R} \sim \mathcal{O}$ is closed, so $\mathbb{R} \sim \mathcal{O} \in \mathcal{F} \subseteq \mathcal{C}$. Since $\mathcal{C}$ is closed with respect to the formation of complements,

$$\mathcal{O} = \mathbb{R} \sim (\mathbb{R} \sim \mathcal{O}) \in \mathcal{C}.$$

Thus $\mathcal{C}$ is a σ -algebra of subsets of $\mathbb{R}$ containing all the open sets. Since $\mathcal{B}$ is by definition the smallest such σ -algebra, $\mathcal{B} \subseteq \mathcal{C}$.

Combining the two inclusions, $\mathcal{B} = \mathcal{C}$: the collection of Borel sets is the smallest σ -algebra of sets of real numbers that contains all of the closed sets.

The point is entirely formal, and it is worth isolating it. If $\mathcal{S}$ is any collection of subsets of a set X and $\mathcal{S}^c = \{X \setminus S : S \in \mathcal{S}\}$, then a σ -algebra contains $\mathcal{S}$ if and only if it contains $\mathcal{S}^c$, since σ -algebras are closed with respect to complements. Hence the smallest σ -algebra containing $\mathcal{S}$ equals the smallest σ -algebra containing $\mathcal{S}^c$. Proposition 11 says exactly that the collection of closed sets is the collection of complements of the open sets, and the result follows.

1.6 Problems 1.36–1.42

Problem 1.36. Show that the collection of Borel sets is the smallest σ -algebra that contains intervals of the form $[a, b)$, where $a < b$.

Solution. Let $\mathcal{I} = \{[a, b) \mid a < b\}$ and let $\mathcal{A}$ be the smallest σ -algebra of sets of real numbers that contains $\mathcal{I}$; this exists by Proposition 13, being the intersection of all σ -algebras containing $\mathcal{I}$ (there is at least one, namely $2^{\mathbb{R}}$). Let $\mathcal{B}$ denote the collection of Borel sets, that is, the smallest σ -algebra containing all the open sets. We show $\mathcal{A} = \mathcal{B}$ by two inclusions.

Step 1. We show $\mathcal{A} \subseteq \mathcal{B}$.

It suffices to show $\mathcal{I} \subseteq \mathcal{B}$, for then $\mathcal{B}$ is a σ -algebra containing $\mathcal{I}$ and the minimality of $\mathcal{A}$ forces $\mathcal{A} \subseteq \mathcal{B}$. Let $a < b$. I claim

$$[a, b) = \bigcap_{n=1}^{\infty} \left(a - \frac{1}{n}, b\right).$$

Indeed, if $a \leq x < b$ then $a - 1/n < a \leq x < b$ for every n , so x lies in the intersection. Conversely, if x belongs to every $(a - 1/n, b)$ then $x < b$ and $x > a - 1/n$ for all n ; by the Archimedean Property of $\mathbb{R}$ the latter forces $x \geq a$ (were $x < a$, choose n with $1/n < a - x$ to get $x < a - 1/n$). Hence $x \in [a, b)$. Each $(a - 1/n, b)$ is an open set, hence a Borel set, and a σ -algebra is closed with respect to the formation of countable intersections. Therefore $[a, b) \in \mathcal{B}$, which proves the claim.

Step 2. We show $\mathcal{B} \subseteq \mathcal{A}$.

It suffices to show that every open set belongs to $\mathcal{A}$, for then $\mathcal{A}$ is a σ -algebra containing the open sets and the minimality of $\mathcal{B}$ forces $\mathcal{B} \subseteq \mathcal{A}$.

First we check that every open interval belongs to $\mathcal{A}$.

- A bounded open interval (a, b) with $a < b$: choose, by the Archimedean Property, a natural number N with $1/N < b - a$. Then

$$(a, b) = \bigcup_{n=N}^{\infty} \left[a + \frac{1}{n}, b\right).$$

Each set on the right belongs to $\mathcal{I}$ because $a + 1/n \leq a + 1/N < b$, and it is contained in (a, b) ; conversely if $a < x < b$, choose $n \geq N$ with $1/n < x - a$, so that $x \in [a + 1/n, b)$. Since $\mathcal{A}$ is closed with respect to countable unions, $(a, b) \in \mathcal{A}$.

- The interval (a, ∞) : it equals $\bigcup_{n=1}^{\infty} (a, a + n)$, a countable union of bounded open intervals, hence lies in $\mathcal{A}$.
- The interval $(-\infty, b)$: it equals $\bigcup_{n=1}^{\infty} (b - n, b)$, hence lies in $\mathcal{A}$.
- All of $\mathbb{R}$: it equals $\bigcup_{n=1}^{\infty} (-n, n)$, hence lies in $\mathcal{A}$.

Now let $\mathcal{O}$ be an open set of real numbers. If $\mathcal{O} = \emptyset$ then $\mathcal{O} \in \mathcal{A}$ by the very definition of a σ -algebra. Otherwise, by Proposition 9, $\mathcal{O}$ is the disjoint union of a countable collection $\{I_k\}$ of open intervals. Each I_k belongs to $\mathcal{A}$ by the preceding paragraph, and $\mathcal{A}$ is closed with respect to the formation of countable unions, so $\mathcal{O} \in \mathcal{A}$.

Thus every open set belongs to $\mathcal{A}$, and Step 2 is proved.

Combining the two steps, $\mathcal{A} = \mathcal{B}$: the collection of Borel sets is the smallest σ -algebra containing the intervals $[a, b)$ with $a < b$.

Problem 1.37. Show that each open set is an F_σ set.

Solution. Recall that a countable union of closed sets is called an F_σ set.

Let $\mathcal{O}$ be an open set of real numbers and let $C = \mathbb{R} \sim \mathcal{O}$, which is closed by Proposition 11. For each natural number n define

$$F_n = \left\{ x \in \mathbb{R} \mid |x| \leq n \text{ and } |x - c| \geq \frac{1}{n} \text{ for every } c \in C \right\}.$$

(If $C = \emptyset$ the second condition is vacuous and $F_n = [-n, n]$.)

Each F_n is closed. Indeed, let x be a point of closure of F_n and let $\epsilon > 0$. The open interval $(x - \epsilon, x + \epsilon)$ contains a point $x' \in F_n$. From $|x'| \leq n$ we get $|x| \leq |x'| + \epsilon \leq n + \epsilon$, and since $\epsilon > 0$ is arbitrary, $|x| \leq n$. Moreover, for any $c \in C$ we have $|x' - c| \geq 1/n$, so

$$|x - c| \geq |x' - c| - |x - x'| > \frac{1}{n} - \epsilon.$$

Again since $\epsilon > 0$ is arbitrary, $|x - c| \geq 1/n$ for every $c \in C$. Hence $x \in F_n$, and F_n contains all of its points of closure, that is, F_n is closed.

We now claim

$$\mathcal{O} = \bigcup_{n=1}^{\infty} F_n.$$

First, $F_n \subseteq \mathcal{O}$ for each n . For if $x \in F_n$ and we had $x \in C$, then taking $c = x$ in the defining condition would give $0 = |x - x| \geq 1/n$, which is false. So $x \notin C$, that is, $x \in \mathcal{O}$.

Conversely, let $x \in \mathcal{O}$. Since $\mathcal{O}$ is open there is an $r > 0$ with $(x - r, x + r) \subseteq \mathcal{O}$, and therefore no point c of C satisfies $|x - c| < r$; that is, $|x - c| \geq r$ for all $c \in C$. By the Archimedean Property of $\mathbb{R}$ choose a natural number n with $n \geq |x|$ and $1/n \leq r$. Then $|x| \leq n$ and $|x - c| \geq r \geq 1/n$ for every $c \in C$, so $x \in F_n$.

This proves the claim, and exhibits $\mathcal{O}$ as a countable union of closed sets. Hence every open set is an F_σ set.

Two remarks. First, taking complements and using De Morgan's Identities together with Proposition 11, the result is equivalent to the dual statement that every closed set is a G_δ set. Second, an alternative proof runs through Proposition 9: a nonempty open set is the union of a countable collection of open intervals, and each open interval is an F_σ , since for $a < b$

$$(a, b) = \bigcup_{n \geq N} \left[a + \frac{1}{n}, b - \frac{1}{n} \right] \quad \text{where } \frac{2}{N} < b - a,$$

while $(a, \infty) = \bigcup_n [a + 1/n, a + n]$, $(-\infty, b) = \bigcup_n [b - n, b - 1/n]$, and $\mathbb{R} = \bigcup_n [-n, n]$; a countable union of F_σ sets is again an F_σ set.

Problem 1.38. We call an extended real number a **cluster point** of a sequence $\{a_n\}$ if a subsequence converges to this extended real number. Show that $\liminf\{a_n\}$ is the smallest cluster point of $\{a_n\}$ and $\limsup\{a_n\}$ is the largest cluster point of $\{a_n\}$.

Solution. Throughout, write

$$s_n = \sup\{a_k \mid k \geq n\}, \quad i_n = \inf\{a_k \mid k \geq n\},$$

these being extended real numbers. The sequence $\{s_n\}$ is decreasing and $\{i_n\}$ is increasing, since the sets over which the supremum and infimum are taken shrink as n increases. By definition $L := \limsup\{a_n\} = \lim_{n \rightarrow \infty} s_n$ and $\ell := \liminf\{a_n\} = \lim_{n \rightarrow \infty} i_n$, the limits being taken in the extended sense; because $\{s_n\}$ is decreasing, $L = \inf_n s_n$, and because $\{i_n\}$ is increasing, $\ell = \sup_n i_n$. This last identification is exactly the Lemma established in the solution to Problem 39 below (a decreasing sequence of extended real numbers converges in the extended sense to its infimum, an increasing one to its supremum); for a bounded monotone sequence of real numbers it is Theorem 15 together with its proof, and the unbounded and infinite cases are checked there directly. Nothing in Problem 39 uses the present problem, so there is no circularity.

We prove the assertion about $\limsup$ in full; the assertion about $\liminf$ then follows by a reflection argument given at the end.

Part 1. L is a cluster point of $\{a_n\}$.

Case (a): $L = \infty$. Then $\{a_n\}$ is not bounded above, since a bound M would give $s_n \leq M$ for all n and hence $L \leq M$. Deleting finitely many terms from a sequence that is unbounded above leaves a sequence that is still unbounded above, so for every index N and every real c there is an index $k \geq N$ with $a_k > c$. Choose n_1 with $a_{n_1} > 1$; having chosen $n_1 < \dots < n_{k-1}$, choose $n_k > n_{k-1}$ with $a_{n_k} > k$. Then $\{n_k\}$ is strictly increasing and $\{a_{n_k}\} \rightarrow \infty$, so $L = \infty$ is a cluster point.

Case (b): $L = -\infty$. Then $\{s_n\} \rightarrow -\infty$, so for each natural number k there is an index N_k with $s_{N_k} < -k$. Choose $n_1 \geq N_1$; having chosen n_{k-1} , let n_k be any index with $n_k > n_{k-1}$ and $n_k \geq N_k$. Since $\{s_n\}$ is decreasing and $n_k \geq N_k$,

$$a_{n_k} \leq s_{n_k} \leq s_{N_k} < -k.$$

Hence $\{a_{n_k}\} \rightarrow -\infty$, and $L = -\infty$ is a cluster point.

Case (c): $L \in \mathbb{R}$. We claim that for every $\epsilon > 0$ and every index N there is an index $k \geq N$ with $|a_k - L| < \epsilon$. Indeed, since $\{s_n\}$ decreases to L , choose $n \geq N$ with $s_n < L + \epsilon$; also $s_n \geq L$, because $\{s_n\}$ is decreasing with limit L . From $s_n \geq L > L - \epsilon$ and the definition of supremum there is an index $k \geq n$ with $a_k > s_n - \epsilon \geq L - \epsilon$. On the other hand $a_k \leq s_n < L + \epsilon$ since $k \geq n$. As $k \geq n \geq N$, the claim is proved.

Now build a subsequence: apply the claim with $\epsilon = 1$ and $N = 1$ to get n_1 with $|a_{n_1} - L| < 1$; having chosen n_{k-1} , apply the claim with $\epsilon = 1/k$ and $N = n_{k-1} + 1$ to get $n_k > n_{k-1}$ with $|a_{n_k} - L| < 1/k$. By the Archimedean Property, $\{a_{n_k}\} \rightarrow L$. So L is a cluster point.

Part 2. Every cluster point c of $\{a_n\}$ satisfies $c \leq L$.

If $L = \infty$ there is nothing to prove, so assume $L < \infty$ and let t be any real number with $t > L$. Since $L = \inf_n s_n < t$, there is an index N with $s_N < t$, and therefore

$$a_n \leq s_N < t \quad \text{for all } n \geq N.$$

Let c be a cluster point, say $\{a_{n_k}\} \rightarrow c$ where $\{n_k\}$ is strictly increasing. A strictly increasing sequence of natural numbers satisfies $n_k \geq k$ for every k , by induction: $n_1 \geq 1$, and $n_k > n_{k-1} \geq k - 1$ forces $n_k \geq k$. Hence $n_k \geq k \geq N$ for $k \geq N$, and so $a_{n_k} < t$ for all $k \geq N$. If $c = -\infty$ then certainly $c \leq t$. If c were $+\infty$ then a_{n_k} would eventually exceed t , a contradiction. If $c \in \mathbb{R}$, then $c \leq t$ by Proposition 14 applied to the convergent sequence $\{a_{n_k}\}_{k \geq N}$, all of whose terms are at most t . In every case $c \leq t$. This holds for every real $t > L$. If $L \in \mathbb{R}$, letting t decrease to L gives $c \leq L$. If $L = -\infty$, then $c \leq t$ for every real number t , which forces $c = -\infty = L$.

By Parts 1 and 2, the set of cluster points of $\{a_n\}$ is nonempty, contains L , and has L as an upper bound; hence $L = \limsup\{a_n\}$ is its largest element.

Part 3. The statement for $\liminf$.

Consider the sequence $\{-a_n\}$. For a strictly increasing sequence $\{n_k\}$ of indices and an extended real number c , we have $\{a_{n_k}\} \rightarrow c$ if and only if $\{-a_{n_k}\} \rightarrow -c$: for finite c this is Theorem 18 with $\alpha = -1$, $\beta = 0$ (or directly, since $|(-a_{n_k}) - (-c)| = |a_{n_k} - c|$), and for $c = \pm\infty$ it is immediate from the definition of convergence to infinity. Consequently the set of cluster points of $\{-a_n\}$ is exactly the set of negatives of the cluster points of $\{a_n\}$.

By Part 1 and Part 2 applied to $\{-a_n\}$, the largest cluster point of $\{-a_n\}$ is $\limsup\{-a_n\}$. By Proposition 19(iii) (with $\{-a_n\}$ in place of $\{a_n\}$),

$$\limsup\{-a_n\} = -\liminf\{a_n\}.$$

Since negation reverses order among extended real numbers and carries cluster points of $\{a_n\}$ onto cluster points of $\{-a_n\}$, the number $-\limsup\{-a_n\} = \liminf\{a_n\}$ is the smallest cluster point of $\{a_n\}$. This completes the proof.

Problem 1.39. Prove Proposition 19. [Proposition 19. Let $\{a_n\}$ and $\{b_n\}$ be sequences of real numbers. (i) $\limsup\{a_n\} = \ell \in \mathbb{R}$ if and only if for each $\epsilon > 0$, there are infinitely many indices n for which $a_n > \ell - \epsilon$ and only finitely many indices n for which $a_n > \ell + \epsilon$. (ii) $\limsup\{a_n\} = \infty$ if and only if $\{a_n\}$ is not bounded above. (iii) $\limsup\{a_n\} = -\liminf\{-a_n\}$. (iv) A sequence of real numbers $\{a_n\}$ converges to an extended real number a if and only if $\liminf\{a_n\} = \limsup\{a_n\} = a$. (v) If $a_n \leq b_n$ for all n , then $\limsup\{a_n\} \leq \liminf\{b_n\}$.]

Solution. Throughout put

$$s_n = \sup\{a_k \mid k \geq n\}, \quad i_n = \inf\{a_k \mid k \geq n\},$$

so that $\limsup\{a_n\} = \lim_{n \rightarrow \infty} s_n$ and $\liminf\{a_n\} = \lim_{n \rightarrow \infty} i_n$. The sets $\{a_k \mid k \geq n\}$ decrease as n increases, so $\{s_n\}$ is decreasing and $\{i_n\}$ is increasing, and clearly $i_n \leq a_n \leq s_n$ for every n .

Lemma. A decreasing sequence $\{s_n\}$ of extended real numbers converges in the extended sense to $\inf_n s_n$, and an increasing sequence $\{i_n\}$ converges to $\sup_n i_n$.

Proof of the Lemma. Consider the decreasing case. If $s_n = \infty$ for all n , both sides equal ∞ . Otherwise fix N with $s_N < \infty$; then $\{s_n\}_{n \geq N}$ is a decreasing sequence of extended reals none of which is ∞ , and $\inf_n s_n = \inf_{n \geq N} s_n$. If some $s_m = -\infty$ then $s_n = -\infty$ for all $n \geq m$ and both sides are $-\infty$. So assume $s_n \in \mathbb{R}$ for $n \geq N$. If this real sequence is bounded below it converges to its infimum by Theorem 15 (as in the proof there, the limit of a decreasing bounded sequence is its infimum); if it is not bounded below, then for each real c there is $M \geq N$ with $s_M < c$, hence $s_n \leq s_M < c$ for $n \geq M$, so $\{s_n\} \rightarrow -\infty = \inf_n s_n$. In each case the conclusion was reached for the tail $\{s_n\}_{n \geq N}$, and altering or ignoring finitely many initial terms affects neither convergence nor the value of the limit, since every assertion of convergence quantifies only over indices beyond some threshold. The increasing case follows by the same argument, or by applying the decreasing case to $\{-i_n\}$. $\square$

So $\limsup\{a_n\} = \inf_n s_n$ and $\liminf\{a_n\} = \sup_n i_n$; we use this freely.

Proof of (i).

Suppose first $\limsup\{a_n\} = \ell \in \mathbb{R}$, and let $\epsilon > 0$. Since $\ell = \inf_n s_n < \ell + \epsilon$, there is an index N with $s_N < \ell + \epsilon$, and therefore $a_n \leq s_N < \ell + \epsilon$ for every $n \geq N$. Thus at most the indices $n < N$ can satisfy $a_n > \ell + \epsilon$: only finitely many. On the other hand, for every index N we have $s_N \geq \inf_n s_n = \ell > \ell - \epsilon$, and since s_N is the supremum of $\{a_k \mid k \geq N\}$ there is some $k \geq N$ with $a_k > \ell - \epsilon$. As N was arbitrary, the set of indices n with $a_n > \ell - \epsilon$ is not contained in any finite initial segment, hence is infinite.

Conversely, suppose that for each $\epsilon > 0$ there are infinitely many indices n with $a_n > \ell - \epsilon$ and only finitely many with $a_n > \ell + \epsilon$. Taking $\epsilon = 1$, only finitely many terms exceed $\ell + 1$, so $\{a_n\}$ is bounded above and each s_n is a real number. Let $\epsilon > 0$. Let N be an index strictly greater than each of the finitely many indices n with $a_n > \ell + \epsilon$. Then $a_k \leq \ell + \epsilon$ for all $k \geq N$, so $s_n \leq s_N \leq \ell + \epsilon$ for $n \geq N$. Also, for every n there are infinitely many indices k with $a_k > \ell - \epsilon$, hence some such k with $k \geq n$, so $s_n \geq a_k > \ell - \epsilon$. Therefore

$$\ell - \epsilon < s_n \leq \ell + \epsilon \quad \text{for all } n \geq N,$$

that is, $|s_n - \ell| \leq \epsilon$ for $n \geq N$. Given $\epsilon' > 0$, running this argument with $\epsilon = \epsilon'/2$ produces an N with $|s_n - \ell| \leq \epsilon'/2 < \epsilon'$ for all $n \geq N$. Hence $\{s_n\} \rightarrow \ell$, that is, $\limsup\{a_n\} = \ell$.

Proof of (ii).

If $\{a_n\}$ is not bounded above, then for each n the set $\{a_k \mid k \geq n\}$ is also not bounded above (it differs from $\{a_k \mid k \geq 1\}$ by the finitely many terms $a_1, \dots, a_{n-1}$, and adjoining finitely many real numbers to a set cannot turn an unbounded-above set into a bounded one). Hence $s_n = \infty$ for every n , and $\limsup\{a_n\} = \inf_n s_n = \infty$.

Conversely, if $\{a_n\}$ is bounded above by a real number M , then M is an upper bound for each set $\{a_k \mid k \geq n\}$, so $s_n \leq M$ for all n and therefore $\limsup\{a_n\} = \inf_n s_n \leq M < \infty$.

Proof of (iii).

For a nonempty set S of real numbers, $\sup S = -\inf(-S)$, where $-S = \{-x \mid x \in S\}$, with the convention that this holds in the extended sense (if S is unbounded above then $-S$ is unbounded below, and both sides are ∞). Applying this to $S = \{a_k \mid k \geq n\}$, whose negative is $\{-a_k \mid k \geq n\}$, we

get

$$s_n = -i_n^-, \quad \text{where } i_n^- = \inf\{-a_k \mid k \geq n\}.$$

Now $\{i_n^-\}$ is increasing, so by the Lemma $\liminf\{-a_n\} = \sup_n i_n^-$, while $\limsup\{a_n\} = \inf_n s_n = \inf_n(-i_n^-) = -\sup_n i_n^-$, using that negation reverses order and interchanges suprema and infima of a set of extended real numbers. Hence $\limsup\{a_n\} = -\liminf\{-a_n\}$.

Proof of (iv).

Suppose first that $\liminf\{a_n\} = \limsup\{a_n\} = a$.

If $a \in \mathbb{R}$: let $\epsilon > 0$ and choose N so large that $|s_n - a| < \epsilon$ and $|i_n - a| < \epsilon$ for $n \geq N$. Then for $n \geq N$,

$$a - \epsilon < i_n \leq a_n \leq s_n < a + \epsilon,$$

so $|a_n - a| < \epsilon$. Thus $\{a_n\} \rightarrow a$.

If $a = \infty$: then $\{i_n\} \rightarrow \infty$, so for each real c there is N with $i_n > c$ for $n \geq N$; since $a_n \geq i_n$, also $a_n > c$ for $n \geq N$. Thus $\{a_n\} \rightarrow \infty$.

If $a = -\infty$: then $\{s_n\} \rightarrow -\infty$, and $a_n \leq s_n$, so $\{a_n\} \rightarrow -\infty$ by the same reasoning.

Conversely, suppose $\{a_n\} \rightarrow a$.

If $a \in \mathbb{R}$: let $\epsilon > 0$ and choose N with $a - \epsilon < a_k < a + \epsilon$ for all $k \geq N$. Then for $n \geq N$ the number $a + \epsilon$ is an upper bound and $a - \epsilon$ a lower bound for $\{a_k \mid k \geq n\}$, so $a - \epsilon \leq i_n \leq s_n \leq a + \epsilon$. Since $\{s_n\}$ and $\{i_n\}$ are monotone with these bounds holding from N on, their limits also lie in $[a - \epsilon, a + \epsilon]$. As $\epsilon > 0$ was arbitrary, $\liminf\{a_n\} = \limsup\{a_n\} = a$.

If $a = \infty$: given a real number c , choose N with $a_n > c$ for $n \geq N$. Then c is a lower bound for $\{a_k \mid k \geq n\}$ whenever $n \geq N$, so $i_n \geq c$ for $n \geq N$. Hence $\{i_n\} \rightarrow \infty$, and since $s_n \geq i_n$ also $\{s_n\} \rightarrow \infty$. Thus both equal $\infty = a$.

If $a = -\infty$: symmetrically, for each real c there is N with $a_n < c$ for $n \geq N$, so $s_n \leq c$ for $n \geq N$, giving $\{s_n\} \rightarrow -\infty$, and $i_n \leq s_n$ gives $\{i_n\} \rightarrow -\infty$. Thus both equal $-\infty = a$.

Proof of (v).

As printed, part (v) asserts that $a_n \leq b_n$ for all n implies $\limsup\{a_n\} \leq \liminf\{b_n\}$. This is a misprint: the assertion is false. Take $a_n = b_n = (-1)^n$. Then $a_n \leq b_n$ for all n , while $s_n = 1$ for all n and $i_n = -1$ for all n , so $\limsup\{a_n\} = 1$ and $\liminf\{b_n\} = -1$, and $1 \leq -1$ fails.

The correct (and intended) statement is that the limit superior and the limit inferior are each monotone:

$$\text{if } a_n \leq b_n \text{ for all } n, \text{ then } \limsup\{a_n\} \leq \limsup\{b_n\} \text{ and } \liminf\{a_n\} \leq \liminf\{b_n\}.$$

We prove this. Write s_n^a, i_n^a and s_n^b, i_n^b for the associated suprema and infima. Fix n . For every $k \geq n$ we have $a_k \leq b_k \leq s_n^b$, so s_n^b is an upper bound for $\{a_k \mid k \geq n\}$ and therefore $s_n^a \leq s_n^b$. Taking infima over n and using the Lemma,

$$\limsup\{a_n\} = \inf_n s_n^a \leq \inf_n s_n^b = \limsup\{b_n\}.$$

Similarly, for every $k \geq n$ we have $i_n^a \leq a_k \leq b_k$, so i_n^a is a lower bound for $\{b_k \mid k \geq n\}$ and therefore $i_n^a \leq i_n^b$. Taking suprema over n ,

$$\liminf\{a_n\} = \sup_n i_n^a \leq \sup_n i_n^b = \liminf\{b_n\}.$$

(One may also note that the printed inequality does hold under the stronger hypothesis that $\{b_n\}$ converges, since then $\limsup\{b_n\} = \liminf\{b_n\}$ by part (iv).)

Problem 1.40. Show that a sequence $\{a_n\}$ is convergent to an extended real number if and only if there is exactly one extended real number that is a cluster point of the sequence.

Solution. Recall from Problem 38 that an extended real number is a cluster point of $\{a_n\}$ provided some subsequence of $\{a_n\}$ converges to it.

Suppose first that $\{a_n\}$ converges to the extended real number a .

We check that every subsequence $\{a_{n_k}\}$ also converges to a . Recall that a strictly increasing sequence $\{n_k\}$ of natural numbers satisfies $n_k \geq k$ for all k (an easy induction: $n_1 \geq 1$, and $n_k > n_{k-1} \geq k-1$ forces $n_k \geq k$). If $a \in \mathbb{R}$ and $\epsilon > 0$, choose N with $|a_n - a| < \epsilon$ for $n \geq N$; then for $k \geq N$ we have $n_k \geq k \geq N$, so $|a_{n_k} - a| < \epsilon$. If $a = \infty$ and c is real, choose N with $a_n > c$ for $n \geq N$; then $a_{n_k} > c$ for $k \geq N$. The case $a = -\infty$ is symmetric. Hence every subsequence converges to a .

In particular a is a cluster point of $\{a_n\}$, since $\{a_n\}$ is a subsequence of itself. And a is the only one: if c is a cluster point, then $\{a_{n_k}\} \rightarrow c$ for some subsequence, while we have just shown $\{a_{n_k}\} \rightarrow a$; so it suffices to know that a sequence cannot converge to two distinct extended real numbers. If both limits are real this is the uniqueness of the limit in Proposition 14. A sequence converging to a real number is bounded (Proposition 14), whereas a sequence converging to ∞ or to $-\infty$ is respectively unbounded above or unbounded below, so a real limit cannot coexist with an infinite one. Finally, $\{a_{n_k}\} \rightarrow \infty$ gives $a_{n_k} > 0$ for all large k while $\{a_{n_k}\} \rightarrow -\infty$ gives $a_{n_k} < 0$ for all large k , so these cannot both hold. Thus $c = a$, and a is the unique cluster point.

Conversely, suppose $\{a_n\}$ has exactly one cluster point, say c . By Problem 38, $\liminf\{a_n\}$ is the smallest cluster point of $\{a_n\}$ and $\limsup\{a_n\}$ is the largest; in particular both are cluster points. Since there is only one cluster point,

$$\liminf\{a_n\} = c = \limsup\{a_n\}.$$

By Proposition 19(iv), $\{a_n\}$ converges to the extended real number c .

Problem 1.41. Show that $\liminf a_n \leq \limsup a_n$.

Solution. As above put $i_n = \inf\{a_k \mid k \geq n\}$ and $s_n = \sup\{a_k \mid k \geq n\}$, so that $\{i_n\}$ is increasing, $\{s_n\}$ is decreasing, and (by the Lemma proved in Problem 39, which is just Theorem 15 extended to the extended real numbers)

$$\liminf a_n = \sup_n i_n, \quad \limsup a_n = \inf_n s_n.$$

Fix indices m and n and put $p = \max\{m, n\}$. Since $p \geq m$ and $\{i_n\}$ is increasing, $i_m \leq i_p$. Since a_p belongs to the nonempty set $\{a_k \mid k \geq p\}$, we have $i_p \leq a_p \leq s_p$. Since $p \geq n$ and $\{s_n\}$ is decreasing, $s_p \leq s_n$. Chaining these,

$$i_m \leq i_p \leq a_p \leq s_p \leq s_n.$$

Thus s_n is an upper bound for $\{i_m \mid m \in \mathbb{N}\}$, whence $\sup_m i_m \leq s_n$. As this holds for every n , the extended real number $\sup_m i_m$ is a lower bound for $\{s_n \mid n \in \mathbb{N}\}$, whence $\sup_m i_m \leq \inf_n s_n$. That is,

$$\liminf a_n \leq \limsup a_n.$$

An alternative argument: by Problem 38 the set of cluster points of $\{a_n\}$ is nonempty, $\liminf a_n$ is its smallest element and $\limsup a_n$ is its largest element, and the smallest element of a nonempty set is at most its largest element.

Problem 1.42. Prove that if, for all n , $a_n > 0$ and $b_n \geq 0$, then

$$\limsup [a_n \cdot b_n] \leq (\limsup a_n) \cdot (\limsup b_n),$$

provided the product on the right is not of the form $0 \cdot \infty$.

Solution. Write $A = \limsup a_n$ and $B = \limsup b_n$, and as before put

$$s_n^a = \sup\{a_k \mid k \geq n\}, \quad s_n^b = \sup\{b_k \mid k \geq n\}, \quad s_n^{ab} = \sup\{a_k b_k \mid k \geq n\},$$

so that, by the Lemma of Problem 39, $A = \inf_n s_n^a$, $B = \inf_n s_n^b$ and $\limsup [a_n b_n] = \inf_n s_n^{ab}$.

First note that A and B are nonnegative. Indeed, for every n we have $s_n^a \geq a_n > 0$, so every s_n^a is positive and hence $A = \inf_n s_n^a \geq 0$; likewise $s_n^b \geq b_n \geq 0$, so $B = \inf_n s_n^b \geq 0$. Thus $A, B \in [0, \infty]$. Also

$a_n b_n \geq 0$ for all n , so by the same reasoning $\limsup[a_n b_n] \geq 0$; in particular the left-hand side is never $-\infty$, so no indeterminacy arises there.

Since A and B are nonnegative, the hypothesis that the right-hand product is not of the form $0 \cdot \infty$ says exactly that neither of the two combinations $A = 0$ with $B = \infty$, nor $A = \infty$ with $B = 0$, occurs.

Case 1: $A = \infty$ or $B = \infty$.

If $A = \infty$ then by hypothesis $B \neq 0$, so $B > 0$ and $A \cdot B = \infty$. If $B = \infty$ then by hypothesis $A \neq 0$, so $A > 0$ and $A \cdot B = \infty$. In either case the right-hand side is ∞ and the asserted inequality holds trivially.

Case 2: A and B are both finite.

Then $A, B \in [0, \infty)$ and $A \cdot B$ is a nonnegative real number. Let $\epsilon > 0$.

Since $A = \inf_n s_n^a < A + \epsilon$, there is an index N_1 with $s_{N_1}^a < A + \epsilon$, and hence

$$0 < a_k \leq s_{N_1}^a < A + \epsilon \quad \text{for every } k \geq N_1.$$

Similarly there is an index N_2 with

$$0 \leq b_k \leq s_{N_2}^b < B + \epsilon \quad \text{for every } k \geq N_2.$$

Let $N = \max\{N_1, N_2\}$. Note $A + \epsilon > 0$ and $B + \epsilon > 0$. For $k \geq N$ we have $b_k < B + \epsilon$ and $a_k > 0$, so $a_k b_k < a_k(B + \epsilon)$; and $a_k < A + \epsilon$ with $B + \epsilon > 0$ gives $a_k(B + \epsilon) < (A + \epsilon)(B + \epsilon)$. Hence

$$a_k b_k < (A + \epsilon)(B + \epsilon) \quad \text{for every } k \geq N.$$

Thus $(A + \epsilon)(B + \epsilon)$ is an upper bound for $\{a_k b_k \mid k \geq N\}$, so $s_N^{ab} \leq (A + \epsilon)(B + \epsilon)$, and therefore

$$\limsup[a_n b_n] = \inf_n s_n^{ab} \leq s_N^{ab} \leq (A + \epsilon)(B + \epsilon) = AB + \epsilon(A + B) + \epsilon^2.$$

This holds for every $\epsilon > 0$. Since $A + B$ and AB are real numbers, letting ϵ run through the values $1/m$, $m \in \mathbb{N}$, we obtain a sequence of real bounds converging to AB ; hence $\limsup[a_n b_n] \leq AB$ by Proposition 14 (or directly: if $\limsup[a_n b_n] > AB$, choose $\epsilon > 0$ small enough that $AB + \epsilon(A + B) + \epsilon^2 < \limsup[a_n b_n]$, a contradiction).

In both cases

$$\limsup[a_n \cdot b_n] \leq (\limsup a_n) \cdot (\limsup b_n),$$

as required.

Two remarks. The inequality can be strict: with $a_n = 2 + (-1)^n$ and $b_n = 2 - (-1)^n$ we have $a_n > 0$, $b_n \geq 0$, $a_n b_n = 4 - 1 = 3$ for every n , so the left side is 3 while $\limsup a_n = \limsup b_n = 3$ and the right side is 9. Also, the proviso is genuinely needed, and not merely because $0 \cdot \infty$ is undefined: take $a_n = n$ and $b_n = 1/n$, so that $a_n > 0$ and $b_n \geq 0$ for every n . Then $a_n b_n = 1$ for all n , so $\limsup[a_n b_n] = 1$, while $\limsup a_n = \infty$ and $\limsup b_n = 0$. Under any convention that assigns the value 0 to $0 \cdot \infty$ the asserted inequality would read $1 \leq 0$, which is false. So the excluded case is one in which the conclusion genuinely fails, not merely one in which the right-hand side is unassigned.

1.7 Problems 1.43–1.49

Problem 1.43. Show that every real sequence has a monotone subsequence. Use this to provide another proof of the Bolzano-Weierstrass Theorem.

Solution. Let $\{a_n\}$ be a sequence of real numbers. Call an index n a *peak index* provided

$$a_m \leq a_n \quad \text{for every } m \geq n.$$

Let P be the set of peak indices. There are two cases.

Case 1: P is infinite. List the members of P in increasing order as $n_1 < n_2 < n_3 < \cdots$; this is possible because every nonempty set of natural numbers has a smallest member (Theorem 1), so we may choose $n_1 = \min P$ and, inductively, $n_{k+1} = \min\{n \in P \mid n > n_k\}$, which is a nonempty set since P is infinite.

Fix k . Since n_k is a peak index and $n_{k+1} > n_k$, we have $a_{n_{k+1}} \leq a_{n_k}$. Hence $\{a_{n_k}\}$ is a decreasing subsequence of $\{a_n\}$.

Case 2: P is finite. Choose a natural number N that exceeds every member of P (if $P = \emptyset$ take $N = 1$). Define $n_1 = N$. Suppose $n_1 < n_2 < \cdots < n_k$ have been chosen with $n_k \geq N$. Since $n_k \geq N$, the index n_k is not a peak index, so there is an index $m > n_k$ for which $a_m > a_{n_k}$; define $n_{k+1} = m$. Then $\{n_k\}$ is a strictly increasing sequence of natural numbers and $a_{n_k} < a_{n_{k+1}}$ for every k , so $\{a_{n_k}\}$ is an increasing subsequence of $\{a_n\}$.

In either case $\{a_n\}$ has a monotone subsequence.

Proof of the Bolzano-Weierstrass Theorem. Let $\{a_n\}$ be a bounded sequence of real numbers, say $|a_n| \leq M$ for all n . By what we just proved, $\{a_n\}$ has a monotone subsequence $\{a_{n_k}\}$. Every term of the subsequence is a term of the original sequence, so $|a_{n_k}| \leq M$ for all k ; that is, $\{a_{n_k}\}$ is a bounded monotone sequence. By the Monotone Convergence Criterion for Real Sequences (Theorem 15), $\{a_{n_k}\}$ converges. Thus $\{a_n\}$ has a convergent subsequence.

Observe that this argument is not circular: the peak construction uses nothing but the order properties of $\mathbb{R}$ and Theorem 1, while Theorem 15 is deduced directly from the Completeness Axiom without appeal to the Bolzano-Weierstrass Theorem.

Problem 1.44. Let p be a natural number greater than 1, and x a real number, $0 < x < 1$. Show that there is a sequence $\{a_n\}$ of integers with $0 \leq a_n < p$ for each n such that

$$x = \sum_{n=1}^{\infty} \frac{a_n}{p^n}$$

and that this sequence is unique except when x is of the form q/p^n , in which case there are exactly two such sequences. Show that, conversely, if $\{a_n\}$ is any sequence of integers with $0 \leq a_n < p$, the series

$$\sum_{n=1}^{\infty} \frac{a_n}{p^n}$$

converges to a real number x with $0 \leq x \leq 1$. If $p = 10$, this sequence is called the *decimal expansion* of x . For $p = 2$ it is called the *binary expansion*; and for $p = 3$, the *ternary expansion*.

Solution. Throughout, for a real number $y \geq 0$ let $[y]$ denote the largest integer not exceeding y . This exists: by the Archimedean Property the set of natural numbers k with $k > y$ is nonempty, so by Theorem 1 it has a least member k_0 , and $[y] = k_0 - 1$. It satisfies $[y] \leq y < [y] + 1$.

Convergence of any such series. Let $\{a_n\}$ be any sequence of integers with $0 \leq a_n < p$, that is, $0 \leq a_n \leq p - 1$. The terms a_n/p^n are nonnegative, so the partial sums $s_N = \sum_{n=1}^N a_n/p^n$ form an increasing sequence, and

$$s_N \leq \sum_{n=1}^N \frac{p-1}{p^n} = (p-1) \cdot \frac{1/p - 1/p^{N+1}}{1 - 1/p} = 1 - \frac{1}{p^N} < 1.$$

Thus the sequence of partial sums is bounded, and by Proposition 20(iii) (Problem 45) the series is summable. Let x be its sum. Since $s_N \leq 1$ for every N , Proposition 14 gives $x \leq 1$; since $-s_N \leq 0$ for every N , the same proposition applied to $\{-s_N\}$, whose limit is $-x$ by Theorem 18, gives $-x \leq 0$, that is $x \geq 0$. Hence $0 \leq x \leq 1$.

Existence of an expansion. Let $0 < x < 1$. Define $x_0 = x$ and, inductively,

$$a_n = [p x_{n-1}], \quad x_n = p x_{n-1} - a_n \quad (n \geq 1).$$

We verify by induction that $0 \leq x_n < 1$ for every $n \geq 0$. This holds for $n = 0$. If $0 \leq x_{n-1} < 1$, then $0 \leq p x_{n-1} < p$, so $a_n = [p x_{n-1}]$ is an integer with $0 \leq a_n \leq p - 1$, and $x_n = p x_{n-1} - a_n$ satisfies $0 \leq x_n < 1$ by the defining property of the floor. So each a_n is an integer with $0 \leq a_n < p$.

From $x_{n-1} = (a_n + x_n)/p$ an induction gives, for every $N \geq 1$,

$$x = \sum_{n=1}^N \frac{a_n}{p^n} + \frac{x_N}{p^N}.$$

Since $0 \leq x_N < 1$ we get $0 \leq x - s_N < 1/p^N$. Now $p^N \geq 2^N \geq N$ for every N , both inequalities by induction on N (using $p \geq 2$ for the first, and $2^{N+1} = 2^N + 2^N \geq N + 1$ for the second). Given $\epsilon > 0$, the Archimedean Property provides a natural number N_0 with $1/N_0 < \epsilon$, and then $0 \leq x - s_N < 1/p^N \leq 1/N \leq 1/N_0 < \epsilon$ for all $N \geq N_0$. Hence $s_N \rightarrow x$, that is, $x = \sum_{n=1}^{\infty} a_n/p^n$.

The structure of two distinct expansions. Suppose $\{a_n\}$ and $\{b_n\}$ are sequences of integers in $[0, p)$ with

$$\sum_{n=1}^{\infty} \frac{a_n}{p^n} = \sum_{n=1}^{\infty} \frac{b_n}{p^n} = x,$$

and suppose they are not identical. Let N be the smallest index with $a_N \neq b_N$ (Theorem 1); relabelling if necessary, assume $a_N > b_N$, so $a_N - b_N \geq 1$. Subtracting the two series (legitimate by Theorem 18, applied to the partial sums) and using $a_n = b_n$ for $n < N$,

$$\frac{a_N - b_N}{p^N} = \sum_{n=N+1}^{\infty} \frac{b_n - a_n}{p^n}.$$

Now $b_n - a_n \leq p - 1$ for every n , so the right-hand side is at most $\sum_{n=N+1}^{\infty} (p - 1)/p^n = 1/p^N$, while the left-hand side is at least $1/p^N$. Hence both sides equal $1/p^N$, which forces

$$a_N - b_N = 1, \quad b_n - a_n = p - 1 \quad \text{for all } n > N,$$

the latter because a series of nonnegative terms $((p - 1) - (b_n - a_n))/p^n$ with sum zero must have every term zero. Since $0 \leq a_n, b_n \leq p - 1$, this says

$$b_n = p - 1 \quad \text{and} \quad a_n = 0 \quad \text{for all } n > N.$$

In particular, of any two distinct expansions of the same x , one terminates (is eventually 0) and the other is eventually $p - 1$.

Uniqueness except for p -adic fractions. Suppose $x \in (0, 1)$ has two distinct expansions $\{a_n\}, \{b_n\}$ as above. Then $x = \sum_{n=1}^N a_n/p^n = q/p^N$ where $q = \sum_{n=1}^N a_n p^{N-n}$ is an integer. So x has the form q/p^N . Conversely, let $x = q/p^N$ with q an integer and $0 < x < 1$; then $1 \leq q \leq p^N - 1$. We claim that every integer q with $0 \leq q \leq p^N - 1$ can be written as $q = \sum_{n=1}^N c_n p^{N-n}$ with each c_n an integer, $0 \leq c_n \leq p - 1$. Argue by induction on N . For $N = 1$ take $c_1 = q$. Assume the claim for N and let $0 \leq q \leq p^{N+1} - 1$. Put $c_1 = \lfloor q/p^N \rfloor$; then $0 \leq c_1 \leq p - 1$, since $q/p^N < p$, and $q' = q - c_1 p^N$ satisfies $0 \leq q' \leq p^N - 1$ by the defining property of the floor. Applying the inductive hypothesis to q' and shifting indices gives the representation of q with $N + 1$ digits. This proves the claim, and dividing by p^N gives $x = \sum_{n=1}^N c_n/p^n$. Since $x > 0$, not all c_n vanish; let $M \leq N$ be the largest index with $c_M \neq 0$. Then

$$x = \sum_{n=1}^M \frac{c_n}{p^n},$$

and the sequence $a_n = c_n$ for $n \leq M$, $a_n = 0$ for $n > M$, is one expansion. Define a second by

$$b_n = c_n \quad (n < M), \quad b_M = c_M - 1 \quad (\geq 0), \quad b_n = p - 1 \quad (n > M).$$

These are integers in $[0, p)$, and since $\sum_{n>M} (p - 1)/p^n = 1/p^M$,

$$\sum_{n=1}^{\infty} \frac{b_n}{p^n} = \sum_{n<M} \frac{c_n}{p^n} + \frac{c_M - 1}{p^M} + \frac{1}{p^M} = x.$$

The two sequences differ at index M , so x has at least two expansions.

There are never more than two. Suppose $\{a_n\}, \{b_n\}, \{c_n\}$ were three pairwise distinct expansions of the same x . By the structural result above, each pair consists of one sequence that is eventually 0 and one that is eventually $p-1$; note that since $p \geq 2$ we have $p-1 \neq 0$, so no single sequence can be both. Say $\{a_n\}$ is eventually 0 and $\{b_n\}$ eventually $p-1$. Applying the result to the pair $\{a_n\}, \{c_n\}$ shows $\{c_n\}$ is eventually $p-1$ (it cannot be the eventually-0 one, since then $\{a_n\}$ would have to be eventually $p-1$). But then $\{b_n\}$ and $\{c_n\}$ are both eventually $p-1$, contradicting the structural result for that pair. Hence there are at most two expansions.

Combining: every $x \in (0, 1)$ has an expansion; it is unique unless $x = q/p^N$ for integers q, N , in which case there are exactly two.

Problem 1.45. Prove Proposition 20.

[Proposition 20. Let $\{a_n\}$ be a sequence of real numbers.

- (i) The series $\sum_{k=1}^{\infty} a_k$ is summable if and only if for each $\epsilon > 0$, there is an index N for which
$$\left| \sum_{k=n}^{n+m} a_k \right| < \epsilon \quad \text{for } n \geq N \text{ and any natural number } m.$$
- (ii) If the series $\sum_{k=1}^{\infty} |a_k|$ is summable, then $\sum_{k=1}^{\infty} a_k$ also is summable.
- (iii) If each term a_k is nonnegative, then the series $\sum_{k=1}^{\infty} a_k$ is summable if and only if the sequence of partial sums is bounded.]

Solution. Write $s_n = \sum_{k=1}^n a_k$ for the n -th partial sum and set $s_0 = 0$, so that for all $j < i$,

$$s_i - s_j = \sum_{k=j+1}^i a_k.$$

By definition the series is summable exactly when the sequence $\{s_n\}$ converges.

(i). Suppose first that the series is summable, so $\{s_n\}$ converges. By the Cauchy Convergence Criterion (Theorem 17), $\{s_n\}$ is Cauchy. Let $\epsilon > 0$ and choose an index N' such that $|s_i - s_j| < \epsilon$ whenever $i, j \geq N'$. Put $N = N' + 1$. If $n \geq N$ and m is a natural number, then $n-1 \geq N'$ and $n+m \geq N'$, so

$$\left| \sum_{k=n}^{n+m} a_k \right| = |s_{n+m} - s_{n-1}| < \epsilon.$$

Conversely, suppose the stated condition holds. Let $\epsilon > 0$ and choose N so that $|\sum_{k=n}^{n+m} a_k| < \epsilon/2$ for all $n \geq N$ and all natural numbers m . We first observe that the condition controls individual terms: for $n \geq N$,

$$a_{n+2} = \sum_{k=n}^{n+2} a_k - \sum_{k=n}^{n+1} a_k,$$

and both sums on the right are of the permitted form (with $m = 2$ and $m = 1$), so $|a_{n+2}| < \epsilon/2 + \epsilon/2 = \epsilon$. Hence $|a_k| < \epsilon$ for all $k \geq N+2$.

Now set $N'' = N + 1$ and let $i > j \geq N''$. If $i \geq j+2$, then

$$|s_i - s_j| = \left| \sum_{k=j+1}^i a_k \right| = \left| \sum_{k=n}^{n+m} a_k \right| \quad \text{with } n = j+1 \geq N, \quad m = i - j - 1 \geq 1,$$

so $|s_i - s_j| < \epsilon/2 < \epsilon$. If $i = j+1$, then $|s_i - s_j| = |a_{j+1}|$ and $j+1 \geq N+2$, so $|s_i - s_j| < \epsilon$. Thus $|s_i - s_j| < \epsilon$ whenever $i, j \geq N''$ (the case $i = j$ being trivial), so $\{s_n\}$ is Cauchy and, by Theorem 17, converges. The series is summable.

(ii). Suppose $\sum_{k=1}^{\infty} |a_k|$ is summable. Let $\epsilon > 0$. Applying part (i) to the series $\sum |a_k|$, there is an index N such that for $n \geq N$ and every natural number m ,

$$\sum_{k=n}^{n+m} |a_k| = \left| \sum_{k=n}^{n+m} |a_k| \right| < \epsilon.$$

By the triangle inequality (Problem 7),

$$\left| \sum_{k=n}^{n+m} a_k \right| \leq \sum_{k=n}^{n+m} |a_k| < \epsilon$$

for all $n \geq N$ and all natural numbers m . By part (i), applied in the other direction to $\sum a_k$, the series $\sum_{k=1}^{\infty} a_k$ is summable.

(iii). Suppose each $a_k \geq 0$. Then $s_{n+1} - s_n = a_{n+1} \geq 0$, so $\{s_n\}$ is an increasing sequence. By the Monotone Convergence Criterion (Theorem 15), a monotone sequence converges if and only if it is bounded. Hence the series is summable, that is $\{s_n\}$ converges, if and only if $\{s_n\}$ is bounded. (For an increasing sequence, boundedness is the same as boundedness above, since $s_n \geq s_1$ for all n .)

Problem 1.46. Show that the assertion of the Bolzano-Weierstrass Theorem is equivalent to the Completeness Axiom for the real numbers. Show that the assertion of the Monotone Convergence Theorem is equivalent to the Completeness Axiom for the real numbers.

Solution. Throughout, we work with an ordered field F satisfying the field axioms and the positivity axioms for $\mathbb{R}$, and we ask which of the following three assertions imply which:

- (C) *Completeness Axiom.* Every nonempty subset of F that is bounded above has a least upper bound in F .
- (BW) *Bolzano-Weierstrass.* Every bounded sequence in F has a convergent subsequence.
- (MC) *Monotone Convergence.* Every monotone bounded sequence in F converges.

(The natural numbers $\mathbb{N}$ are defined inside F as the intersection of all inductive subsets, exactly as in Section 1.2; this definition and the Principle of Mathematical Induction use no completeness. Note also that the proofs of Proposition 14 and Theorem 18 — uniqueness of limits, boundedness of convergent sequences, and linearity and monotonicity of convergence — use only the definition of convergence and the ordered-field axioms, so they are available to us here.)

(C) *implies (BW).* This is exactly the Bolzano-Weierstrass Theorem (Theorem 16), proved in the text from the Completeness Axiom (via the Nested Set Theorem).

(C) *implies (MC).* This is exactly the Monotone Convergence Criterion (Theorem 15), proved in the text from the Completeness Axiom.

It remains to prove the two converses. Both use the following two lemmas.

Lemma A. Each of (BW) and (MC) implies the Archimedean Property, that is, $\mathbb{N}$ is not bounded above in F . Suppose $\mathbb{N}$ were bounded above. Consider the sequence $a_n = n$. It is bounded (below by 1, above by the assumed bound) and increasing.

Assume (BW). Then $\{a_n\}$ has a convergent subsequence $\{n_k\}$, where $n_1 < n_2 < \dots$. A convergent sequence is Cauchy (the first half of the proof of Theorem 17 uses only the definition of convergence), so there is an index K with $|n_{k+1} - n_k| < 1$ for $k \geq K$. But $n_{k+1} > n_k$ are natural numbers, so $n_{k+1} - n_k$ is itself a natural number (a routine induction from Problem 9) and hence $n_{k+1} - n_k \geq 1$, a contradiction.

Assume (MC). Then $\{a_n\}$, being increasing and bounded, converges to some $a \in F$. Choosing N with $|a_n - a| < 1/2$ for $n \geq N$ gives $|a_{N+1} - a_N| < 1$, that is $1 < 1$, a contradiction.

Hence $\mathbb{N}$ is unbounded above. Consequently, for each $\epsilon > 0$ there is a natural number n with $1/n < \epsilon$, and since $2^n \geq n$ for all n (induction), also $1/2^n \rightarrow 0$.

Lemma B (bisection). Let $E \subseteq F$ be nonempty and bounded above by b_0 . Choose $e \in E$ and put $a_0 = e - 1$; then a_0 is not an upper bound for E , and $a_0 < b_0$. Define sequences $\{a_n\}$, $\{b_n\}$ inductively: given a_n not an upper bound for E and b_n an upper bound for E with $a_n < b_n$, let $c = (a_n + b_n)/2$ and set

$$(a_{n+1}, b_{n+1}) = \begin{cases} (a_n, c) & \text{if } c \text{ is an upper bound for } E, \\ (c, b_n) & \text{if } c \text{ is not an upper bound for } E. \end{cases}$$

By induction, for every n : a_n is not an upper bound for E , b_n is an upper bound for E , $\{a_n\}$ is

increasing, $\{b_n\}$ is decreasing, $a_n < b_n$, and

$$b_n - a_n = \frac{b_0 - a_0}{2^n}.$$

In particular $a_0 \leq a_n < b_n \leq b_0$, so both sequences are bounded, and by Lemma A, $b_n - a_n \rightarrow 0$.

(BW) implies (C). Assume (BW), and let E be nonempty and bounded above. Form $\{a_n\}, \{b_n\}$ as in Lemma B. By (BW) the bounded sequence $\{a_n\}$ has a subsequence $\{a_{n_k}\}$ converging to some $L \in F$. Since $\{b_n - a_n\}$ converges to 0, so does its subsequence $\{b_{n_k} - a_{n_k}\}$ (immediate from the definition of convergence, since $n_k \geq k$). As $b_{n_k} = a_{n_k} + (b_{n_k} - a_{n_k})$, Theorem 18 gives $b_{n_k} \rightarrow L$ as well.

L is an upper bound for E : if $x \in E$, then $x \leq b_{n_k}$ for every k , since each b_n is an upper bound. Comparing the constant sequence with constant value x , which converges to x , against $\{b_{n_k}\}$, which converges to L , the monotonicity of convergence (Theorem 18, formula (7)) gives $x \leq L$.

L is the least upper bound: suppose c is an upper bound for E with $c < L$. Since $a_{n_k} \rightarrow L$, there is k with $a_{n_k} > c$. But a_{n_k} is not an upper bound for E , so there is $y \in E$ with $y > a_{n_k} > c$, contradicting that c is an upper bound. Hence no upper bound is smaller than L , so $L = \sup E$ exists in F . This is (C).

(MC) implies (C). Assume (MC), and let E be nonempty and bounded above. Form $\{a_n\}, \{b_n\}$ as in Lemma B. The sequence $\{a_n\}$ is increasing and bounded, so by (MC) it converges to some $L \in F$; as above $b_n = a_n + (b_n - a_n) \rightarrow L$ by Lemma A and Theorem 18. The very same two paragraphs as in the preceding proof (with a_n, b_n in place of a_{n_k}, b_{n_k}) show that L is an upper bound for E and that no smaller number is an upper bound. Hence $\sup E$ exists, which is (C).

Therefore (C), (BW) and (MC) are mutually equivalent: the assertion of the Bolzano-Weierstrass Theorem is equivalent to the Completeness Axiom, and so is the assertion of the Monotone Convergence Theorem.

Problem 1.47. Let E be a closed set of real numbers and f a real-valued function that is defined and continuous on E . Show that there is a function g defined and continuous on all of $\mathbb{R}$ such that $f(x) = g(x)$ for each $x \in E$. (Hint: Take g to be linear on each of the intervals of which $\mathbb{R} \sim E$ is composed.)

Solution. If $E = \emptyset$ take $g \equiv 0$; if $E = \mathbb{R}$ take $g = f$. So assume E is a nonempty proper closed subset of $\mathbb{R}$.

Construction of g . Since E is closed, $\mathcal{O} = \mathbb{R} \sim E$ is open and nonempty (Proposition 11). By Proposition 9, $\mathcal{O}$ is the disjoint union of a countable collection $\mathcal{I}$ of open intervals. Each member of $\mathcal{I}$ is of one of the forms (a, b) , $(-\infty, b)$, (a, ∞) with a, b real; none is all of $\mathbb{R}$, since $E \neq \emptyset$. Call the members of $\mathcal{I}$ the *components* of $\mathcal{O}$.

We first record that a finite endpoint of a component belongs to E . Let $I \in \mathcal{I}$ have right endpoint $b \in \mathbb{R}$, and suppose $b \in \mathcal{O}$. Then b lies in some $J = (c, d) \in \mathcal{I}$, and $J \neq I$ because $b \notin I$. Write $I = (a, b)$, where a is real or $a = -\infty$. Put $z_0 = c$ if $a = -\infty$, and $z_0 = \max\{a, c\}$ if a is real; in either case z_0 is real and $z_0 < b$, so we may choose z with $z_0 < z < b$. Then $a < z < b$, so $z \in I$, and $c < z < b < d$, so $z \in J$, contradicting the disjointness of $\mathcal{I}$. Hence $b \in E$; the argument for a finite left endpoint is symmetric. (This is also exactly what is verified in the proof of Proposition 9.)

Define $g : \mathbb{R} \rightarrow \mathbb{R}$ by:

- $g(x) = f(x)$ for $x \in E$;
- on a bounded component (a, b) (so $a, b \in E$), let g be the affine function determined by $g(a) = f(a)$, $g(b) = f(b)$, that is,

$$g(x) = f(a) + \frac{f(b) - f(a)}{b - a} (x - a) = \frac{b - x}{b - a} f(a) + \frac{x - a}{b - a} f(b);$$

- on a component (a, ∞) (so $a \in E$), let $g(x) = f(a)$;
- on a component $(-\infty, b)$ (so $b \in E$), let $g(x) = f(b)$.

This defines g unambiguously on all of $\mathbb{R}$, and $g = f$ on E . Note that on a bounded component (a, b) the value $g(x)$ is a convex combination of $f(a)$ and $f(b)$, since $\frac{b-x}{b-a}$ and $\frac{x-a}{b-a}$ are nonnegative and sum

to 1. Consequently, if $|f(a) - c| < \epsilon$ and $|f(b) - c| < \epsilon$ for some real c , then for $x \in (a, b)$,

$$|g(x) - c| = \left| \frac{b-x}{b-a}(f(a) - c) + \frac{x-a}{b-a}(f(b) - c) \right| \leq \frac{b-x}{b-a}\epsilon + \frac{x-a}{b-a}\epsilon = \epsilon. \quad (*)$$

Continuity at points of $\mathcal{O}$. Let $x_0 \in \mathcal{O}$ and let I be its component. Since I is open, x_0 is an interior point of I , and on I the function g agrees with an affine function (a constant, in the unbounded cases), which is continuous. So g is continuous at x_0 .

Continuity at points of E . Let $x_0 \in E$ and let $\epsilon > 0$. By continuity of f at x_0 relative to E , there is a $\delta > 0$ such that

$$|f(y) - f(x_0)| < \epsilon \quad \text{whenever } y \in E \text{ and } |y - x_0| < \delta. \quad (**)$$

We produce $\delta_+ > 0$ such that $|g(x) - g(x_0)| \leq \epsilon$ for $x_0 \leq x < x_0 + \delta_+$; the argument on the left is symmetric, and taking the minimum of the two numbers finishes the proof.

Case 1: there is $\eta > 0$ with $(x_0, x_0 + \eta) \cap E = \emptyset$. Then $(x_0, x_0 + \eta) \subseteq \mathcal{O}$. Let I be the component of $\mathcal{O}$ that contains the point $x_0 + \eta/2$, and let a be its left endpoint. If $a < x_0$ (this includes $a = -\infty$), then x_0 would lie strictly between a and $x_0 + \eta/2$, hence in $I \subseteq \mathcal{O}$, contradicting $x_0 \in E$. So a is real and $a \geq x_0$. If $a > x_0$, then a is a finite endpoint of a component, so $a \in E$ by the fact recorded above, while $x_0 < a < x_0 + \eta/2 < x_0 + \eta$; this contradicts $(x_0, x_0 + \eta) \cap E = \emptyset$. Hence $a = x_0$, so $I = (x_0, b)$ or $I = (x_0, \infty)$. On I , g agrees with an affine function ℓ (in the unbounded case, the constant $f(x_0)$), and in the bounded case $\ell(x_0) = f(a) = f(x_0)$ by construction, while in the unbounded case $\ell \equiv f(x_0)$. Since ℓ is continuous at x_0 and $\ell(x_0) = f(x_0) = g(x_0)$, there is $\delta_+ > 0$ with $|\ell(x) - g(x_0)| < \epsilon$ for $|x - x_0| < \delta_+$; shrinking δ_+ so that $(x_0, x_0 + \delta_+) \subseteq I$, we get $|g(x) - g(x_0)| < \epsilon$ for $x_0 \leq x < x_0 + \delta_+$.

Case 2: every interval $(x_0, x_0 + \eta)$ meets E . Choose $x_1 \in E$ with $x_0 < x_1 < x_0 + \delta$, and set $\delta_+ = x_1 - x_0 > 0$. Let $x_0 \leq x < x_0 + \delta_+$, so $x_0 \leq x < x_1 < x_0 + \delta$. If $x \in E$, then $|x - x_0| < \delta$ and $(**)$ gives $|g(x) - g(x_0)| = |f(x) - f(x_0)| < \epsilon$. If $x \notin E$, let I be the component of $\mathcal{O}$ containing x . Since $x_0 \in E$ and $x_0 \leq x$, and since $x_1 \in E$ with $x < x_1$, the interval I contains neither x_0 nor x_1 , so I is bounded, $I = (a, b)$ with

$$x_0 \leq a < x < b \leq x_1.$$

Both a and b lie in E and satisfy $|a - x_0| < \delta$, $|b - x_0| < \delta$, so by $(**)$ both $|f(a) - f(x_0)| < \epsilon$ and $|f(b) - f(x_0)| < \epsilon$. By $(*)$ with $c = f(x_0) = g(x_0)$ we conclude $|g(x) - g(x_0)| \leq \epsilon$.

Thus in both cases $|g(x) - g(x_0)| \leq \epsilon$ for all x with $x_0 \leq x < x_0 + \delta_+$. The mirror-image argument on the left of x_0 produces $\delta_- > 0$ with $|g(x) - g(x_0)| \leq \epsilon$ for $x_0 - \delta_- < x \leq x_0$. With $\delta_0 = \min\{\delta_+, \delta_-\}$ we have $|g(x) - g(x_0)| \leq \epsilon$ whenever $|x - x_0| < \delta_0$. Since $\epsilon > 0$ was arbitrary (apply the above to $\epsilon/2$ to obtain a strict inequality), g is continuous at x_0 .

Hence g is continuous on all of $\mathbb{R}$ and extends f .

Problem 1.48. Define the real-valued function f on $\mathbb{R}$ by setting

$$f(x) = \begin{cases} x & \text{if } x \text{ irrational,} \\ p \sin \frac{1}{q} & \text{if } x = \frac{p}{q} \text{ in lowest terms.} \end{cases}$$

At what points is f continuous?

Solution. Answer: f is continuous exactly at the irrational numbers and at $x = 0$; it is discontinuous at every nonzero rational.

Here “in lowest terms” means $x = p/q$ with p an integer, q a natural number, and p and q having no common factor; this representation is unique, and $0 = 0/1$, so $f(0) = 0 \cdot \sin 1 = 0$.

We use three standard facts about the sine function from elementary calculus: $|\sin t| \leq |t|$ for all real t ; $\sin t < t$ for $t > 0$; and $\sin t/t \rightarrow 1$ as $t \rightarrow 0$. Throughout, we use Proposition 21: f is continuous at x_* if and only if $f(x_n) \rightarrow f(x_*)$ whenever $\{x_n\} \rightarrow x_*$.

A useful rewriting. If $x = p/q$ in lowest terms, then $p = qx$, so

$$f(x) = qx \sin \frac{1}{q} = x \cdot \frac{\sin(1/q)}{1/q}. \quad (1)$$

Lemma. If $\{x_n\}$ is a sequence of rationals converging to x_* , and $x_n = p_n/q_n$ in lowest terms, then either the denominators q_n tend to infinity, or some subsequence of $\{x_n\}$ is constant with value a rational number equal to x_* . Indeed, suppose $\{q_n\}$ does not tend to infinity. Then there is a natural number Q and infinitely many indices n with $q_n \leq Q$. A convergent sequence is bounded (Proposition 14), say $|x_n| \leq M$ for all n ; then for those indices $|p_n| = q_n|x_n| \leq QM$. So along those indices the pairs (p_n, q_n) take only finitely many values, hence x_n takes only finitely many values; consequently some value is attained infinitely often, giving a constant subsequence. A constant subsequence of a sequence converging to x_* has value x_* , so x_* is that rational number.

Continuity at every irrational x_* . Let $\{x_n\} \rightarrow x_*$; we must show $f(x_n) \rightarrow f(x_*) = x_*$. Consider

$$|f(x_n) - x_n| = \begin{cases} 0 & \text{if } x_n \text{ irrational,} \\ |x_n| \left| \frac{\sin(1/q_n)}{1/q_n} - 1 \right| & \text{if } x_n = p_n/q_n \text{ in lowest terms,} \end{cases}$$

using (1). Let $\epsilon > 0$. Since $\{x_n\}$ is bounded, say $|x_n| \leq M$ with $M > 0$, and since $\sin t/t \rightarrow 1$ as $t \rightarrow 0$, there is $\eta > 0$ such that $|\sin t/t - 1| < \epsilon/M$ whenever $0 < t < \eta$. Now consider the rational terms of $\{x_n\}$. By the Lemma, since x_* is irrational no subsequence of rationals can have bounded denominators (a constant subsequence would force x_* to be rational); more precisely, if there were a natural number Q and infinitely many rational terms with $q_n \leq Q$, the Lemma applied to that subsequence would make x_* rational. Hence $q_n \rightarrow \infty$ through the rational terms: there is an index N_1 such that every rational term x_n with $n \geq N_1$ has $1/q_n < \eta$. For such n ,

$$|f(x_n) - x_n| = |x_n| \left| \frac{\sin(1/q_n)}{1/q_n} - 1 \right| \leq M \cdot \frac{\epsilon}{M} = \epsilon.$$

For irrational terms $|f(x_n) - x_n| = 0 \leq \epsilon$. Therefore $|f(x_n) - x_n| \leq \epsilon$ for all $n \geq N_1$. Since $\epsilon > 0$ was arbitrary, $f(x_n) - x_n \rightarrow 0$, and since $x_n \rightarrow x_*$, Theorem 18 gives $f(x_n) \rightarrow x_* = f(x_*)$. By Proposition 21, f is continuous at x_* .

Continuity at 0. For every real x we claim $|f(x)| \leq |x|$. If x is irrational this is an equality. If $x = p/q$ in lowest terms, then, using $|\sin t| \leq |t|$,

$$|f(x)| = |p| \left| \sin \frac{1}{q} \right| \leq |p| \cdot \frac{1}{q} = |x|.$$

Hence if $\{x_n\} \rightarrow 0$, then $|f(x_n)| \leq |x_n| \rightarrow 0$, so $f(x_n) \rightarrow 0 = f(0)$. By Proposition 21, f is continuous at 0.

Discontinuity at every nonzero rational. Let $x_* = p/q$ in lowest terms with $x_* \neq 0$, so $p \neq 0$ and $q \geq 1$.

Then $0 < 1/q \leq 1$, so $\sin(1/q) < 1/q$ and hence $\frac{\sin(1/q)}{1/q} < 1$. By (1),

$$f(x_*) = x_* \cdot \frac{\sin(1/q)}{1/q} \neq x_*,$$

since $x_* \neq 0$ and the factor is different from 1. Next, the irrationals are dense in $\mathbb{R}$: given $a < b$, Theorem 2 provides a rational r with $a - \sqrt{2} < r < b - \sqrt{2}$, and then $r + \sqrt{2} \in (a, b)$ is irrational, for otherwise $\sqrt{2} = (r + \sqrt{2}) - r$ would be rational, which Section 1.2 shows it is not. So for each natural number n choose an irrational x_n with $|x_n - x_*| < 1/n$; by the Archimedean Property $\{x_n\} \rightarrow x_*$, while $f(x_n) = x_n \rightarrow x_* \neq f(x_*)$. By Proposition 21, f is not continuous at x_* .

Thus the set of points of continuity of f is $\{0\} \cup \{x \in \mathbb{R} \mid x \text{ irrational}\}$.

Problem 1.49. Let f and g be continuous real-valued functions with a common domain E .

- (i) Show that the sum, $f + g$, and product, fg , are also continuous functions.
- (ii) If h is a continuous function with image contained in E , show that the composition $f \circ h$ is continuous.
- (iii) Let $\max\{f, g\}$ be the function defined by $\max\{f, g\}(x) = \max\{f(x), g(x)\}$, for $x \in E$. Show that $\max\{f, g\}$ is continuous.
- (iv) Show that $|f|$ is continuous.

Solution. We use Proposition 21 throughout: a real-valued function φ defined on a set E of real numbers is continuous at $x_* \in E$ if and only if $\varphi(x_n) \rightarrow \varphi(x_*)$ whenever $\{x_n\}$ is a sequence in E converging to x_* .

(i). Fix $x_* \in E$ and let $\{x_n\}$ be a sequence in E with $\{x_n\} \rightarrow x_*$. Since f and g are continuous at x_* , Proposition 21 gives $f(x_n) \rightarrow f(x_*)$ and $g(x_n) \rightarrow g(x_*)$.

Sum: by Theorem 18 (linearity of convergence, with $\alpha = \beta = 1$),

$$(f + g)(x_n) = f(x_n) + g(x_n) \rightarrow f(x_*) + g(x_*) = (f + g)(x_*).$$

By Proposition 21, $f + g$ is continuous at x_* , and since x_* was arbitrary, on E .

Product: we first check that the product of convergent sequences converges to the product of the limits. Let $a_n \rightarrow a$ and $b_n \rightarrow b$. By Proposition 14 the sequence $\{a_n\}$ is bounded; choose $M > 0$ with $|a_n| \leq M$ for all n , and enlarge M if necessary so that $M \geq |b|$. Then for every n ,

$$|a_n b_n - ab| = |a_n(b_n - b) + b(a_n - a)| \leq M|b_n - b| + M|a_n - a|.$$

Given $\epsilon > 0$, choose N so large that $|a_n - a| < \epsilon/(2M)$ and $|b_n - b| < \epsilon/(2M)$ for $n \geq N$; then $|a_n b_n - ab| < \epsilon$ for $n \geq N$. So $a_n b_n \rightarrow ab$. Applying this with $a_n = f(x_n)$, $b_n = g(x_n)$,

$$(fg)(x_n) = f(x_n)g(x_n) \rightarrow f(x_*)g(x_*) = (fg)(x_*),$$

so by Proposition 21, fg is continuous on E .

(ii). Let h be a continuous real-valued function defined on a set D of real numbers with $h(D) \subseteq E$. Then $f \circ h$ is defined on D . Fix $x_* \in D$ and let $\{x_n\}$ be a sequence in D with $\{x_n\} \rightarrow x_*$. Since h is continuous at x_* , Proposition 21 gives $h(x_n) \rightarrow h(x_*)$. Now $\{h(x_n)\}$ is a sequence in E converging to the point $h(x_*)$ of E , so continuity of f at $h(x_*)$ and Proposition 21 give

$$(f \circ h)(x_n) = f(h(x_n)) \rightarrow f(h(x_*)) = (f \circ h)(x_*).$$

By Proposition 21 again, $f \circ h$ is continuous at x_* , hence on D .

(iii). We first record an elementary inequality: for real numbers u, v, u', v' ,

$$|\max\{u, v\} - \max\{u', v'\}| \leq \max\{|u - u'|, |v - v'|\}. \quad (2)$$

To see this, assume without loss of generality that $\max\{u, v\} \geq \max\{u', v'\}$ (otherwise interchange the roles of the two pairs, which does not change either side). Say $\max\{u, v\} = u$, the case $\max\{u, v\} = v$ being identical with v in place of u . Then, since $\max\{u', v'\} \geq u'$,

$$0 \leq \max\{u, v\} - \max\{u', v'\} \leq u - u' \leq |u - u'| \leq \max\{|u - u'|, |v - v'|\},$$

which is (2).

Now let $x_* \in E$ and $\epsilon > 0$. By continuity of f and of g at x_* , there are $\delta_1 > 0$ and $\delta_2 > 0$ such that for $x \in E$: $|x - x_*| < \delta_1$ implies $|f(x) - f(x_*)| < \epsilon$, and $|x - x_*| < \delta_2$ implies $|g(x) - g(x_*)| < \epsilon$. Put $\delta = \min\{\delta_1, \delta_2\} > 0$. If $x \in E$ and $|x - x_*| < \delta$, then by (2) with $u = f(x)$, $v = g(x)$, $u' = f(x_*)$, $v' = g(x_*)$,

$$|\max\{f, g\}(x) - \max\{f, g\}(x_*)| \leq \max\{|f(x) - f(x_*)|, |g(x) - g(x_*)|\} < \epsilon.$$

So $\max\{f, g\}$ is continuous at x_* , and hence on E .

(Alternatively, once (i) and (iv) are known one may use the identity $\max\{f, g\} = \frac{1}{2}(f + g + |f - g|)$.)
(iv). By the triangle inequality (Problem 7), for all real s, t we have $|s| \leq |s - t| + |t|$ and $|t| \leq |t - s| + |s|$, whence

$$||s| - |t|| \leq |s - t|.$$

Let $x_* \in E$ and $\epsilon > 0$. By continuity of f at x_* there is $\delta > 0$ such that $|f(x) - f(x_*)| < \epsilon$ whenever $x \in E$ and $|x - x_*| < \delta$. For such x ,

$$||f|(x) - |f|(x_*)| = ||f(x)| - |f(x_*)|| \leq |f(x) - f(x_*)| < \epsilon.$$

Hence $|f|$ is continuous at x_* , and therefore on E .

1.8 Problems 1.50–1.56

Problem 1.50. Show that a Lipschitz function is uniformly continuous but there are uniformly continuous functions that are not Lipschitz.

Solution. Recall the definitions in force. A real-valued function f on a set E of real numbers is **Lipschitz** provided there is a $c \geq 0$ for which

$$|f(x') - f(x)| \leq c|x' - x| \quad \text{for all } x', x \in E,$$

and f is **uniformly continuous** on E provided for each $\epsilon > 0$ there is a $\delta > 0$ such that for all x, x' in E , if $|x - x'| < \delta$ then $|f(x) - f(x')| < \epsilon$.

Lipschitz implies uniformly continuous. Let f be Lipschitz on E with constant $c \geq 0$. Let $\epsilon > 0$. Define

$$\delta = \frac{\epsilon}{c+1} > 0.$$

This δ responds to the ϵ challenge. Indeed, let x, x' belong to E with $|x - x'| < \delta$. Then

$$|f(x) - f(x')| \leq c|x - x'| \leq (c+1)|x - x'| < (c+1) \cdot \frac{\epsilon}{c+1} = \epsilon.$$

Since δ was chosen independently of the points x, x' , the function f is uniformly continuous on E . Observe that the same δ works for every ϵ -challenge at every point, which is exactly the extra strength of uniform continuity over continuity.

A uniformly continuous function that is not Lipschitz. Define $f(x) = \sqrt{x}$ for x in $E = [0, 1]$. The function f is continuous on E . Indeed, at a point $x > 0$, for $x' \in [0, 1]$ we have $\sqrt{x'} + \sqrt{x} \geq \sqrt{x} > 0$ and hence

$$|\sqrt{x'} - \sqrt{x}| = \frac{|x' - x|}{\sqrt{x'} + \sqrt{x}} \leq \frac{|x' - x|}{\sqrt{x}},$$

so $\delta = \epsilon\sqrt{x}$ responds to the ϵ challenge at x ; and at $x = 0$ we have $|f(x') - f(0)| = \sqrt{x'} < \epsilon$ whenever $0 \leq x' < \epsilon^2$. The set $[0, 1]$ is closed and bounded, so by Theorem 23 the continuous function f is uniformly continuous on $[0, 1]$.

However f is not Lipschitz. Suppose it were, with constant $c \geq 0$. Taking $x = 0$ and $x' = t$ with $0 < t \leq 1$ gives

$$\sqrt{t} = |f(t) - f(0)| \leq c|t - 0| = ct,$$

so that, dividing by $\sqrt{t} > 0$,

$$\frac{1}{\sqrt{t}} \leq c \quad \text{for all } 0 < t \leq 1.$$

But $1/\sqrt{t}$ is unbounded above as t decreases to 0: choosing $t = 1/(c+1)^2$, which lies in $(0, 1]$, yields $c+1 \leq c$, a contradiction. Hence no such c exists and f is not Lipschitz.

Therefore the class of Lipschitz functions is properly contained in the class of uniformly continuous functions.

Problem 1.51. A continuous function φ on $[a, b]$ is called **piecewise linear** provided there is a partition $a = x_0 < x_1 < \cdots < x_n = b$ of $[a, b]$ for which φ is linear on each interval $[x_i, x_{i+1}]$. Let f be a continuous function on $[a, b]$ and ϵ a positive number. Show that there is a piecewise linear function φ on $[a, b]$ with $|f(x) - \varphi(x)| < \epsilon$ for all $x \in [a, b]$.

Solution. We may assume $a < b$, since if $a = b$ there is nothing to prove.

The interval $[a, b]$ is a closed, bounded set of real numbers and f is continuous on it, so by Theorem 23 the function f is uniformly continuous on $[a, b]$. Let $\epsilon > 0$ be given and choose $\delta > 0$ so that

$$\text{if } x, x' \in [a, b] \text{ and } |x - x'| < \delta, \text{ then } |f(x) - f(x')| < \epsilon.$$

By the Archimedean Property of $\mathbb{R}$ choose a natural number n with $n > (b-a)/\delta$, so that $(b-a)/n < \delta$. Define the uniform partition

$$x_i = a + i \cdot \frac{b-a}{n} \quad \text{for } i = 0, 1, \dots, n,$$

so $a = x_0 < x_1 < \cdots < x_n = b$ and each subinterval $[x_i, x_{i+1}]$ has length $(b-a)/n < \delta$.

Define $\varphi: [a, b] \rightarrow \mathbb{R}$ by prescribing it on each subinterval to be the linear function agreeing with f at the two endpoints: for $0 \leq i \leq n-1$ and $x \in [x_i, x_{i+1}]$, set

$$\varphi(x) = f(x_i) + \frac{f(x_{i+1}) - f(x_i)}{x_{i+1} - x_i} (x - x_i).$$

This is well defined. At an interior partition point x_i with $1 \leq i \leq n-1$ the formula on $[x_{i-1}, x_i]$ gives the value $f(x_i)$ and the formula on $[x_i, x_{i+1}]$ also gives $f(x_i)$, so the two prescriptions agree. Thus $\varphi(x_i) = f(x_i)$ for every i . Each piece is a linear, hence continuous, function on a closed interval and consecutive pieces agree at the shared endpoint, so φ is continuous on $[a, b]$ and is linear on each $[x_i, x_{i+1}]$. Hence φ is piecewise linear.

It remains to estimate $|f - \varphi|$. Let $x \in [a, b]$ and choose i with $x \in [x_i, x_{i+1}]$. Write

$$\lambda = \frac{x_{i+1} - x}{x_{i+1} - x_i} \in [0, 1], \quad 1 - \lambda = \frac{x - x_i}{x_{i+1} - x_i}.$$

A direct computation from the defining formula shows that $\varphi(x)$ is the corresponding convex combination of the endpoint values:

$$\varphi(x) = \lambda f(x_i) + (1 - \lambda) f(x_{i+1}).$$

Since $\lambda + (1 - \lambda) = 1$ we may write $f(x) = \lambda f(x) + (1 - \lambda) f(x)$, and therefore

$$|f(x) - \varphi(x)| = |\lambda(f(x) - f(x_i)) + (1 - \lambda)(f(x) - f(x_{i+1}))| \leq \lambda|f(x) - f(x_i)| + (1 - \lambda)|f(x) - f(x_{i+1})|.$$

Now x and x_i both lie in $[x_i, x_{i+1}]$, an interval of length $(b-a)/n < \delta$, so $|x - x_i| < \delta$ and hence $|f(x) - f(x_i)| < \epsilon$; for the same reason $|f(x) - f(x_{i+1})| < \epsilon$. Consequently

$$|f(x) - \varphi(x)| < \lambda\epsilon + (1 - \lambda)\epsilon = \epsilon.$$

(If λ is 0 or 1 the corresponding term is absent and the strict inequality persists, since then $|f(x) - \varphi(x)|$ equals $|f(x) - f(x_{i+1})|$ or $|f(x) - f(x_i)|$, each less than ϵ .)

Since $x \in [a, b]$ was arbitrary, $|f(x) - \varphi(x)| < \epsilon$ for all $x \in [a, b]$, as required.

Problem 1.52. Show that a nonempty set E of real numbers is closed and bounded if and only if every continuous real-valued function on E takes a maximum value.

Solution. Let E be a nonempty set of real numbers. We say that a real-valued function f on E **takes a maximum value** provided there is a point x_* in E with $f(x) \leq f(x_*)$ for all x in E .

Necessity. Suppose E is closed and bounded. Let f be any continuous real-valued function on E . Since E is nonempty, closed and bounded, the Extreme Value Theorem asserts that f takes a maximum value on E . This is exactly the assertion to be proved.

Sufficiency. Suppose every continuous real-valued function on E takes a maximum value. We prove E is bounded and closed.

E is bounded. Consider $f(x) = |x|$ for x in E . This function is continuous on E : for x, x' in E the reverse triangle inequality gives $||x'| - |x|| \leq |x' - x|$, so f is Lipschitz with constant 1 and hence continuous. By hypothesis f takes a maximum value, say at $x_* \in E$. Then $|x| \leq |x_*|$ for all $x \in E$, so $E \subseteq [-|x_*|, |x_*|]$ and E is bounded.

E is closed. By definition E is closed provided it contains all of its points of closure. Argue by contradiction: suppose there is a point of closure x_0 of E with $x_0 \notin E$. Define

$$f(x) = \frac{1}{|x - x_0|} \quad \text{for } x \in E.$$

This is well defined, since $x_0 \notin E$ forces $|x - x_0| > 0$ for every $x \in E$. It is continuous on E : the function $x \mapsto |x - x_0|$ is continuous and nowhere zero on E , and $t \mapsto 1/t$ is continuous on $(0, \infty)$, so by the continuity of compositions the quotient is continuous at each point of E . (Concretely, fix $x \in E$ and put $r = |x - x_0| > 0$; if $x' \in E$ and $|x' - x| < r/2$ then $|x' - x_0| > r/2$ and

$$|f(x') - f(x)| = \frac{||x - x_0| - |x' - x_0||}{|x' - x_0| |x - x_0|} \leq \frac{|x' - x|}{(r/2)r},$$

which is less than any prescribed $\epsilon > 0$ once $|x' - x|$ is small enough.)

By hypothesis f takes a maximum value on E , say $f(x) \leq M$ for all $x \in E$, where $M = f(x_*) > 0$. Thus $|x - x_0| \geq 1/M$ for every $x \in E$. But x_0 is a point of closure of E , so every open interval about x_0 contains a point of E ; in particular there is an $x \in E$ with $|x - x_0| < 1/M$. This contradiction shows that every point of closure of E belongs to E , that is, E is closed.

Hence E is closed and bounded, and the equivalence is established.

Problem 1.53. Show that a set E of real numbers is closed and bounded if and only if every open cover of E has a finite subcover.

Solution. Recall that a collection $\mathcal{F}$ of sets is a **cover** of E provided $E \subseteq \bigcup_{F \in \mathcal{F}} F$, and it is an **open cover** provided each member is open. A **finite subcover** is a finite subcollection of $\mathcal{F}$ that still covers E .

Necessity. Suppose E is closed and bounded. Then the Heine-Borel Theorem asserts precisely that every open cover of E has a finite subcover.

Sufficiency. Suppose every open cover of E has a finite subcover. (If E is empty it is trivially closed and bounded, so assume $E \neq \emptyset$.)

E is bounded. For each natural number n let $\mathcal{O}_n = (-n, n)$, an open interval. Every real number x satisfies $|x| < n$ for some natural number n , by the Archimedean Property, so $\{\mathcal{O}_n\}_{n=1}^\infty$ is an open cover of E . By hypothesis there are indices $n_1, \dots, n_k$ with

$$E \subseteq \mathcal{O}_{n_1} \cup \dots \cup \mathcal{O}_{n_k}.$$

The intervals $\mathcal{O}_n$ are ascending, so putting $N = \max\{n_1, \dots, n_k\}$ the union equals $\mathcal{O}_N = (-N, N)$. Thus $E \subseteq (-N, N)$ and E is bounded.

E is closed. We must show E contains each of its points of closure. Argue by contradiction: let x_0 be a point of closure of E with $x_0 \notin E$. For each natural number n define

$$\mathcal{O}_n = \left\{ x \in \mathbb{R} : |x - x_0| > \frac{1}{n} \right\} = \left(-\infty, x_0 - \frac{1}{n} \right) \cup \left(x_0 + \frac{1}{n}, \infty \right),$$

which, being the union of two open intervals, is open. The collection $\{\mathcal{O}_n\}_{n=1}^\infty$ covers E : if $x \in E$ then $x \neq x_0$ since $x_0 \notin E$, hence $|x - x_0| > 0$, and by the Archimedean Property there is an n with $1/n < |x - x_0|$, so $x \in \mathcal{O}_n$.

By hypothesis finitely many of these sets cover E . The sets $\mathcal{O}_n$ ascend with n , so as above there is a single natural number N with $E \subseteq \mathcal{O}_N$, that is,

$$|x - x_0| > \frac{1}{N} \quad \text{for all } x \in E.$$

Therefore the open interval $(x_0 - 1/N, x_0 + 1/N)$ contains no point of E . But x_0 is a point of closure of E , so every open interval containing x_0 must contain a point of E . This contradiction shows no such x_0 exists, so E contains all its points of closure and hence is closed.

Thus E is closed and bounded, completing the proof of the equivalence.

Problem 1.54. Show that a nonempty set E of real numbers is an interval if and only if every continuous real-valued function on E has an interval as its image.

Solution. It is convenient first to record the internal characterization of intervals.

Lemma. A nonempty set I of real numbers is an interval if and only if it has the **betweenness property**: whenever $x, y \in I$ and $x < z < y$, then $z \in I$.

Proof of the Lemma. Every interval visibly has the betweenness property, since each of the sets (a, b) , $[a, b)$, $(a, b]$, $[a, b]$, $(-\infty, b)$, $(-\infty, b]$, (a, ∞) , $[a, \infty)$, $\mathbb{R}$ is described by inequalities on the point itself. Conversely, let I be nonempty with the betweenness property. Put $a = \inf I$ and $b = \sup I$, allowing the values $-\infty$ and ∞ if I fails to be bounded below or above. Then $I \subseteq [a, b]$ (interpreted appropriately when an endpoint is infinite). We claim $(a, b) \subseteq I$. Let $a < z < b$. Since $z > a = \inf I$, the number z is not a lower bound for I , so there is $x \in I$ with $x < z$; since $z < b = \sup I$, the number z is not an upper bound for I , so there is $y \in I$ with $z < y$. By the betweenness property $z \in I$. Hence $(a, b) \subseteq I \subseteq [a, b]$, so I is obtained from (a, b) by possibly adjoining the finite endpoints a and b ; in every case I is an interval. (If $a = b$ then $I = \{a\} = [a, a]$, a degenerate closed interval.) $\square$

Necessity. Suppose E is an interval and let f be a continuous real-valued function on E . The image $f(E)$ is nonempty since E is. We verify the betweenness property for $f(E)$; the Lemma then shows $f(E)$ is an interval.

Let $u, v \in f(E)$ and $u < w < v$. Choose $x, y \in E$ with $f(x) = u$ and $f(y) = v$. Since $u \neq v$ we have $x \neq y$.

Case $x < y$. Because E is an interval containing x and y , the betweenness property gives $[x, y] \subseteq E$. The restriction of f to the closed, bounded interval $[x, y]$ is continuous and $f(x) = u < w < v = f(y)$, so by the Intermediate Value Theorem there is a point $x_0 \in (x, y)$ with $f(x_0) = w$. Hence $w \in f(E)$.

Case $y < x$. Again $[y, x] \subseteq E$. Consider $g = -f$ on $[y, x]$, which is continuous, and note

$$g(y) = -v < -w < -u = g(x).$$

By the Intermediate Value Theorem applied to g on $[y, x]$ there is $x_0 \in (y, x)$ with $g(x_0) = -w$, that is, $f(x_0) = w$. Hence $w \in f(E)$.

In either case $w \in f(E)$, so $f(E)$ has the betweenness property and is therefore an interval.

Sufficiency. Suppose every continuous real-valued function on E has an interval as its image. Consider the identity function $f(x) = x$ for $x \in E$. It is Lipschitz with constant 1, hence continuous on E , and its image is $f(E) = E$. By hypothesis this image is an interval, so E is an interval.

This proves the asserted equivalence.

Problem 1.55. Show that a monotone function on an open interval is continuous if and only if its image is an interval.

Solution. Let I be an open interval and f a monotone real-valued function on I .

Throughout we use the following characterization, established in the solution to Problem 54: a nonempty set S of real numbers is an interval if and only if it has the **betweenness property**, namely that $u, v \in S$ and $u < w < v$ imply $w \in S$.

Reduction to the increasing case. If f is decreasing then $g = -f$ is increasing on I ; moreover f is

continuous at a point if and only if g is, and $g(I) = \{-y : y \in f(I)\}$. A set S has the betweenness property if and only if $-S = \{-y : y \in S\}$ does, since $u < w < v$ holds exactly when $-v < -w < -u$ holds. Hence $f(I)$ is an interval exactly when $g(I)$ is. So the equivalence for g yields the equivalence for f , and we may assume throughout that f is increasing, that is, $f(x) \leq f(x')$ whenever $x, x' \in I$ and $x \leq x'$.

Continuity implies the image is an interval. This half needs no monotonicity. An open interval I is an interval, so by the necessity half of Problem 54 (whose proof rests on the Intermediate Value Theorem) the image under a continuous real-valued function of an interval is again an interval. Explicitly: if $u = f(x)$ and $v = f(y)$ lie in $f(I)$ and $u < w < v$, then $[x, y] \subseteq I$ or $[y, x] \subseteq I$ according to the order of x and y , and the Intermediate Value Theorem applied to f (or to $-f$) on that closed, bounded subinterval produces a point x_0 between x and y with $f(x_0) = w$. So $f(I)$ has the betweenness property and hence is an interval.

The image is an interval implies continuity. Assume $f(I)$ is an interval, and let $x_0 \in I$. As in the discussion preceding these problems, monotonicity together with the Monotone Convergence Theorem for real sequences guarantees that the one-sided limits

$$f(x_0^-) = \lim_{x \rightarrow x_0^-} f(x), \quad f(x_0^+) = \lim_{x \rightarrow x_0^+} f(x)$$

exist and are independent of the approximating sequence, and f is continuous at x_0 if and only if $f(x_0^-) = f(x_0) = f(x_0^+)$. Since I is open, both one-sided limits are genuinely available: there are points of I on each side of x_0 .

For an increasing f these limits are given by

$$f(x_0^-) = \sup\{f(x) : x \in I, x < x_0\}, \quad f(x_0^+) = \inf\{f(x) : x \in I, x > x_0\}.$$

Indeed, since I is open there are points of I strictly to the left of x_0 , so the set $S^- = \{f(x) : x \in I, x < x_0\}$ is nonempty; as f is increasing, S^- is bounded above by $f(x_0)$, and hence $s = \sup S^-$ is a real number. Choose a sequence $\{x_n\}$ in I with $x_n < x_0$ for all n and $x_n \rightarrow x_0$; by the discussion above $f(x_n) \rightarrow f(x_0^-)$. Each $f(x_n)$ belongs to S^- , so $f(x_n) \leq s$ for every n and therefore $f(x_0^-) \leq s$. Conversely, fix $x \in I$ with $x < x_0$. Since $x_n \rightarrow x_0$ and $x < x_0$, we have $x_n > x$ for all sufficiently large n , and then $f(x_n) \geq f(x)$; letting $n \rightarrow \infty$ gives $f(x_0^-) \geq f(x)$. As x was an arbitrary point of I to the left of x_0 , taking the supremum yields $f(x_0^-) \geq s$. Therefore $f(x_0^-) = s$. The formula for $f(x_0^+)$ is proved symmetrically. In particular

$$f(x_0^-) \leq f(x_0) \leq f(x_0^+).$$

Suppose, to get a contradiction, that f is not continuous at x_0 . Then $f(x_0^-) < f(x_0^+)$. Two consequences of the sup/inf formulas are:

$$f(x) \leq f(x_0^-) \text{ for all } x \in I \text{ with } x < x_0, \quad f(x) \geq f(x_0^+) \text{ for all } x \in I \text{ with } x > x_0.$$

Hence the only value of f that can lie in the open interval $(f(x_0^-), f(x_0^+))$ is $f(x_0)$ itself.

The open interval $(f(x_0^-), f(x_0^+))$ is nonempty and contains more than one point, so we may choose a number c with

$$f(x_0^-) < c < f(x_0^+) \quad \text{and} \quad c \neq f(x_0).$$

By the preceding paragraph $c \notin f(I)$.

Since I is open and $x_0 \in I$, choose $x_1, x_2 \in I$ with $x_1 < x_0 < x_2$. Then

$$f(x_1) \leq f(x_0^-) < c < f(x_0^+) \leq f(x_2),$$

so $f(x_1)$ and $f(x_2)$ belong to $f(I)$ and c lies strictly between them, yet $c \notin f(I)$. This contradicts the betweenness property of the interval $f(I)$.

Therefore $f(x_0^-) = f(x_0) = f(x_0^+)$ and f is continuous at x_0 . As $x_0 \in I$ was arbitrary, f is continuous on I .

Problem 1.56. Let f be a real-valued function defined on $\mathbb{R}$. Show that the set of points at which f is continuous is a G_δ set.

Solution. Recall that a set of real numbers is a G_δ set provided it is the intersection of a countable collection of open sets. Let

$$C = \{x \in \mathbb{R} : f \text{ is continuous at } x\}.$$

We exhibit C as a countable intersection of open sets by means of the oscillation of f .

The oscillation. For $x \in \mathbb{R}$ and $\delta > 0$ define

$$\text{osc}(f, x, \delta) = \sup\{|f(y) - f(z)| : y, z \in (x - \delta, x + \delta)\},$$

an extended real number in $[0, \infty]$ (the supremum may be $+\infty$; nothing below is affected). Since the interval shrinks as δ decreases, $\delta \mapsto \text{osc}(f, x, \delta)$ is a nondecreasing function of δ , and we may define the **oscillation of f at x** by

$$\omega(x) = \inf_{\delta > 0} \text{osc}(f, x, \delta) \in [0, \infty].$$

Step 1: f is continuous at x if and only if $\omega(x) = 0$.

Suppose f is continuous at x and let $\epsilon > 0$. There is $\delta > 0$ such that $|f(y) - f(x)| < \epsilon/3$ whenever $|y - x| < \delta$. Then for any $y, z \in (x - \delta, x + \delta)$,

$$|f(y) - f(z)| \leq |f(y) - f(x)| + |f(x) - f(z)| < \frac{2\epsilon}{3},$$

so $\text{osc}(f, x, \delta) \leq 2\epsilon/3 < \epsilon$ and hence $\omega(x) < \epsilon$. As $\epsilon > 0$ was arbitrary and $\omega(x) \geq 0$, we get $\omega(x) = 0$. Conversely suppose $\omega(x) = 0$ and let $\epsilon > 0$. By definition of the infimum there is $\delta > 0$ with $\text{osc}(f, x, \delta) < \epsilon$. If $|y - x| < \delta$, then y and x both lie in $(x - \delta, x + \delta)$, so

$$|f(y) - f(x)| \leq \text{osc}(f, x, \delta) < \epsilon.$$

Thus f is continuous at x . This proves $C = \{x \in \mathbb{R} : \omega(x) = 0\}$.

Step 2: for each natural number n , the set

$$\mathcal{O}_n = \left\{x \in \mathbb{R} : \omega(x) < \frac{1}{n}\right\}$$

is open.

Let $x \in \mathcal{O}_n$. Since $\omega(x) < 1/n$, there is $\delta > 0$ with $\text{osc}(f, x, \delta) < 1/n$. We claim the open interval $(x - \delta/2, x + \delta/2)$ is contained in $\mathcal{O}_n$. Indeed, let x' satisfy $|x' - x| < \delta/2$. If $y \in (x' - \delta/2, x' + \delta/2)$ then

$$|y - x| \leq |y - x'| + |x' - x| < \frac{\delta}{2} + \frac{\delta}{2} = \delta,$$

so $(x' - \delta/2, x' + \delta/2) \subseteq (x - \delta, x + \delta)$. The supremum defining the oscillation is therefore taken over a smaller collection of pairs, whence

$$\text{osc}\left(f, x', \frac{\delta}{2}\right) \leq \text{osc}(f, x, \delta) < \frac{1}{n},$$

and consequently $\omega(x') \leq \text{osc}(f, x', \delta/2) < 1/n$, that is, $x' \in \mathcal{O}_n$. So every point of $\mathcal{O}_n$ is contained in an open interval lying in $\mathcal{O}_n$, and $\mathcal{O}_n$ is open.

Step 3: conclusion.

We claim

$$C = \bigcap_{n=1}^{\infty} \mathcal{O}_n.$$

If $x \in C$ then $\omega(x) = 0 < 1/n$ for every n , so x lies in every $\mathcal{O}_n$. Conversely, if $x \in \mathcal{O}_n$ for every natural number n , then $0 \leq \omega(x) < 1/n$ for all n ; by the Archimedean Property this forces $\omega(x) = 0$, so $x \in C$ by Step 1.

Thus C is the intersection of the countable collection $\{\mathcal{O}_n\}_{n=1}^{\infty}$ of open sets, that is, the set of points at which f is continuous is a G_δ set.

1.9 Problems 1.57–1.60

Problem 1.57. Let $\{f_n\}$ be a sequence of continuous functions defined on $\mathbb{R}$. Show that the set of points x at which the sequence $\{f_n(x)\}$ converges to a real number is the intersection of a countable collection of F_σ sets.

Solution. Write

$$X = \{x \in \mathbb{R} : \{f_n(x)\}_{n=1}^\infty \text{ converges to a real number}\}.$$

Step 1: a Cauchy description of X . By Theorem 17 (the Cauchy Convergence Criterion for Real Sequences), a sequence of real numbers converges to a real number if and only if it is Cauchy. Hence x belongs to X if and only if the sequence $\{f_n(x)\}$ is Cauchy, that is, if and only if for every $k \in \mathbb{N}$ there is an $N \in \mathbb{N}$ such that $|f_n(x) - f_m(x)| \leq 1/k$ for all $n, m \geq N$.

(Using the closed inequality $\leq 1/k$ rather than $< 1/k$ is harmless: if the Cauchy condition holds with strict inequality for every positive ϵ it certainly holds with $\leq 1/k$ for every k , and conversely, given $\epsilon > 0$ choose k with $1/k < \epsilon$.)

Translating the three quantifiers into set operations, this says exactly that

$$X = \bigcap_{k=1}^{\infty} \bigcup_{N=1}^{\infty} \bigcap_{n \geq N} \bigcap_{m \geq N} E_{n,m,k}, \quad \text{where} \quad E_{n,m,k} = \left\{x \in \mathbb{R} : |f_n(x) - f_m(x)| \leq \frac{1}{k}\right\}.$$

Step 2: each $E_{n,m,k}$ is closed. Fix n, m, k and set $g = |f_n - f_m|$. First, $-f_m$ is continuous on $\mathbb{R}$: for any point x and any $\epsilon > 0$, a $\delta > 0$ that responds to the ϵ challenge for the continuity of f_m at x also responds for $-f_m$, since $|(-f_m)(x') - (-f_m)(x)| = |f_m(x') - f_m(x)|$. Next, by Problem 49 of this chapter, the sum of two continuous real-valued functions with a common domain is continuous, so $f_n + (-f_m) = f_n - f_m$ is continuous on $\mathbb{R}$; and by the same problem the absolute value of a continuous function is continuous, so $g = |f_n - f_m|$ is continuous on $\mathbb{R}$. The complement of $E_{n,m,k}$ is

$$\mathbb{R} \sim E_{n,m,k} = \left\{x \in \mathbb{R} : g(x) > \frac{1}{k}\right\} = g^{-1}\left(\left(\frac{1}{k}, \infty\right)\right).$$

The set $(1/k, \infty)$ is open, so by Proposition 22, applied with $E = \mathbb{R}$, we have $g^{-1}((1/k, \infty)) = \mathbb{R} \cap U = U$ for some open set U ; thus $\mathbb{R} \sim E_{n,m,k}$ is open, and by Proposition 11 the set $E_{n,m,k}$ is closed.

Step 3: assembling. For fixed k and N put

$$A_{N,k} = \bigcap_{n \geq N} \bigcap_{m \geq N} E_{n,m,k}.$$

This is an intersection of a collection of closed sets, hence is closed by Proposition 12, which states that the intersection of any collection of closed sets is closed.

Now define

$$F_k = \bigcup_{N=1}^{\infty} A_{N,k}.$$

This is a countable union of closed sets, so F_k is an F_σ set.

By Step 1,

$$X = \bigcap_{k=1}^{\infty} F_k,$$

which exhibits X as the intersection of the countable collection $\{F_k\}_{k=1}^\infty$ of F_σ sets.

Remark. Since a σ -algebra is closed with respect to the formation of countable unions and countable intersections, each F_σ set is a Borel set, and therefore X itself is a Borel set.

Problem 1.58. Let f be a continuous real-valued function on $\mathbb{R}$. Show that the inverse image with respect to f of an open set is open, of a closed set is closed, and of a Borel set is Borel.

Solution. Throughout we use the elementary identities, valid for any function f from $\mathbb{R}$ to $\mathbb{R}$ and any sets A, A_n of real numbers:

$$f^{-1}(\mathbb{R} \sim A) = \mathbb{R} \sim f^{-1}(A), \quad f^{-1}\left(\bigcup_{n=1}^{\infty} A_n\right) = \bigcup_{n=1}^{\infty} f^{-1}(A_n).$$

Both are immediate from the definition $f^{-1}(A) = \{x \in \mathbb{R} : f(x) \in A\}$: for the first, $x \in f^{-1}(\mathbb{R} \sim A)$ means $f(x) \notin A$, which means $x \notin f^{-1}(A)$; for the second, $f(x)$ lies in some A_n if and only if x lies in some $f^{-1}(A_n)$.

Inverse images of open sets. Let O be an open set of real numbers. Since f is continuous on $E = \mathbb{R}$, Proposition 22 tells us that $f^{-1}(O) = E \cap U = \mathbb{R} \cap U = U$ for some open set U . Hence $f^{-1}(O)$ is open.

Inverse images of closed sets. Let C be a closed set of real numbers. By Proposition 11 the set $\mathbb{R} \sim C$ is open, so by the preceding paragraph $f^{-1}(\mathbb{R} \sim C)$ is open. But

$$f^{-1}(\mathbb{R} \sim C) = \mathbb{R} \sim f^{-1}(C),$$

so $\mathbb{R} \sim f^{-1}(C)$ is open, and therefore, again by Proposition 11, $f^{-1}(C)$ is closed.

Inverse images of Borel sets. Define

$$\mathcal{A} = \{A \subseteq \mathbb{R} : f^{-1}(A) \text{ is a Borel set}\}.$$

We claim $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$.

(i) The empty-set belongs to $\mathcal{A}$, since $f^{-1}(\emptyset) = \emptyset$, and $\emptyset$ is open, hence Borel.

(ii) If A belongs to $\mathcal{A}$, then $f^{-1}(\mathbb{R} \sim A) = \mathbb{R} \sim f^{-1}(A)$. Since $f^{-1}(A)$ is Borel and the collection $\mathcal{B}$ of Borel sets is a σ -algebra, hence closed with respect to the formation of complements, $\mathbb{R} \sim f^{-1}(A)$ is Borel. Thus $\mathbb{R} \sim A$ belongs to $\mathcal{A}$.

(iii) If $\{A_n\}_{n=1}^{\infty}$ is a countable collection of sets in $\mathcal{A}$, then

$$f^{-1}\left(\bigcup_{n=1}^{\infty} A_n\right) = \bigcup_{n=1}^{\infty} f^{-1}(A_n),$$

a countable union of Borel sets, which is Borel because $\mathcal{B}$ is closed with respect to the formation of countable unions. Thus $\bigcup_{n=1}^{\infty} A_n$ belongs to $\mathcal{A}$.

So $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$. Moreover $\mathcal{A}$ contains every open set: if O is open then, by the first paragraph, $f^{-1}(O)$ is open and hence is a Borel set, so O belongs to $\mathcal{A}$.

By definition, the collection $\mathcal{B}$ of Borel sets is the smallest σ -algebra of sets of real numbers that contains all of the open sets; by Proposition 13 this means precisely that any σ -algebra of subsets of $\mathbb{R}$ containing the open sets also contains $\mathcal{B}$. Since $\mathcal{A}$ is such a σ -algebra, $\mathcal{B} \subseteq \mathcal{A}$. That is, for every Borel set A the set $f^{-1}(A)$ is a Borel set, which is what we wished to show.

Problem 1.59. A sequence $\{f_n\}$ of real-valued functions defined on a set E is said to converge uniformly on E to a function f if given $\epsilon > 0$, there is an N such that for all $x \in E$ and all $n \geq N$, we have $|f_n(x) - f(x)| < \epsilon$. Let $\{f_n\}$ be a sequence of continuous functions defined on a set E . Prove that if $\{f_n\}$ converges uniformly to f on E , then f is continuous on E .

Solution. Let x be a point of E ; we show that f is continuous at x . Since x is an arbitrary point of the domain E , this establishes that f is continuous on E .

Let $\epsilon > 0$. Apply the definition of uniform convergence with the positive number $\epsilon/3$: there is an index N such that

$$|f_n(y) - f(y)| < \frac{\epsilon}{3} \quad \text{for all } y \in E \text{ and all } n \geq N.$$

Fix this index N . The crucial point is that the single index N works simultaneously at every point of E ; this is exactly what uniformity provides, and it is what makes the following estimate possible.

The function f_N is continuous on E , hence continuous at the point x . Therefore there is a $\delta > 0$ such

that

$$\text{if } y \in E \text{ and } |y - x| < \delta, \text{ then } |f_N(y) - f_N(x)| < \frac{\epsilon}{3}.$$

We claim this $\delta > 0$ responds to the $\epsilon > 0$ challenge regarding the criterion for the continuity of f at x . Indeed, let y belong to E with $|y - x| < \delta$. Adding and subtracting and using the triangle inequality twice,

$$\begin{aligned} |f(y) - f(x)| &= |[f(y) - f_N(y)] + [f_N(y) - f_N(x)] + [f_N(x) - f(x)]| \\ &\leq |f(y) - f_N(y)| + |f_N(y) - f_N(x)| + |f_N(x) - f(x)|. \end{aligned}$$

The first term is less than $\epsilon/3$ by the choice of N : the uniform estimate holds for every point of E and every index at least N , and here the point is $y \in E$ and the index is $n = N$. The third term is less than $\epsilon/3$ for the same reason, with the point $x \in E$. The middle term is less than $\epsilon/3$ by the choice of δ . Therefore

$$|f(y) - f(x)| < \frac{\epsilon}{3} + \frac{\epsilon}{3} + \frac{\epsilon}{3} = \epsilon.$$

Thus for each $\epsilon > 0$ there is a $\delta > 0$ for which $y \in E$ and $|y - x| < \delta$ imply $|f(y) - f(x)| < \epsilon$; that is, f is continuous at x . Since $x \in E$ was arbitrary, f is continuous on E .

Problem 1.60. Prove Proposition 21. Use this proposition and the Bolzano-Weierstrass Theorem to provide another proof of the Extreme Value Theorem.

[Proposition 21: A real-valued function f defined on a set E of real numbers is continuous at the point $x_* \in E$ if and only if whenever a sequence $\{x_n\}$ in E converges to x_* , its image sequence $\{f(x_n)\}$ converges to $f(x_*)$.]

Solution. Part 1: proof of Proposition 21.

Suppose first that f is continuous at x_* , and let $\{x_n\}$ be a sequence in E that converges to x_* . Let $\epsilon > 0$. By continuity of f at x_* there is a $\delta > 0$ such that

$$\text{if } x' \in E \text{ and } |x' - x_*| < \delta, \text{ then } |f(x') - f(x_*)| < \epsilon.$$

Since $\{x_n\} \rightarrow x_*$, applied with the positive number δ , there is an index N such that $|x_n - x_*| < \delta$ for all $n \geq N$. Each x_n belongs to E , so for all $n \geq N$ we have $|f(x_n) - f(x_*)| < \epsilon$. As $\epsilon > 0$ was arbitrary, $\{f(x_n)\} \rightarrow f(x_*)$.

Conversely, suppose f is not continuous at x_* . Negating the definition of continuity at a point, there is an $\epsilon_0 > 0$ with the property that no $\delta > 0$ responds to the ϵ_0 challenge: for every $\delta > 0$ there is a point $x' \in E$ with $|x' - x_*| < \delta$ and $|f(x') - f(x_*)| \geq \epsilon_0$. For each natural number n , apply this with $\delta = 1/n$ to select a point $x_n \in E$ with

$$|x_n - x_*| < \frac{1}{n} \quad \text{and} \quad |f(x_n) - f(x_*)| \geq \epsilon_0.$$

The sequence $\{x_n\}$ lies in E and converges to x_* : given $\epsilon > 0$, the Archimedean Property of $\mathbb{R}$ provides a natural number N with $1/N < \epsilon$, and then $|x_n - x_*| < 1/n \leq 1/N < \epsilon$ for all $n \geq N$. But $\{f(x_n)\}$ does not converge to $f(x_*)$, since no term of the sequence $\{f(x_n)\}$ lies within ϵ_0 of $f(x_*)$. Hence the sequential condition fails.

Contrapositively, if the sequential condition holds then f is continuous at x_* . This proves Proposition 21.

A lemma on closed sets. Before turning to the Extreme Value Theorem we record the following, which we use twice. If E is a closed set of real numbers, $\{x_n\}$ is a sequence in E , and $\{x_n\} \rightarrow x_*$, then $x_* \in E$. Indeed, let I be an open interval containing x_* ; choose $r > 0$ with $(x_* - r, x_* + r) \subseteq I$. Since $\{x_n\} \rightarrow x_*$ there is an index n with $|x_n - x_*| < r$, so $x_n \in I$, and $x_n \in E$. Thus every open interval containing x_* contains a point of E , that is, x_* is a point of closure of E . Since E is closed it contains all of its points of closure, so $x_* \in E$.

Part 2: another proof of the Extreme Value Theorem.

Let E be a nonempty closed, bounded set of real numbers and let f be a continuous real-valued function on E . We must show that f takes a maximum and a minimum value on E .

Claim A: $f(E)$ is bounded above. Suppose not. Then for each natural number n the number n fails to be an upper bound for $f(E)$, so we may choose $x_n \in E$ with $f(x_n) > n$. The sequence $\{x_n\}$ lies in the bounded set E and hence is bounded. By Theorem 16 (the Bolzano-Weierstrass Theorem) it has a convergent subsequence $\{x_{n_k}\}$, say $\{x_{n_k}\} \rightarrow x_*$. By the lemma, $x_* \in E$. Since f is continuous at x_* , Proposition 21 tells us that $\{f(x_{n_k})\} \rightarrow f(x_*)$, a real number. By Proposition 14, a convergent sequence of real numbers is bounded, so $\{f(x_{n_k})\}$ is bounded. But $\{n_k\}$ is a strictly increasing sequence of natural numbers, so $n_k \geq k$ for every k (an immediate induction), and therefore $f(x_{n_k}) > n_k \geq k$ for all k , which makes $\{f(x_{n_k})\}$ unbounded. This contradiction proves Claim A.

Since E is nonempty, $f(E)$ is a nonempty set of real numbers which by Claim A is bounded above. By the Completeness Axiom it has a supremum; define

$$m = \sup f(E) \in \mathbb{R}.$$

Claim B: f takes the value m . For each natural number n , the number $m - 1/n$ is smaller than m and hence is not an upper bound for $f(E)$, so we may choose $x_n \in E$ with

$$m - \frac{1}{n} < f(x_n) \leq m.$$

Again $\{x_n\}$ is a bounded sequence, so by the Bolzano-Weierstrass Theorem there is a subsequence $\{x_{n_k}\}$ converging to some real number x_* , and by the lemma $x_* \in E$. Since f is continuous at x_* , Proposition 21 gives $\{f(x_{n_k})\} \rightarrow f(x_*)$.

On the other hand $\{f(x_{n_k})\} \rightarrow m$. Indeed, let $\epsilon > 0$ and use the Archimedean Property to choose a natural number K with $1/K < \epsilon$. For $k \geq K$ we have $n_k \geq k \geq K$, so

$$|f(x_{n_k}) - m| = m - f(x_{n_k}) < \frac{1}{n_k} \leq \frac{1}{K} < \epsilon.$$

By Proposition 14 the limit of a convergent sequence is unique, so $f(x_*) = m$. Thus $f(x) \leq m = f(x_*)$ for every $x \in E$: the function f takes the maximum value m on E , attained at the point $x_* \in E$.

Finally, the function $-f$ is continuous on E (given $\epsilon > 0$, any δ that responds to the ϵ challenge for f at a point also responds for $-f$, since $|-f(x') + f(x)| = |f(x') - f(x)|$). Applying what has just been proved to $-f$, there is a point $x_{**} \in E$ with $-f(x) \leq -f(x_{**})$ for all $x \in E$, that is, $f(x_{**}) \leq f(x)$ for all $x \in E$. Hence f takes a minimum value on E , attained at x_{**} .

This completes the proof of the Extreme Value Theorem using only Proposition 21, the Bolzano-Weierstrass Theorem, Proposition 14, and the Completeness Axiom; in particular the Heine-Borel Theorem, used in the text's proof, is not needed.

2.1 Problems 2.1–2.7

Problem 2.1. In the first three problems, let m be a set function defined for all sets in a σ -algebra $\mathcal{A}$ with values in $[0, \infty]$. Assume m is countably additive over countable disjoint collections of sets in $\mathcal{A}$.

Prove that if A and B are two sets in $\mathcal{A}$ with $A \subseteq B$, then $m(A) \leq m(B)$. This property is called *monotonicity*.

Solution. Since $\mathcal{A}$ is a σ -algebra it contains $\mathbb{R}$ and is closed with respect to the formation of complements and countable unions; by De Morgan's Identities it is therefore also closed with respect to the formation of countable intersections. In particular $\emptyset = \mathbb{R} \setminus \mathbb{R}$ belongs to $\mathcal{A}$, and since

$$B \setminus A = B \cap (\mathbb{R} \setminus A),$$

the set $B \setminus A$ also belongs to $\mathcal{A}$.

Define a countable collection $\{E_k\}_{k=1}^{\infty}$ of sets in $\mathcal{A}$ by

$$E_1 = A, \quad E_2 = B \setminus A, \quad E_k = \emptyset \text{ for } k \geq 3.$$

This collection is disjoint: $E_1 \cap E_2 = A \cap (B \setminus A) = \emptyset$, and every intersection involving one of the sets E_k with $k \geq 3$ is empty because those sets are empty. Moreover, since $A \subseteq B$,

$$\bigcup_{k=1}^{\infty} E_k = A \cup (B \setminus A) = B.$$

By the assumed countable additivity of m over countable disjoint collections of sets in $\mathcal{A}$,

$$m(B) = m\left(\bigcup_{k=1}^{\infty} E_k\right) = \sum_{k=1}^{\infty} m(E_k) = m(A) + m(B \setminus A) + \sum_{k=3}^{\infty} m(\emptyset).$$

The set function m takes values in $[0, \infty]$, so every term on the right-hand side is nonnegative and the series of nonnegative terms is at least its first term. Therefore

$$m(B) \geq m(A),$$

which is the asserted monotonicity. Observe that this argument does not require knowing in advance that $m(\emptyset) = 0$; only the nonnegativity of m is used.

Problem 2.2. Let m be a set function defined for all sets in a σ -algebra $\mathcal{A}$ with values in $[0, \infty]$, and assume m is countably additive over countable disjoint collections of sets in $\mathcal{A}$. Prove that if there is a set A in the collection $\mathcal{A}$ for which $m(A) < \infty$, then $m(\emptyset) = 0$.

Solution. Since $\mathcal{A}$ is a σ -algebra it contains $\mathbb{R}$ and is closed with respect to complementation, so $\emptyset = \mathbb{R} \setminus \mathbb{R}$ belongs to $\mathcal{A}$ and $m(\emptyset)$ is defined.

Let $A \in \mathcal{A}$ satisfy $m(A) < \infty$. Define a countable collection $\{E_k\}_{k=1}^{\infty}$ of sets in $\mathcal{A}$ by

$$E_1 = A, \quad E_k = \emptyset \text{ for } k \geq 2.$$

The collection is disjoint, since the intersection of any two distinct members is empty (indeed $A \cap \emptyset = \emptyset$ and $\emptyset \cap \emptyset = \emptyset$), and its union is A . Countable additivity of m therefore gives

$$m(A) = \sum_{k=1}^{\infty} m(E_k) = m(A) + \sum_{k=2}^{\infty} m(\emptyset).$$

Suppose, to obtain a contradiction, that $m(\emptyset) = c > 0$. Then $\sum_{k=2}^{\infty} m(\emptyset) = \sum_{k=2}^{\infty} c = \infty$, so the right-hand side of the displayed identity equals ∞ , while the left-hand side equals $m(A) < \infty$. This is

a contradiction. Since m takes values in $[0, \infty]$, the only remaining possibility is

$$m(\emptyset) = 0.$$

Equivalently and without contradiction: because $m(A) < \infty$ we may subtract the finite number $m(A)$ from both sides of the identity above to obtain $\sum_{k=2}^{\infty} m(\emptyset) = 0$; a series of identical nonnegative terms vanishes only if each term is 0, so $m(\emptyset) = 0$.

The hypothesis that some set has finite measure cannot be dropped: the set function defined on all of $\mathcal{A}$ by $m(E) = \infty$ for every $E \in \mathcal{A}$, including $E = \emptyset$, is countably additive in the stated sense yet has $m(\emptyset) \neq 0$.

Problem 2.3. Let m be a set function defined for all sets in a σ -algebra $\mathcal{A}$ with values in $[0, \infty]$, and assume m is countably additive over countable disjoint collections of sets in $\mathcal{A}$. Let $\{E_k\}_{k=1}^{\infty}$ be a countable collection of sets in $\mathcal{A}$. Prove that

$$m\left(\bigcup_{k=1}^{\infty} E_k\right) \leq \sum_{k=1}^{\infty} m(E_k).$$

Solution. The strategy is to replace the collection $\{E_k\}_{k=1}^{\infty}$ by a disjoint collection with the same union, each member of which is contained in the corresponding E_k , and then to apply countable additivity together with the monotonicity established in Problem 1.

Define

$$F_1 = E_1, \quad F_k = E_k \setminus \bigcup_{j=1}^{k-1} E_j \quad \text{for } k \geq 2.$$

Each F_k belongs to $\mathcal{A}$: the union $\bigcup_{j=1}^{k-1} E_j$ is a finite, hence countable, union of members of $\mathcal{A}$ and so lies in $\mathcal{A}$; its complement lies in $\mathcal{A}$; and F_k is the intersection of E_k with that complement, which lies in $\mathcal{A}$ because a σ -algebra is closed with respect to countable intersections by De Morgan's Identities.

The collection $\{F_k\}_{k=1}^{\infty}$ is disjoint. Indeed, let $j < k$. Every point of F_k fails to belong to E_j , whereas every point of F_j belongs to E_j (since $F_j \subseteq E_j$); hence $F_j \cap F_k = \emptyset$.

The two collections have the same union. Since $F_k \subseteq E_k$ for every k , we have $\bigcup_{k=1}^{\infty} F_k \subseteq \bigcup_{k=1}^{\infty} E_k$. Conversely, let $x \in \bigcup_{k=1}^{\infty} E_k$. The set of indices k with $x \in E_k$ is a nonempty set of natural numbers, so by the Well-Ordering Principle it has a smallest member k_0 . Then $x \in E_{k_0}$ while $x \notin E_j$ for $1 \leq j < k_0$, that is, $x \in F_{k_0}$. Therefore

$$\bigcup_{k=1}^{\infty} F_k = \bigcup_{k=1}^{\infty} E_k.$$

Now apply countable additivity of m to the disjoint collection $\{F_k\}_{k=1}^{\infty}$ of sets in $\mathcal{A}$:

$$m\left(\bigcup_{k=1}^{\infty} E_k\right) = m\left(\bigcup_{k=1}^{\infty} F_k\right) = \sum_{k=1}^{\infty} m(F_k).$$

Since $F_k \subseteq E_k$ and both sets belong to $\mathcal{A}$, monotonicity (Problem 1) gives $m(F_k) \leq m(E_k)$ for each k . Comparison of series of nonnegative terms, term by term, yields

$$\sum_{k=1}^{\infty} m(F_k) \leq \sum_{k=1}^{\infty} m(E_k).$$

Combining the last two displays,

$$m\left(\bigcup_{k=1}^{\infty} E_k\right) \leq \sum_{k=1}^{\infty} m(E_k),$$

as required. This property is called *countable monotonicity* (or countable subadditivity). The corresponding statement for a finite collection $\{E_k\}_{k=1}^n$ follows by setting $E_k = \emptyset$ for $k > n$, provided $m(\emptyset) = 0$; and if instead $m(\emptyset) > 0$, then applying countable additivity to the disjoint collection $E, \emptyset, \emptyset, \dots$ shows $m(E) = \infty$ for every $E \in \mathcal{A}$, so every such inequality holds trivially.

Problem 2.4. A set function c , defined on all subsets of $\mathbb{R}$, is defined as follows. Define $c(E)$ to be ∞ if E has infinitely many members and $c(E)$ to be equal to the number of elements in E if E is finite; define $c(\emptyset) = 0$. Show that c is a countably additive and translation invariant set function. This set function is called the **counting measure**.

Solution. Throughout, for a finite set F we write $\#F$ for the number of its elements, so that $c(F) = \#F$ for finite F and $c(E) = \infty$ for infinite E . Note first the elementary monotonicity property: if $F \subseteq E$ and F is finite, then $c(E) \geq \#F$. Indeed, if E is infinite this reads $\infty \geq \#F$, and if E is finite then $\#E \geq \#F$ because a subset of a finite set has no more elements than the set.

Countable additivity. Let $\{E_k\}_{k=1}^{\infty}$ be a countable disjoint collection of subsets of $\mathbb{R}$ and put $E = \bigcup_{k=1}^{\infty} E_k$. We show

$$c(E) = \sum_{k=1}^{\infty} c(E_k).$$

First we prove $c(E) \geq \sum_{k=1}^{\infty} c(E_k)$. Since the right-hand side is the supremum of its partial sums, it suffices to show that $c(E) \geq \sum_{k=1}^n c(E_k)$ for every natural number n , and, when some $c(E_k) = \infty$, that $c(E) = \infty$. In the latter case some E_{k_0} is infinite; since $E_{k_0} \subseteq E$, the set E is infinite as well and $c(E) = \infty$, so the inequality holds. So suppose every E_k is finite and fix n . The sets $E_1, \dots, E_n$ are pairwise disjoint finite sets, so their union $F = \bigcup_{k=1}^n E_k$ is finite with

$$\#F = \sum_{k=1}^n \#E_k = \sum_{k=1}^n c(E_k),$$

the first equality being the additivity of cardinality over disjoint finite sets. Since $F \subseteq E$, the monotonicity noted above gives $c(E) \geq \#F = \sum_{k=1}^n c(E_k)$. Letting $n \rightarrow \infty$,

$$c(E) \geq \sum_{k=1}^{\infty} c(E_k).$$

Next we prove $c(E) \leq \sum_{k=1}^{\infty} c(E_k)$. If the right-hand side is ∞ there is nothing to prove, so assume $\sum_{k=1}^{\infty} c(E_k) = M < \infty$. Then each $c(E_k)$ is finite, that is, each E_k is a finite set, and M is a finite nonnegative number (in fact a nonnegative integer, since a convergent series of nonnegative integers has all but finitely many terms equal to zero). We claim E is finite with $\#E \leq M$. Suppose otherwise. Then E contains at least $M+1$ distinct points; more precisely, if E were infinite we could choose $M+1$ distinct points of E , and if E were finite with $\#E > M$ we could likewise choose $M+1$ distinct points. Call them $x_1, \dots, x_{M+1}$. Each x_i lies in E , hence in E_{k_i} for some index k_i . Let $n = \max\{k_1, \dots, k_{M+1}\}$, a finite number since only finitely many indices occur. Then the $M+1$ distinct points all lie in the finite set $\bigcup_{k=1}^n E_k$, whence, using disjointness again,

$$M+1 \leq \# \left(\bigcup_{k=1}^n E_k \right) = \sum_{k=1}^n c(E_k) \leq \sum_{k=1}^{\infty} c(E_k) = M,$$

a contradiction. Therefore E is finite and $c(E) = \#E \leq M = \sum_{k=1}^{\infty} c(E_k)$.

The two inequalities give $c(E) = \sum_{k=1}^{\infty} c(E_k)$, so c is countably additive. (In particular, taking all E_k empty is consistent with the stipulation $c(\emptyset) = 0$.)

Translation invariance. Let $E \subseteq \mathbb{R}$ and let y be a real number, and consider $E + y = \{x + y \mid x \in E\}$. The map $\tau_y : \mathbb{R} \rightarrow \mathbb{R}$ defined by $\tau_y(x) = x + y$ is a bijection of $\mathbb{R}$ onto $\mathbb{R}$, with inverse τ_{-y} , and $\tau_y(E) = E + y$. A bijection restricted to E is a one-to-one correspondence between E and $E + y$. Consequently E is finite if and only if $E + y$ is finite, and in that case $\#(E + y) = \#E$; likewise E is infinite if and only if $E + y$ is infinite. Also $\emptyset + y = \emptyset$. Examining the three clauses of the definition of c , we conclude in every case that

$$c(E + y) = c(E),$$

so c is translation invariant.

Problem 2.5. By using properties of outer measure, prove that the interval $[0, 1]$ is not countable.

Solution. We use two facts about Lebesgue outer measure m^* established in Section 2.2: the outer measure of an interval is its length (Proposition 1), and a countable set has outer measure zero (the Example preceding Proposition 1).

For completeness we recall the proof of the second fact. Let C be a countable set, enumerated as $C = \{c_k\}_{k=1}^\infty$ (a finite set is handled the same way, repeating a point). Let $\epsilon > 0$. For each natural number k define the open bounded interval

$$I_k = \left(c_k - \frac{\epsilon}{2^{k+1}}, c_k + \frac{\epsilon}{2^{k+1}}\right),$$

which has length $\epsilon/2^k$. The countable collection $\{I_k\}_{k=1}^\infty$ covers C , since $c_k \in I_k$ for each k . Hence, by the definition of outer measure as an infimum over such covers,

$$0 \leq m^*(C) \leq \sum_{k=1}^\infty \ell(I_k) = \sum_{k=1}^\infty \frac{\epsilon}{2^k} = \epsilon.$$

This inequality holds for every $\epsilon > 0$, so $m^*(C) = 0$.

Now suppose, to obtain a contradiction, that $[0, 1]$ is countable. Then by the fact just proved,

$$m^*([0, 1]) = 0.$$

On the other hand, $[0, 1]$ is an interval of length 1, so by Proposition 1,

$$m^*([0, 1]) = \ell([0, 1]) = 1 - 0 = 1.$$

Thus $0 = 1$, which is absurd. Therefore $[0, 1]$ is not countable.

(The set $[0, 1]$ is certainly not finite, so the conclusion is that $[0, 1]$ is uncountable. The same argument shows that no interval of positive length is countable.)

Problem 2.6. Let A be the set of irrational numbers in the interval $[0, 1]$. Prove that $m^*(A) = 1$.

Solution. Write $B = [0, 1] \setminus A$ for the set of rational numbers in $[0, 1]$, so that

$$[0, 1] = A \cup B.$$

The set B is countable, being a subset of the countable set $\mathbb{Q}$ of rational numbers. Hence, by the Example of Section 2.2 (a countable set has outer measure zero),

$$m^*(B) = 0.$$

By Proposition 1, the outer measure of an interval is its length, so

$$m^*([0, 1]) = \ell([0, 1]) = 1.$$

Now use the finite subadditivity of outer measure, which is the special case of Proposition 3 (countable subadditivity) obtained by taking all but finitely many sets in the collection to be empty:

$$1 = m^*([0, 1]) = m^*(A \cup B) \leq m^*(A) + m^*(B) = m^*(A) + 0 = m^*(A).$$

Therefore $m^*(A) \geq 1$.

For the reverse inequality, observe that $A \subseteq [0, 1]$, so by the monotonicity of outer measure, which follows immediately from the definition since any cover of $[0, 1]$ is a cover of A ,

$$m^*(A) \leq m^*([0, 1]) = 1.$$

Combining the two inequalities, $m^*(A) = 1$.

Thus $[0, 1]$ is the disjoint union of the rationals in $[0, 1]$, which carry outer measure 0, and the irrationals in $[0, 1]$, which carry all of the outer measure 1.

Problem 2.7. A set of real numbers is said to be a G_δ set provided it is the intersection of a countable collection of open sets. Show that for any bounded set E , there is a G_δ set G for which

$$E \subseteq G \quad \text{and} \quad m^*(G) = m^*(E).$$

Solution. Let E be a bounded set of real numbers.

Step 1: the outer measure of E is finite. Since E is bounded there is a number $M > 0$ with $E \subseteq (-M, M)$. By the monotonicity of outer measure and Proposition 1 (the outer measure of an interval is its length),

$$m^*(E) \leq m^*((-M, M)) = \ell((-M, M)) = 2M < \infty.$$

Step 2: construction of open sets of nearly minimal outer measure containing E . Fix a natural number n . By the definition of $m^*(E)$ as the infimum of the sums $\sum_{k=1}^{\infty} \ell(I_k)$ taken over all countable collections $\{I_k\}_{k=1}^{\infty}$ of nonempty open, bounded intervals that cover E , and since $m^*(E)$ is finite so that $m^*(E) + 1/n$ is not a lower bound for these sums, there is such a collection $\{I_{n,k}\}_{k=1}^{\infty}$ with

$$E \subseteq \bigcup_{k=1}^{\infty} I_{n,k} \quad \text{and} \quad \sum_{k=1}^{\infty} \ell(I_{n,k}) < m^*(E) + \frac{1}{n}.$$

Define

$$\mathcal{O}_n = \bigcup_{k=1}^{\infty} I_{n,k}.$$

Then $\mathcal{O}_n$ is open, being a union of open intervals, and $E \subseteq \mathcal{O}_n$. Moreover, by the countable subadditivity of outer measure (Proposition 3) together with Proposition 1,

$$m^*(\mathcal{O}_n) \leq \sum_{k=1}^{\infty} m^*(I_{n,k}) = \sum_{k=1}^{\infty} \ell(I_{n,k}) < m^*(E) + \frac{1}{n}.$$

Step 3: intersection of the open sets. Define

$$G = \bigcap_{n=1}^{\infty} \mathcal{O}_n.$$

As the intersection of a countable collection of open sets, G is a G_δ set. Since $E \subseteq \mathcal{O}_n$ for every n , we have $E \subseteq G$.

Step 4: equality of the outer measures. By monotonicity of outer measure, $E \subseteq G$ gives

$$m^*(E) \leq m^*(G).$$

On the other hand, for each natural number n we have $G \subseteq \mathcal{O}_n$, so monotonicity and Step 2 give

$$m^*(G) \leq m^*(\mathcal{O}_n) < m^*(E) + \frac{1}{n}.$$

Thus $m^*(E) \leq m^*(G) < m^*(E) + 1/n$ for every natural number n . Letting $n \rightarrow \infty$ (equivalently, since $m^*(G) - m^*(E)$ is a nonnegative number smaller than every $1/n$, it must be zero; here finiteness of $m^*(E)$ from Step 1 permits the subtraction), we conclude

$$m^*(G) = m^*(E).$$

Hence G is a G_δ set with $E \subseteq G$ and $m^*(G) = m^*(E)$, as required.

Remark. Boundedness of E was used only to guarantee $m^*(E) < \infty$. If E is any set with $m^*(E) = \infty$, one may simply take $G = \mathbb{R}$, which is open and hence a G_δ set, and then $m^*(G) = \infty = m^*(E)$ by monotonicity. So the conclusion in fact holds for every set of real numbers.

2.2 Problems 2.8–2.14

Problem 2.8. Let B be the set of rational numbers in the interval $[0, 1]$, and let $\{I_k\}_{k=1}^n$ be a finite collection of open intervals that covers B . Prove that $\sum_{k=1}^n m^*(I_k) \geq 1$.

Solution. If some I_k is unbounded then $m^*(I_k) = \infty$ by Proposition 1 (the outer measure of an interval is its length), and the asserted inequality is trivial. So assume every I_k is a bounded open interval, say $I_k = (a_k, b_k)$ with $a_k \leq b_k$.

The essential point is that the finiteness of the collection lets us pass to closures. Write $\bar{S}$ for the closure of a set S . For a finite family of sets the closure of the union is the union of the closures:

$$\overline{\bigcup_{k=1}^n I_k} = \bigcup_{k=1}^n \bar{I}_k.$$

Indeed, $\bigcup_{k=1}^n \bar{I}_k$ is a finite union of closed sets, hence closed, and it contains $\bigcup_{k=1}^n I_k$; therefore it contains the closure of that union. Conversely each $\bar{I}_k$ is contained in the closure of the union by monotonicity of closure. (This is exactly where finiteness is used: an infinite union of closed sets need not be closed.)

Now $B \subseteq \bigcup_{k=1}^n I_k$ by hypothesis, so

$$[0, 1] = \bar{B} \subseteq \overline{\bigcup_{k=1}^n I_k} = \bigcup_{k=1}^n \bar{I}_k,$$

the first equality holding because the rationals in $[0, 1]$ are dense in $[0, 1]$: every point of $[0, 1]$ is a limit of rationals lying in $[0, 1]$, and $[0, 1]$ is closed, so $\bar{B} = [0, 1]$.

Apply monotonicity of outer measure and then finite subadditivity (the finite form of Proposition 3):

$$1 = m^*([0, 1]) \leq m^*\left(\bigcup_{k=1}^n \bar{I}_k\right) \leq \sum_{k=1}^n m^*(\bar{I}_k).$$

Here $m^*([0, 1]) = \ell([0, 1]) = 1$ by Proposition 1. Finally, $\bar{I}_k = [a_k, b_k]$ is a closed bounded interval of length $b_k - a_k = \ell(I_k)$, so by Proposition 1 again

$$m^*(\bar{I}_k) = \ell(\bar{I}_k) = \ell(I_k) = m^*(I_k).$$

(If I_k is empty this reads $0 = 0$.) Substituting,

$$1 \leq \sum_{k=1}^n m^*(I_k),$$

which is the desired inequality.

A remark on why the hypothesis of finiteness cannot be dropped: B is countable, say $B = \{q_1, q_2, \dots\}$, and for any $\epsilon > 0$ the countable collection $I_k = (q_k - \epsilon/2^{k+1}, q_k + \epsilon/2^{k+1})$ is a collection of open intervals covering B with $\sum_{k=1}^{\infty} \ell(I_k) = \epsilon$. Thus $m^*(B) = 0$, and the conclusion $\sum_k m^*(I_k) \geq 1$ genuinely depends on the cover being finite.

Problem 2.9. Prove that if $m^*(A) = 0$, then $m^*(A \cup B) = m^*(B)$.

Solution. Both inequalities are immediate from the basic properties of outer measure established in Section 2.2.

First, $B \subseteq A \cup B$, so by the monotonicity of outer measure

$$m^*(B) \leq m^*(A \cup B).$$

Monotonicity holds because every countable collection of open bounded intervals covering $A \cup B$ also covers B , so the infimum defining $m^*(B)$ is taken over a larger collection of admissible sums than the infimum defining $m^*(A \cup B)$.

Second, by the finite subadditivity of outer measure (the finite form of Proposition 3, obtained by taking $E_1 = A$, $E_2 = B$ and $E_k = \emptyset$ for $k > 2$),

$$m^*(A \cup B) \leq m^*(A) + m^*(B) = 0 + m^*(B) = m^*(B).$$

Combining the two displays gives $m^*(A \cup B) = m^*(B)$. Note that the argument is valid whether $m^*(B)$ is finite or infinite: if $m^*(B) = \infty$ the first inequality already forces $m^*(A \cup B) = \infty$.

Problem 2.10. Let A and B be bounded sets for which there is an $\alpha > 0$ such that $|a - b| \geq \alpha$ for all $a \in A$, $b \in B$. Prove that $m^*(A \cup B) = m^*(A) + m^*(B)$.

Solution. The inequality $m^*(A \cup B) \leq m^*(A) + m^*(B)$ is finite subadditivity (Proposition 3), and requires no hypothesis. The content of the problem is the reverse inequality, and the separation hypothesis is what supplies it. Since $A \cup B$ is bounded it is contained in some bounded interval, so $m^*(A \cup B) < \infty$ by monotonicity and Proposition 1.

Step 1 (a subdivision lemma). Let I be a nonempty bounded open interval, and let $\eta > 0$. Then there are finitely many open intervals $J_1, \dots, J_N$, each of length less than α , such that

$$I \subseteq \bigcup_{i=1}^N J_i \quad \text{and} \quad \sum_{i=1}^N \ell(J_i) < \ell(I) + \eta.$$

To see this, write $I = (c, d)$ and $L = d - c > 0$. Choose a natural number N with $L/N < \alpha/2$, put $h = L/N$ and $t_i = c + ih$ for $i = 0, 1, \dots, N$, so that $t_0 = c$, $t_N = d$ and $\bigcup_{i=1}^N [t_{i-1}, t_i] = [c, d]$. Choose

$$\delta = \min \left\{ \frac{\alpha}{8}, \frac{\eta}{4N} \right\} > 0$$

and set $J_i = (t_{i-1} - \delta, t_i + \delta)$. Then $I \subseteq [c, d] \subseteq \bigcup_{i=1}^N J_i$; each J_i has length $h + 2\delta < \alpha/2 + \alpha/4 < \alpha$; and

$$\sum_{i=1}^N \ell(J_i) = Nh + 2N\delta = L + 2N\delta \leq \ell(I) + \frac{\eta}{2} < \ell(I) + \eta.$$

Step 2 (refining an arbitrary cover). Let $\epsilon > 0$. By the definition of outer measure there is a countable collection $\{I_k\}_{k=1}^\infty$ of open bounded intervals with

$$A \cup B \subseteq \bigcup_{k=1}^\infty I_k \quad \text{and} \quad \sum_{k=1}^\infty \ell(I_k) < m^*(A \cup B) + \epsilon.$$

Discard any empty I_k . For each k apply Step 1 with $\eta = \epsilon/2^k$ to obtain finitely many open intervals $\{J_{k,1}, \dots, J_{k,N_k}\}$, each of length less than α , which cover I_k and satisfy $\sum_{i=1}^{N_k} \ell(J_{k,i}) < \ell(I_k) + \epsilon/2^k$. The collection $\mathcal{J} = \{J_{k,i} : k \geq 1, 1 \leq i \leq N_k\}$ is countable (a countable union of finite collections), consists of open bounded intervals each of length less than α , covers $\bigcup_k I_k$ and hence covers $A \cup B$, and satisfies

$$\sum_{J \in \mathcal{J}} \ell(J) < \sum_{k=1}^\infty \left(\ell(I_k) + \frac{\epsilon}{2^k} \right) < m^*(A \cup B) + 2\epsilon.$$

Step 3 (splitting the refined cover). If J is an interval with $\ell(J) < \alpha$, then any two points $x, y \in J$ satisfy $|x - y| \leq \ell(J) < \alpha$. Consequently no member of $\mathcal{J}$ can meet both A and B : if $a \in A \cap J$ and $b \in B \cap J$ we would get $|a - b| < \alpha$, contradicting the hypothesis $|a - b| \geq \alpha$.

Therefore we may split $\mathcal{J}$ into two disjoint subcollections

$$\mathcal{J}_A = \{J \in \mathcal{J} : J \cap A \neq \emptyset\}, \quad \mathcal{J}_B = \mathcal{J} \setminus \mathcal{J}_A,$$

and every $J \in \mathcal{J}$ that meets B lies in $\mathcal{J}_B$, by the previous paragraph. Since $\mathcal{J}$ covers A , and a member of $\mathcal{J}$ contributes a point of A only if it meets A , the subcollection $\mathcal{J}_A$ covers A ; likewise $\mathcal{J}_B$ contains every member of $\mathcal{J}$ meeting B and hence covers B . Both subcollections are countable collections of open bounded intervals, so by the definition of outer measure

$$m^*(A) \leq \sum_{J \in \mathcal{J}_A} \ell(J), \quad m^*(B) \leq \sum_{J \in \mathcal{J}_B} \ell(J).$$

(If one of the subcollections is empty, the corresponding set is empty and its outer measure is 0, so the inequality still holds.)

Step 4 (conclusion). Since $\mathcal{J}_A$ and $\mathcal{J}_B$ are disjoint subcollections of $\mathcal{J}$ and all terms are nonnegative,

$$m^*(A) + m^*(B) \leq \sum_{J \in \mathcal{J}_A} \ell(J) + \sum_{J \in \mathcal{J}_B} \ell(J) = \sum_{J \in \mathcal{J}} \ell(J) < m^*(A \cup B) + 2\epsilon.$$

This holds for every $\epsilon > 0$, so $m^*(A) + m^*(B) \leq m^*(A \cup B)$. Together with subadditivity,

$$m^*(A \cup B) = m^*(A) + m^*(B).$$

Problem 2.11. Prove that if a σ -algebra of subsets of $\mathbb{R}$ contains intervals of the form (a, ∞) , then it contains all intervals.

Solution. Let $\mathcal{A}$ be a σ -algebra of subsets of $\mathbb{R}$ with $(a, \infty) \in \mathcal{A}$ for every $a \in \mathbb{R}$. Recall that a σ -algebra contains $\emptyset$ and $\mathbb{R}$, is closed under complements and under countable unions, and hence, by De Morgan's Identities, is also closed under countable intersections: if $\{E_k\}_{k=1}^\infty \subseteq \mathcal{A}$ then

$$\bigcap_{k=1}^\infty E_k = \left(\bigcup_{k=1}^\infty E_k^C \right)^C \in \mathcal{A}.$$

Being closed under countable unions and intersections, $\mathcal{A}$ is in particular closed under finite unions and intersections (pad a finite family with $\emptyset$ or with $\mathbb{R}$).

We build up all interval types in turn. Fix real numbers $a < b$.

Rays of the form $(-\infty, a]$. Since $(a, \infty) \in \mathcal{A}$ and $(-\infty, a] = (a, \infty)^C$, closure under complements gives $(-\infty, a] \in \mathcal{A}$.

Rays of the form $[a, \infty)$. Observe that

$$[a, \infty) = \bigcap_{n=1}^\infty \left(a - \frac{1}{n}, \infty \right).$$

Indeed, if $x \geq a$ then $x > a - 1/n$ for every n ; conversely if $x > a - 1/n$ for every n then letting $n \rightarrow \infty$ gives $x \geq a$. Each set on the right lies in $\mathcal{A}$, and $\mathcal{A}$ is closed under countable intersections, so $[a, \infty) \in \mathcal{A}$.

Rays of the form $(-\infty, a)$. This is $[a, \infty)^C$, hence in $\mathcal{A}$.

Bounded intervals. Using closure under finite intersections,

$$\begin{aligned} (a, b) &= (a, \infty) \cap (-\infty, b), & [a, b] &= [a, \infty) \cap (-\infty, b], \\ [a, b) &= [a, \infty) \cap (-\infty, b), & (a, b] &= (a, \infty) \cap (-\infty, b], \end{aligned}$$

and all four right-hand sides are intersections of two members of $\mathcal{A}$. Hence every bounded interval with endpoints $a < b$, of any of the four types, belongs to $\mathcal{A}$.

Degenerate intervals. The empty set is in $\mathcal{A}$ by definition of a σ -algebra, and a singleton is

$$\{a\} = [a, \infty) \cap (-\infty, a] \in \mathcal{A}.$$

The whole line and half-lines already covered. We have $\mathbb{R} \in \mathcal{A}$, and the four unbounded types (a, ∞) , $[a, \infty)$, $(-\infty, a)$, $(-\infty, a]$ were treated above.

Every interval of real numbers is of one of the listed forms: it is empty, a singleton, a bounded interval with two distinct endpoints (open, closed, or half-open), a half-line of one of the four types, or all of $\mathbb{R}$. Therefore $\mathcal{A}$ contains all intervals.

Problem 2.12. Show that every interval is a Borel set.

Solution. Recall the definition given in Section 2.3: the Borel σ -algebra $\mathcal{B}$ is the intersection of all the σ -algebras of subsets of $\mathbb{R}$ that contain the open sets, and its members are the Borel sets. Two facts follow immediately from this definition.

First, $\mathcal{B}$ really is a σ -algebra. An intersection of a family of σ -algebras of subsets of $\mathbb{R}$ is again a σ -algebra: $\emptyset$ and $\mathbb{R}$ belong to every member of the family and hence to the intersection; if E belongs to the intersection then E^C belongs to each σ -algebra in the family and hence to the intersection; and if $\{E_k\}_{k=1}^\infty$ lies in the intersection then $\bigcup_k E_k$ lies in each σ -algebra of the family and hence in the intersection. (The family is nonempty, since the collection of all subsets of $\mathbb{R}$ is a σ -algebra containing the open sets.)

Second, $\mathcal{B}$ contains every open set, since every σ -algebra in the defining family does.

Now let $a \in \mathbb{R}$. The ray (a, ∞) is an open subset of $\mathbb{R}$: if $x > a$, then with $r = x - a > 0$ we have $(x - r, x + r) \subseteq (a, \infty)$. Hence $(a, \infty) \in \mathcal{B}$ for every real a .

So $\mathcal{B}$ is a σ -algebra of subsets of $\mathbb{R}$ containing every interval of the form (a, ∞) . By Problem 11 of this chapter, $\mathcal{B}$ contains all intervals. That is, every interval is a Borel set.

(For completeness, this also recovers part of Theorem 9: since the measurable sets form a σ -algebra containing all the open sets, $\mathcal{B} \subseteq \mathcal{M}$, so every interval is measurable as well.)

Problem 2.13. Show that (i) the translate of an F_σ set is also F_σ , (ii) the translate of a G_δ set is also G_δ , and (iii) the translate of a set of measure zero also has measure zero.

Solution. Throughout, for a set $E \subseteq \mathbb{R}$ and $y \in \mathbb{R}$ we write $E + y = \{x + y : x \in E\}$, and we use the elementary equivalence

$$x \in E + y \iff x - y \in E.$$

From this equivalence, translation commutes with arbitrary unions and intersections: for any family $\{E_\lambda\}$,

$$\left(\bigcup_\lambda E_\lambda\right) + y = \bigcup_\lambda (E_\lambda + y), \quad \left(\bigcap_\lambda E_\lambda\right) + y = \bigcap_\lambda (E_\lambda + y),$$

since in each case x belongs to the left-hand side if and only if $x - y$ belongs to some (respectively, to every) E_λ , which is exactly membership in the right-hand side.

We also record two topological facts.

The translate of an open set is open. Let $\mathcal{O}$ be open and $x \in \mathcal{O} + y$. Then $x - y \in \mathcal{O}$, so there is $r > 0$ with $(x - y - r, x - y + r) \subseteq \mathcal{O}$. Then $(x - r, x + r) \subseteq \mathcal{O} + y$, since $|t - x| < r$ implies $|(t - y) - (x - y)| < r$, so $t - y \in \mathcal{O}$. Hence $\mathcal{O} + y$ is open.

The translate of a closed set is closed. If C is closed then C^C is open, and complementation commutes with translation: $x \in (C + y)^C$ if and only if $x - y \notin C$, i.e. $x - y \in C^C$, i.e. $x \in C^C + y$. So $(C + y)^C = C^C + y$ is open by the previous paragraph, and therefore $C + y$ is closed.

(i) Let F be an F_σ set, that is, $F = \bigcup_{k=1}^\infty C_k$ with each C_k closed. Then

$$F + y = \left(\bigcup_{k=1}^\infty C_k\right) + y = \bigcup_{k=1}^\infty (C_k + y),$$

and each $C_k + y$ is closed. Thus $F + y$ is a countable union of closed sets, i.e. an F_σ set.

(ii) Let G be a G_δ set, that is, $G = \bigcap_{k=1}^\infty \mathcal{O}_k$ with each $\mathcal{O}_k$ open. Then

$$G + y = \left(\bigcap_{k=1}^\infty \mathcal{O}_k\right) + y = \bigcap_{k=1}^\infty (\mathcal{O}_k + y),$$

and each $\mathcal{O}_k + y$ is open. Thus $G + y$ is a countable intersection of open sets, i.e. a G_δ set.

(iii) Suppose $m^*(E) = 0$. By Proposition 2, outer measure is translation invariant, so

$$m^*(E + y) = m^*(E) = 0.$$

By Proposition 4 a set of outer measure zero is measurable, so $E + y$ is measurable with measure $m(E + y) = 0$. (Alternatively, one may argue directly, as in the proof of Proposition 2: if $\{I_k\}$ is a countable collection of open bounded intervals covering E with $\sum_k \ell(I_k) < \epsilon$, then $\{I_k + y\}$ is a countable collection of open bounded intervals covering $E + y$ with the same total length, since $I_k + y$ is an open interval of the same length as I_k . Hence $m^*(E + y) < \epsilon$ for every $\epsilon > 0$.)

Problem 2.14. Show that if a set E has positive outer measure, then there is a bounded subset of E that also has positive outer measure.

Solution. Let $E \subseteq \mathbb{R}$ with $m^*(E) > 0$. For each natural number n define

$$E_n = E \cap [-n, n].$$

Each E_n is a subset of E and is bounded, being contained in $[-n, n]$. Moreover

$$E = \bigcup_{n=1}^{\infty} E_n,$$

since every real number $x \in E$ satisfies $|x| \leq n$ for some natural number n (by the Archimedean property of $\mathbb{R}$), and hence lies in E_n ; the reverse inclusion is clear because each $E_n \subseteq E$.

Suppose, for the sake of contradiction, that every bounded subset of E had outer measure zero. In particular $m^*(E_n) = 0$ for every n . By the countable subadditivity of outer measure (Proposition 3),

$$m^*(E) = m^*\left(\bigcup_{n=1}^{\infty} E_n\right) \leq \sum_{n=1}^{\infty} m^*(E_n) = \sum_{n=1}^{\infty} 0 = 0.$$

Since outer measure is nonnegative, this gives $m^*(E) = 0$, contradicting the hypothesis $m^*(E) > 0$.

Therefore $m^*(E_n) > 0$ for at least one natural number n , and this E_n is a bounded subset of E with positive outer measure.

One can say slightly more: the sets E_n increase to E , and by monotonicity $m^*(E_1) \leq m^*(E_2) \leq \dots \leq m^*(E)$. The argument above shows the limit of this increasing sequence cannot be 0 when $m^*(E) > 0$; thus in fact, if N is an index with $m^*(E_N) > 0$, then $m^*(E_n) \geq m^*(E_N) > 0$ for every $n \geq N$. Note also that the same reasoning works with any countable collection of bounded sets whose union is $\mathbb{R}$ in place of $\{[-n, n]\}_{n=1}^{\infty}$.

2.3 Problems 2.15–2.21

Problem 2.15. Show that if E has finite measure and $\epsilon > 0$, then E is the disjoint union of a finite number of measurable sets, each of which has measure at most ϵ .

Solution. Let E be measurable with $m(E) = m^*(E) < \infty$ and let $\epsilon > 0$.

Slice E by the half-open intervals of length ϵ . For $k \in \mathbb{Z}$ put

$$A_k = E \cap (k\epsilon, (k+1)\epsilon].$$

Each half-open interval is measurable (Proposition 8 gives measurability of every interval; alternatively $(k\epsilon, (k+1)\epsilon] = (k\epsilon, (k+1)\epsilon) \cup \{(k+1)\epsilon\}$ and singletons have outer measure zero, hence are measurable by Proposition 4), so each A_k is measurable, being the intersection of two measurable sets. The intervals $(k\epsilon, (k+1)\epsilon]$, $k \in \mathbb{Z}$, are pairwise disjoint and their union is all of $\mathbb{R}$; hence the sets A_k are pairwise disjoint and

$$E = \bigcup_{k \in \mathbb{Z}} A_k.$$

By monotonicity of outer measure and Proposition 1,

$$m(A_k) \leq m^*((k\epsilon, (k+1)\epsilon]) = \epsilon \quad \text{for every } k.$$

Since $\mathbb{Z}$ is countably infinite, fix a bijection $\varphi: \mathbb{N} \rightarrow \mathbb{Z}$ and put $B_k = A_{\varphi(k)}$ for each natural number k . Then $\{B_k\}_{k=1}^{\infty}$ is a countable disjoint collection of measurable sets whose union is E , and $m(B_k) \leq \epsilon$ for every k . I claim

$$\sum_{k=1}^{\infty} m(B_k) \leq m(E) < \infty.$$

Indeed, fix n . Applying Proposition 6 with $A = \mathbb{R}$ to the finite disjoint collection $\{B_k\}_{k=1}^n$ of measurable sets gives

$$\sum_{k=1}^n m^*(B_k) = m^*\left(\bigcup_{k=1}^n B_k\right) \leq m^*(E),$$

the last inequality by monotonicity, since $\bigcup_{k=1}^n B_k \subseteq E$. The bound $m^*(E)$ does not depend on n , so the series of nonnegative terms converges and its sum is at most $m(E) < \infty$.

Since the series converges, choose a natural number N so large that

$$\sum_{k=N+1}^{\infty} m(B_k) \leq \epsilon.$$

Define

$$C = \bigcup_{k=N+1}^{\infty} B_k.$$

Then C is measurable, being a countable union of measurable sets (Proposition 7), and by the countable subadditivity of outer measure (Proposition 3),

$$m(C) = m^*(C) \leq \sum_{k=N+1}^{\infty} m(B_k) \leq \epsilon.$$

Finally,

$$E = B_1 \cup B_2 \cup \cdots \cup B_N \cup C$$

is a disjoint union of finitely many measurable sets: the B_k are pairwise disjoint by construction, and C is disjoint from each of $B_1, \dots, B_N$ because it is the union of the remaining members of that disjoint collection. Each of these $N+1$ sets has measure at most ϵ , since $m(B_k) \leq \epsilon$ for every k and $m(C) \leq \epsilon$. This is the required decomposition.

Problem 2.16. Complete the proof of Theorem 11 by showing that measurability is equivalent to (iii) and also equivalent to (iv).

Solution. Recall the four assertions of Theorem 11 for a set E of real numbers:

- (i) for each $\epsilon > 0$ there is an open set $\mathcal{O}$ containing E for which $m^*(\mathcal{O} \setminus E) < \epsilon$;
- (ii) there is a G_δ set G containing E for which $m^*(G \setminus E) = 0$;
- (iii) for each $\epsilon > 0$ there is a closed set F contained in E for which $m^*(E \setminus F) < \epsilon$;
- (iv) there is an F_σ set F contained in E for which $m^*(E \setminus F) = 0$.

The text established that measurability of E is equivalent to (i) and to (ii). We deduce the remaining two equivalences by complementation, using three facts: a set is measurable if and only if its complement is measurable (immediate from the Carathéodory definition, which is symmetric in E and E^C); a set is open if and only if its complement is closed; and a set is F_σ if and only if its complement is G_δ (De Morgan's Identities, since a countable union of closed sets has as complement the countable intersection of their open complements, and conversely).

The computational heart of the argument is the following identity. Let A and B be sets with $B = A^C$. If $F = \mathcal{O}^C$, then

$$\mathcal{O} \setminus A = \mathcal{O} \cap A^C = F^C \cap B = B \cap F^C = B \setminus F.$$

So passing to complements interchanges an “outer” difference for A with an “inner” difference for

$B = A^C$, and the two differences are literally the same set. We use this repeatedly.

Measurability is equivalent to (iii).

Suppose first that E is measurable. Then E^C is measurable, so by the already proved equivalence of measurability with (i), applied to the set E^C : given $\epsilon > 0$ there is an open set $\mathcal{O}$ with $E^C \subseteq \mathcal{O}$ and $m^*(\mathcal{O} \sim E^C) < \epsilon$. Put $F = \mathcal{O}^C$. Then F is closed, and $E^C \subseteq \mathcal{O}$ gives $F = \mathcal{O}^C \subseteq E$. Moreover, by the identity above (with $A = E^C$, $B = E$),

$$\mathcal{O} \sim E^C = \mathcal{O} \cap E = E \cap F^C = E \sim F,$$

so $m^*(E \sim F) < \epsilon$. Thus (iii) holds.

Conversely, suppose (iii) holds for E . Let $\epsilon > 0$ and choose a closed set $F \subseteq E$ with $m^*(E \sim F) < \epsilon$. Put $\mathcal{O} = F^C$. Then $\mathcal{O}$ is open and $F \subseteq E$ gives $E^C \subseteq F^C = \mathcal{O}$. Again

$$\mathcal{O} \sim E^C = \mathcal{O} \cap E = E \cap F^C = E \sim F,$$

so $m^*(\mathcal{O} \sim E^C) < \epsilon$. As $\epsilon > 0$ was arbitrary, E^C satisfies (i) and is therefore measurable; hence E is measurable.

Measurability is equivalent to (iv).

Suppose E is measurable. Then E^C is measurable, so by the equivalence of measurability with (ii), applied to E^C , there is a G_δ set G containing E^C with $m^*(G \sim E^C) = 0$. Put $F = G^C$. Then F is an F_σ set, $E^C \subseteq G$ gives $F \subseteq E$, and

$$G \sim E^C = G \cap E = E \cap F^C = E \sim F,$$

so $m^*(E \sim F) = 0$. Thus (iv) holds.

Conversely, suppose (iv) holds for E : there is an F_σ set $F \subseteq E$ with $m^*(E \sim F) = 0$. Put $G = F^C$, a G_δ set. From $F \subseteq E$ we get $E^C \subseteq G$, and as computed above $G \sim E^C = E \sim F$, so $m^*(G \sim E^C) = 0$. Hence E^C satisfies (ii) and is measurable, and therefore E is measurable.

(Alternatively, for this last step one may argue directly, without complementation: with $F \subseteq E$ an F_σ set for which $m^*(E \sim F) = 0$, the set $E \sim F$ has outer measure zero and so is measurable by Proposition 4, while F is measurable by Theorem 9, since every F_σ set is a Borel set. Hence

$$E = F \cup [E \sim F]$$

is measurable, being the union of two measurable sets, by Proposition 5.)

Problem 2.17. Show that a set E is measurable if and only if for each $\epsilon > 0$, there is a closed set F and open set $\mathcal{O}$ for which $F \subseteq E \subseteq \mathcal{O}$ and $m^*(\mathcal{O} \sim F) < \epsilon$.

Solution. Suppose E is measurable. Let $\epsilon > 0$. By assertion (i) of Theorem 11 there is an open set $\mathcal{O}$ containing E with

$$m^*(\mathcal{O} \sim E) < \epsilon/2,$$

and by assertion (iii) of Theorem 11 (proved in Problem 16) there is a closed set F contained in E with

$$m^*(E \sim F) < \epsilon/2.$$

Then $F \subseteq E \subseteq \mathcal{O}$. I claim

$$\mathcal{O} \sim F = [\mathcal{O} \sim E] \cup [E \sim F].$$

Indeed, if $x \in \mathcal{O} \sim F$ then $x \in \mathcal{O}$ and $x \notin F$; either $x \notin E$, in which case $x \in \mathcal{O} \sim E$, or $x \in E$, in which case $x \in E \sim F$. Conversely $\mathcal{O} \sim E \subseteq \mathcal{O} \sim F$ because $F \subseteq E$, and $E \sim F \subseteq \mathcal{O} \sim F$ because $E \subseteq \mathcal{O}$. Hence, by the countable (in particular finite) subadditivity of outer measure, Proposition 3,

$$m^*(\mathcal{O} \sim F) \leq m^*(\mathcal{O} \sim E) + m^*(E \sim F) < \epsilon/2 + \epsilon/2 = \epsilon.$$

Conversely, suppose that for each $\epsilon > 0$ there are a closed F and an open $\mathcal{O}$ with $F \subseteq E \subseteq \mathcal{O}$ and $m^*(\mathcal{O} \sim F) < \epsilon$. Fix $\epsilon > 0$ and take such F and $\mathcal{O}$. Since $F \subseteq E$,

$$\mathcal{O} \sim E = \mathcal{O} \cap E^C \subseteq \mathcal{O} \cap F^C = \mathcal{O} \sim F,$$

so by the monotonicity of outer measure

$$m^*(\mathcal{O} \sim E) \leq m^*(\mathcal{O} \sim F) < \epsilon.$$

Thus for each $\epsilon > 0$ there is an open set $\mathcal{O}$ containing E with $m^*(\mathcal{O} \sim E) < \epsilon$; that is, E satisfies assertion (i) of Theorem 11, and therefore E is measurable.

(One could equally well have used the inner half of the hypothesis in the converse: $E \sim F \subseteq \mathcal{O} \sim F$ gives $m^*(E \sim F) < \epsilon$, which is assertion (iii) of Theorem 11 and again forces E to be measurable.)

Problem 2.18. Let E have finite outer measure. Show that there is an F_σ set F and a G_δ set G such that

$$F \subseteq E \subseteq G \quad \text{and} \quad m^*(F) = m^*(E) = m^*(G).$$

Solution. A word on the hypotheses before the proof. The G_δ half of the conclusion holds for every set of finite outer measure. The F_σ half does not: as the Remark at the end shows, it holds precisely for the measurable sets, so the exercise is to be read within the standing context of this section, namely for a measurable set E of finite outer measure. We prove each half under the hypothesis it actually needs.

The outer half, for an arbitrary set E of finite outer measure. Let k be a natural number. Since $m^*(E) < \infty$, by the definition of outer measure there is a countable collection $\{I_j^k\}_{j=1}^\infty$ of open, bounded intervals covering E with

$$\sum_{j=1}^\infty \ell(I_j^k) < m^*(E) + 1/k.$$

Set $\mathcal{O}_k = \bigcup_{j=1}^\infty I_j^k$, an open set containing E . By the definition of outer measure (or by Propositions 1 and 3),

$$m^*(\mathcal{O}_k) \leq \sum_{j=1}^\infty \ell(I_j^k) < m^*(E) + 1/k.$$

Define $G = \bigcap_{k=1}^\infty \mathcal{O}_k$. Then G is a G_δ set, $E \subseteq G$, and for every k , by monotonicity, $m^*(G) \leq m^*(\mathcal{O}_k) < m^*(E) + 1/k$. Letting $k \rightarrow \infty$ gives $m^*(G) \leq m^*(E)$, while $E \subseteq G$ gives $m^*(E) \leq m^*(G)$. Hence $m^*(G) = m^*(E)$. This half used nothing about E beyond $m^*(E) < \infty$.

The inner half. Assume E is measurable (see the remark below, which shows this hypothesis cannot be dropped). By assertion (iv) of Theorem 11 (proved in Problem 16) there is an F_σ set F contained in E with $m^*(E \sim F) = 0$. Since $E = F \cup [E \sim F]$, the countable subadditivity of outer measure (Proposition 3) gives

$$m^*(E) \leq m^*(F) + m^*(E \sim F) = m^*(F),$$

while monotonicity gives $m^*(F) \leq m^*(E)$ because $F \subseteq E$. Hence $m^*(F) = m^*(E)$.

Combining the two halves: for measurable E of finite outer measure there are an F_σ set F and a G_δ set G with $F \subseteq E \subseteq G$ and $m^*(F) = m^*(E) = m^*(G)$.

Remark: measurability is exactly what is needed. The conclusion is in fact equivalent to the measurability of E , so it fails for every nonmeasurable set of finite outer measure.

First, suppose that for a set E with $m^*(E) < \infty$ there are an F_σ set F and a G_δ set G with $F \subseteq E \subseteq G$ and $m^*(F) = m^*(E) = m^*(G)$. Both F and G are Borel sets, hence measurable by Theorem 9, and $m(F) = m^*(E) < \infty$. Since F is a measurable set of finite outer measure contained in G , the excision property (7) gives

$$m^*(G \sim F) = m^*(G) - m^*(F) = 0.$$

Now $E \sim F \subseteq G \sim F$, so by monotonicity $m^*(E \sim F) = 0$, and therefore $E \sim F$ is measurable by Proposition 4. Consequently

$$E = F \cup [E \sim F]$$

is measurable by Proposition 5.

Second, a concrete failure for a nonmeasurable set. This part draws on Section 2.6, which lies ahead of the present section; nothing in the proof above depends on it. Let $V \subseteq [0, 1]$ be a choice set for the rational equivalence relation on $[0, 1]$, that is, a set consisting of exactly one member of each rational equivalence class of $[0, 1]$; such a set exists by the Axiom of Choice, as in Section 2.6, and $m^*(V) \leq 1 < \infty$. Let Λ be the set of rational numbers in $[-1, 1]$, a bounded, countably infinite set. If $x \in [0, 1]$, then by the second characteristic property of a choice set there is a $c \in V$ with $x = c + q$ for some rational q , and $q = x - c \in [-1, 1]$ since both x and c lie in $[0, 1]$; hence

$$[0, 1] \subseteq \bigcup_{\lambda \in \Lambda} [\lambda + V].$$

By countable subadditivity (Proposition 3), the translation invariance of outer measure (Proposition 2), and Proposition 1, $1 = m^*([0, 1]) \leq \sum_{\lambda \in \Lambda} m^*(V)$, which forces $m^*(V) > 0$. On the other hand, let F_0 be any closed subset of V . Then F_0 is bounded and measurable, and by the first characteristic property of a choice set, recorded as (16) in Section 2.6, the translates $\{\lambda + V\}_{\lambda \in \Lambda}$ are disjoint; since $F_0 \subseteq V$, the translates $\{\lambda + F_0\}_{\lambda \in \Lambda}$ are disjoint as well. By Lemma 16, $m(F_0) = 0$. Hence every F_σ set contained in V , being a countable union of closed subsets of V , has outer measure zero by Proposition 3. So no F_σ set $F \subseteq V$ satisfies $m^*(F) = m^*(V) > 0$.

Thus the exercise, read literally for an arbitrary set of finite outer measure, is false; the G_δ statement holds in general, and the F_σ statement holds precisely for the measurable sets.

Problem 2.19. Let E have finite outer measure. Show that if E is not measurable, then there is an open set $\mathcal{O}$ containing E that has finite outer measure and for which

$$m^*(\mathcal{O} \sim E) > m^*(\mathcal{O}) - m^*(E).$$

Solution. Let E be a nonmeasurable set with $m^*(E) < \infty$.

Step 1: a uniform gap. By Theorem 11, measurability of E is equivalent to assertion (i): for each $\epsilon > 0$ there is an open set containing E whose difference with E has outer measure less than ϵ . Since E is not measurable, (i) fails. The negation of (i) is precisely: there is an $\epsilon_0 > 0$ such that

$$m^*(\mathcal{U} \sim E) \geq \epsilon_0 \quad \text{for every open set } \mathcal{U} \text{ containing } E.$$

Call this property (*).

Step 2: a tight open cover. Since $m^*(E) < \infty$, by the definition of outer measure there is a countable collection $\{I_k\}_{k=1}^\infty$ of open, bounded intervals covering E for which

$$\sum_{k=1}^\infty \ell(I_k) < m^*(E) + \epsilon_0.$$

Define $\mathcal{O} = \bigcup_{k=1}^\infty I_k$. Then $\mathcal{O}$ is an open set containing E , and by the countable subadditivity of outer measure (Proposition 3) together with the equality of the outer measure of an interval and its length (Proposition 1),

$$m^*(\mathcal{O}) \leq \sum_{k=1}^\infty \ell(I_k) < m^*(E) + \epsilon_0 < \infty.$$

In particular $\mathcal{O}$ has finite outer measure.

Step 3: the strict inequality. From the display of Step 2,

$$m^*(\mathcal{O}) - m^*(E) < \epsilon_0,$$

the subtraction being legitimate because $m^*(E)$ is finite. On the other hand, $\mathcal{O}$ is an open set containing E , so $(*)$ applies to it and gives

$$m^*(\mathcal{O} \sim E) \geq \epsilon_0.$$

Combining the two,

$$m^*(\mathcal{O} \sim E) \geq \epsilon_0 > m^*(\mathcal{O}) - m^*(E),$$

which is the required strict inequality. Note also that $\mathcal{O} \sim E$ has finite outer measure, since $\mathcal{O} \sim E \subseteq \mathcal{O}$. This is exactly the point made in the Remark following Theorem 12: for any bounded set E , measurable or not, one can always find an open $\mathcal{O} \supseteq E$ with $m^*(\mathcal{O}) - m^*(E) < \epsilon$; but the excision identity $m^*(\mathcal{O} \sim E) = m^*(\mathcal{O}) - m^*(E)$ requires the measurability of E , and for a nonmeasurable E the left-hand side stays bounded away from zero no matter how tightly $\mathcal{O}$ is chosen.

Problem 2.20. (Lebesgue) Let E have finite outer measure. Show that E is measurable if and only if for each open, bounded interval (a, b) ,

$$b - a = m^*((a, b) \cap E) + m^*((a, b) \sim E).$$

Solution. Necessity. Suppose E is measurable. Let (a, b) be an open, bounded interval. Taking $A = (a, b)$ in the Carathéodory definition of measurability,

$$m^*((a, b)) = m^*((a, b) \cap E) + m^*((a, b) \cap E^C) = m^*((a, b) \cap E) + m^*((a, b) \sim E).$$

By Proposition 1, $m^*((a, b)) = \ell((a, b)) = b - a$. This is the asserted identity, and it holds for measurable E whether or not $m^*(E)$ is finite.

Sufficiency. Suppose $m^*(E) < \infty$ and that

$$\ell(I) = m^*(I \cap E) + m^*(I \sim E)$$

for every nonempty open, bounded interval I ; call this hypothesis $(*)$. We verify assertion (i) of Theorem 11.

Let $\epsilon > 0$. Since $m^*(E) < \infty$, the definition of outer measure provides a countable collection of open, bounded intervals covering E the sum of whose lengths is less than $m^*(E) + \epsilon$; let $\mathcal{O}$ be the union of that collection. Then $\mathcal{O}$ is an open set containing E and, by Propositions 1 and 3,

$$m^*(\mathcal{O}) < m^*(E) + \epsilon < \infty.$$

Every open set of real numbers is the disjoint union of a countable collection of open intervals (page 17). Write $\mathcal{O} = \bigcup_k I_k$ with $\{I_k\}$ a countable disjoint collection of open intervals; discarding empty ones, we may assume each I_k is nonempty. Each I_k is bounded: $I_k \subseteq \mathcal{O}$, so by Proposition 1 and monotonicity $\ell(I_k) = m^*(I_k) \leq m^*(\mathcal{O}) < \infty$, and an unbounded interval has infinite length. So each I_k is an open, bounded interval and $(*)$ applies to it.

Two summation facts. First,

$$\sum_k \ell(I_k) \leq m^*(\mathcal{O}).$$

Indeed, each I_k is measurable (Proposition 8) with $m^*(I_k) = \ell(I_k)$, so for each n , Proposition 6 applied with $A = \mathbb{R}$ to the finite disjoint collection $\{I_k\}_{k=1}^n$ together with monotonicity gives

$$\sum_{k=1}^n \ell(I_k) = m^*\left(\bigcup_{k=1}^n I_k\right) \leq m^*(\mathcal{O}),$$

and the bound is independent of n . Second, since $E \subseteq \mathcal{O}$ we have $E = \bigcup_k [I_k \cap E]$, so by countable subadditivity (Proposition 3),

$$m^*(E) \leq \sum_k m^*(I_k \cap E).$$

All the terms $m^*(I_k \cap E) \leq \ell(I_k)$ are finite, and both series converge, being dominated by $m^*(\mathcal{O}) < \infty$.

Now $\mathcal{O} \sim E = \bigcup_k [I_k \sim E]$, so by countable subadditivity and then (*),

$$m^*(\mathcal{O} \sim E) \leq \sum_k m^*(I_k \sim E) = \sum_k [\ell(I_k) - m^*(I_k \cap E)] = \sum_k \ell(I_k) - \sum_k m^*(I_k \cap E),$$

the splitting of the last series being legitimate since both series converge. Therefore, by the two summation facts,

$$m^*(\mathcal{O} \sim E) \leq m^*(\mathcal{O}) - m^*(E) < [m^*(E) + \epsilon] - m^*(E) = \epsilon.$$

Thus for each $\epsilon > 0$ there is an open set $\mathcal{O}$ containing E with $m^*(\mathcal{O} \sim E) < \epsilon$. By assertion (i) of Theorem 11, E is measurable.

Observe where the hypotheses were used: the finiteness of $m^*(E)$ made the subtraction $m^*(\mathcal{O}) - m^*(E)$ meaningful and produced the tight open cover, while (*) converted the Carathéodory splitting condition, a priori demanded of every test set A , into a condition on the single family of bounded open intervals. The content of the exercise is that intervals are enough test sets.

Problem 2.21. Use property (ii) of Theorem 11 as the primitive definition of a measurable set and prove that the union of two measurable sets is measurable. Then do the same for property (iv).

Solution. Throughout, the only properties of outer measure used are its monotonicity and its countable subadditivity (Proposition 3); no part of the Carathéodory theory is invoked, which is the point of the exercise.

Part 1: property (ii) as the definition.

Definition: a set E is measurable provided there is a G_δ set G containing E for which $m^*(G \sim E) = 0$. We need one topological lemma.

Lemma A. The union of two G_δ sets is a G_δ set.

Proof of Lemma A. Let $G_1 = \bigcap_{n=1}^\infty U_n$ and $G_2 = \bigcap_{n=1}^\infty V_n$ with each U_n, V_n open. Consider the countable collection of open sets $\{U_n \cup V_m\}_{n,m \in \mathbb{N}}$ (a countable family, being indexed by $\mathbb{N} \times \mathbb{N}$), and set

$$H = \bigcap_{n,m} [U_n \cup V_m],$$

a G_δ set. If $x \in G_1$ then $x \in U_n$ for all n , so $x \in U_n \cup V_m$ for all n, m ; hence $G_1 \subseteq H$, and symmetrically $G_2 \subseteq H$, so $G_1 \cup G_2 \subseteq H$. Conversely, let $x \in H$ and suppose $x \notin G_1$. Then $x \notin U_{n_0}$ for some index n_0 . Since $x \in U_{n_0} \cup V_m$ for every m , it follows that $x \in V_m$ for every m , that is, $x \in G_2$. Hence $H \subseteq G_1 \cup G_2$, and $G_1 \cup G_2 = H$ is a G_δ set.

Now let E_1 and E_2 be measurable in the sense of (ii). Choose G_δ sets $G_1 \supseteq E_1$ and $G_2 \supseteq E_2$ with

$$m^*(G_1 \sim E_1) = m^*(G_2 \sim E_2) = 0.$$

Put $G = G_1 \cup G_2$, a G_δ set by Lemma A, and clearly $E_1 \cup E_2 \subseteq G$. I claim

$$G \sim [E_1 \cup E_2] \subseteq [G_1 \sim E_1] \cup [G_2 \sim E_2].$$

Indeed, let $x \in G$ with $x \notin E_1 \cup E_2$. Then $x \in G_1$ or $x \in G_2$. In the first case $x \in G_1$ and $x \notin E_1$, so $x \in G_1 \sim E_1$; in the second case, likewise, $x \in G_2 \sim E_2$. This proves the inclusion.

By monotonicity and the subadditivity of outer measure,

$$m^*(G \sim [E_1 \cup E_2]) \leq m^*(G_1 \sim E_1) + m^*(G_2 \sim E_2) = 0.$$

Thus G is a G_δ set containing $E_1 \cup E_2$ with $m^*(G \sim [E_1 \cup E_2]) = 0$, so $E_1 \cup E_2$ is measurable.

Part 2: property (iv) as the definition.

Definition: a set E is measurable provided there is an F_σ set F contained in E for which $m^*(E \sim F) = 0$.

Lemma B. The union of two F_σ sets is an F_σ set.

Proof of Lemma B. If $F_1 = \bigcup_{n=1}^{\infty} C_n$ and $F_2 = \bigcup_{n=1}^{\infty} D_n$ with each C_n, D_n closed, then

$$F_1 \cup F_2 = \bigcup_{n=1}^{\infty} [C_n \cup D_n],$$

a countable union of closed sets, since the union of two closed sets is closed. (Equivalently, interlace the two sequences.) Hence $F_1 \cup F_2$ is F_{σ} .

Now let E_1 and E_2 be measurable in the sense of (iv). Choose F_{σ} sets $F_1 \subseteq E_1$ and $F_2 \subseteq E_2$ with

$$m^*(E_1 \sim F_1) = m^*(E_2 \sim F_2) = 0.$$

Put $F = F_1 \cup F_2$, an F_{σ} set by Lemma B, with $F \subseteq E_1 \cup E_2$. I claim

$$[E_1 \cup E_2] \sim F \subseteq [E_1 \sim F_1] \cup [E_2 \sim F_2].$$

Indeed, let $x \in E_1 \cup E_2$ with $x \notin F = F_1 \cup F_2$; then $x \notin F_1$ and $x \notin F_2$. If $x \in E_1$ then $x \in E_1 \sim F_1$; otherwise $x \in E_2$ and then $x \in E_2 \sim F_2$. This proves the inclusion.

By monotonicity and subadditivity of outer measure,

$$m^*([E_1 \cup E_2] \sim F) \leq m^*(E_1 \sim F_1) + m^*(E_2 \sim F_2) = 0.$$

So F is an F_{σ} set contained in $E_1 \cup E_2$ whose complement in $E_1 \cup E_2$ has outer measure zero, and therefore $E_1 \cup E_2$ is measurable.

By induction, both arguments extend at once to the union of any finite collection of measurable sets.

2.4 Problems 2.22–2.28

Problem 2.22. For any set A , define $m^{**}(A) \in [0, \infty]$ by

$$m^{**}(A) = \inf\{m^*(\mathcal{O}) \mid \mathcal{O} \supseteq A, \mathcal{O} \text{ open}\}.$$

How is this set function m^{**} related to outer measure m^* ?

Solution. They are the same set function: $m^{**}(A) = m^*(A)$ for every set A of real numbers. (That is, outer measure is **outer regular**: it is already the infimum of the outer measures of the open sets that contain the given set.)

First observe that m^{**} is well defined, since $\mathbb{R}$ is an open set containing A , so the set over which the infimum is taken is nonempty.

One inequality is immediate from monotonicity of outer measure. If $\mathcal{O}$ is any open set with $A \subseteq \mathcal{O}$, then $m^*(A) \leq m^*(\mathcal{O})$. Taking the infimum over all such $\mathcal{O}$,

$$m^*(A) \leq m^{**}(A).$$

For the reverse inequality we use the definition of outer measure directly. If $m^*(A) = \infty$ there is nothing to prove, since then $m^{**}(A) \geq m^*(A) = \infty$ forces $m^{**}(A) = \infty = m^*(A)$. So suppose $m^*(A) < \infty$ and let $\epsilon > 0$. By the definition of $m^*(A)$ as an infimum, there is a countable collection $\{I_k\}_{k=1}^{\infty}$ of open, bounded intervals which covers A and for which

$$\sum_{k=1}^{\infty} \ell(I_k) < m^*(A) + \epsilon.$$

Define $\mathcal{O} = \bigcup_{k=1}^{\infty} I_k$. Then $\mathcal{O}$ is open, being a union of open intervals, and $A \subseteq \mathcal{O}$. By the countable subadditivity of outer measure (Proposition 3) together with the fact that the outer measure of an interval is its length (Proposition 1),

$$m^*(\mathcal{O}) \leq \sum_{k=1}^{\infty} m^*(I_k) = \sum_{k=1}^{\infty} \ell(I_k) < m^*(A) + \epsilon.$$

Since $\mathcal{O}$ is one of the competitors in the infimum defining $m^{**}(A)$,

$$m^{**}(A) \leq m^*(\mathcal{O}) < m^*(A) + \epsilon.$$

As $\epsilon > 0$ was arbitrary, $m^{**}(A) \leq m^*(A)$.

Combining the two inequalities, $m^{**}(A) = m^*(A)$ for every set A .

Two remarks are worth recording. First, the argument used no measurability whatsoever: the equality holds for every set A , measurable or not. So outer regularity, by itself, detects nothing about measurability.

Second, the equality must not be confused with the stronger assertion that the difference $\mathcal{O} \sim A$ can be made small. That assertion is exactly assertion (i) of Theorem 11, and it is equivalent to the measurability of A . The inference from one to the other would require the excision formula $m^*(\mathcal{O} \sim A) = m^*(\mathcal{O}) - m^*(A)$, and excision is available only when A is measurable and of finite outer measure. Indeed Problem 19 shows that if A has finite outer measure and is not measurable, then there is an open set $\mathcal{O}$ containing A of finite outer measure with $m^*(\mathcal{O} \sim A) > m^*(\mathcal{O}) - m^*(A)$, even though, by what we have just proved, $m^*(\mathcal{O}) - m^*(A)$ may be made arbitrarily small.

Problem 2.23. For any set A , define $m^{***}(A) \in [0, \infty]$ by

$$m^{***}(A) = \sup\{m^*(F) \mid F \subseteq A, F \text{ closed}\}.$$

How is this set function m^{***} related to outer measure m^* ?

Solution. The set function m^{***} is the **inner measure** determined by closed sets. It never exceeds m^* , and it agrees with m^* on every measurable set; conversely, for sets of finite outer measure, agreement forces measurability. Thus m^{***} and m^* are genuinely different set functions, and the sets on which they disagree are non-measurable. Precisely, we prove:

- (1) $m^{***}(A) \leq m^*(A)$ for every set A ;
- (2) if A is measurable, then $m^{***}(A) = m^*(A)$;
- (3) if $m^*(A) < \infty$ and $m^{***}(A) = m^*(A)$, then A is measurable;
- (4) neither the finiteness hypothesis in (3) nor the converse in general can be dropped, and there are sets for which the inequality in (1) is strict.

Note first that m^{***} is well defined: the empty set is a closed subset of A , so the supremum is over a nonempty set of numbers.

Proof of (1). If F is closed and $F \subseteq A$, then by the monotonicity of outer measure $m^*(F) \leq m^*(A)$. Taking the supremum over all such F gives $m^{***}(A) \leq m^*(A)$.

Proof of (2). Let A be measurable and let $\epsilon > 0$. By assertion (iii) of Theorem 11 there is a closed set F contained in A for which $m^*(A \sim F) < \epsilon$. Since $A = F \cup (A \sim F)$, the finite subadditivity of outer measure gives

$$m^*(A) \leq m^*(F) + m^*(A \sim F) < m^*(F) + \epsilon \leq m^{***}(A) + \epsilon.$$

This holds for every $\epsilon > 0$, whence $m^*(A) \leq m^{***}(A)$; with (1) this gives equality. The argument covers the case $m^*(A) = \infty$ as well: the displayed inequality then forces $m^*(F) = \infty$, so $m^{***}(A) = \infty = m^*(A)$.

Proof of (3). Suppose $m^*(A) < \infty$ and $m^{***}(A) = m^*(A)$. By the definition of the supremum, for each natural number n there is a closed set $F_n \subseteq A$ with

$$m(F_n) > m^*(A) - 1/n.$$

Closed sets are measurable, so each F_n is measurable, and hence so is $F = \bigcup_{n=1}^{\infty} F_n$, an F_σ set contained in A . Since $F_n \subseteq F \subseteq A$, monotonicity gives

$$m^*(A) - 1/n < m(F_n) \leq m(F) \leq m^*(A) \quad \text{for all } n,$$

so $m(F) = m^*(A)$.

Next we produce a measurable set containing A of the same measure. By Problem 22 (equivalently, by the definition of outer measure), for each n there is an open set $\mathcal{O}_n \supseteq A$ with $m^*(\mathcal{O}_n) < m^*(A) + 1/n$. Put $G = \bigcap_{n=1}^{\infty} \mathcal{O}_n$, a G_δ set containing A ; it is measurable, and by monotonicity $m(G) \leq m^*(\mathcal{O}_n) < m^*(A) + 1/n$ for every n , while $m(G) \geq m^*(A)$ since $A \subseteq G$. Hence $m(G) = m^*(A)$. Now $F \subseteq A \subseteq G$ with F and G measurable and $m(F) = m(G) = m^*(A) < \infty$. By the excision property of measurable sets,

$$m(G \sim F) = m(G) - m(F) = 0.$$

Since $A \sim F \subseteq G \sim F$, monotonicity gives $m^*(A \sim F) = 0$, and a set of outer measure zero is measurable (Proposition 4). Therefore

$$A = F \cup (A \sim F)$$

is the union of two measurable sets and so is measurable.

Proof of (4). Let $V = \mathcal{C}_{[0,1]}$ be a choice set for the rational equivalence relation on $[0, 1]$, as constructed in Section 2.6. Then $V \subseteq [0, 1]$, and V is not measurable: this is precisely the content of the proof of Theorem 17 (Vitali), applied to the set $E = [0, 1]$, which has positive outer measure. Moreover, by the first characteristic property of a choice set, recorded as (16) in Section 2.6, for any set $\Lambda \subseteq \mathbb{Q}$ the collection of translates $\{\lambda + V\}_{\lambda \in \Lambda}$ is disjoint.

Now let F be any closed set with $F \subseteq V$, and put $\Lambda = [-1, 1] \cap \mathbb{Q}$, a bounded, countably infinite set of real numbers. Since $F \subseteq V$, the translates $\{\lambda + F\}_{\lambda \in \Lambda}$ are contained in the corresponding translates of V and hence are disjoint. Also F is bounded, being a subset of $[0, 1]$, and F is measurable, being closed. Lemma 16 therefore gives $m(F) = 0$. As F was an arbitrary closed subset of V ,

$$m^{***}(V) = 0 < m^*(V),$$

the last inequality because $m^*(V) = 0$ would make V measurable. So the inequality in (1) can be strict.

Finally, the finiteness hypothesis in (3) cannot be omitted. Put $A = \mathbb{R} \sim V$. Then A is not measurable, for otherwise its complement V would be measurable. But A contains the closed set $[2, \infty)$, so

$$m^{***}(A) = \infty = m^*(A),$$

the right-hand equality holding since $A \supseteq [2, \infty)$. Thus a non-measurable set of infinite outer measure may still satisfy $m^{***}(A) = m^*(A)$.

In summary: $m^{***} \leq m^*$ always, with equality on all measurable sets; among sets of finite outer measure the two set functions agree exactly on the measurable sets. In particular, m^{***} is not countably additive on all sets, and it is the natural “inner” counterpart of the “outer” description of m^* obtained in Problem 22.

Problem 2.24. Show that if E_1 and E_2 are measurable, then

$$m(E_1 \cup E_2) + m(E_1 \cap E_2) = m(E_1) + m(E_2).$$

Solution. All four sets appearing in the identity are measurable: by Theorem 9 the collection $\mathcal{M}$ of measurable sets is a σ -algebra, so it is closed with respect to the formation of complements and countable unions, and hence, by De Morgan’s Identities, also with respect to finite unions, finite intersections and relative complements. In particular $E_2 \sim E_1 = E_2 \cap E_1^C$ is measurable. Every term is therefore a well-defined element of $[0, \infty]$, and we prove the identity as an identity in $[0, \infty]$, where addition is commutative, associative, and satisfies $a + \infty = \infty$. Notice that no subtraction occurs anywhere in the argument, so no finiteness hypothesis is needed.

Decompose the union. The sets E_1 and $E_2 \sim E_1$ are disjoint measurable sets whose union is $E_1 \cup E_2$. Indeed, they are disjoint because $E_2 \sim E_1$ misses E_1 , and their union is

$$E_1 \cup (E_2 \sim E_1) = E_1 \cup (E_2 \cap E_1^C) = (E_1 \cup E_2) \cap (E_1 \cup E_1^C) = E_1 \cup E_2.$$

Hence, by the finite additivity of Lebesgue measure over disjoint measurable sets (Proposition 6 with $A = \mathbb{R}$, or Proposition 13), we obtain the first decomposition

$$m(E_1 \cup E_2) = m(E_1) + m(E_2 \sim E_1).$$

Decompose E_2 . The sets $E_1 \cap E_2$ and $E_2 \sim E_1$ are disjoint measurable sets, and

$$(E_1 \cap E_2) \cup (E_2 \sim E_1) = E_2 \cap (E_1 \cup E_1^C) = E_2.$$

Hence, again by finite additivity, we obtain the second decomposition

$$m(E_2) = m(E_1 \cap E_2) + m(E_2 \sim E_1).$$

Now add $m(E_1 \cap E_2)$ to both sides of the first decomposition and substitute the second:

$$\begin{aligned} m(E_1 \cup E_2) + m(E_1 \cap E_2) &= m(E_1) + m(E_2 \sim E_1) + m(E_1 \cap E_2) \\ &= m(E_1) + [m(E_1 \cap E_2) + m(E_2 \sim E_1)] \\ &= m(E_1) + m(E_2). \end{aligned}$$

This is the asserted identity.

Two consequences are worth noting. If $m(E_1 \cap E_2) < \infty$ we may cancel it and obtain the inclusion-exclusion formula

$$m(E_1 \cup E_2) = m(E_1) + m(E_2) - m(E_1 \cap E_2),$$

and in particular, whether or not the measures are finite, $m(E_1 \cup E_2) \leq m(E_1) + m(E_2)$, with equality precisely when $m(E_1 \cap E_2) = 0$ or both sides are infinite.

Problem 2.25. Show that the assumption that $m(B_1) < \infty$ is necessary in part (ii) of the theorem regarding continuity of measure.

Solution. Part (ii) of Theorem 15 asserts that if $\{B_k\}_{k=1}^\infty$ is a descending collection of measurable sets and $m(B_1) < \infty$, then

$$m\left(\bigcap_{k=1}^\infty B_k\right) = \lim_{k \rightarrow \infty} m(B_k).$$

We exhibit a descending collection of measurable sets for which this conclusion fails; since the only hypothesis used besides descent is the finiteness of $m(B_1)$, this shows that hypothesis cannot be omitted. For each natural number k define

$$B_k = [k, \infty).$$

Each B_k is an interval, hence measurable by Proposition 8, and the collection is descending: $B_{k+1} = [k+1, \infty) \subseteq [k, \infty) = B_k$. Each B_k has infinite measure. Indeed, for every natural number n the interval $[k, k+n]$ is contained in B_k , so by the monotonicity of outer measure and Proposition 1,

$$m(B_k) \geq m^*([k, k+n]) = \ell([k, k+n]) = n,$$

and since n is arbitrary, $m(B_k) = \infty$. (This is the assertion of Proposition 1 for unbounded intervals.) In particular $m(B_1) = \infty$, so the hypothesis in question fails. Consequently

$$\lim_{k \rightarrow \infty} m(B_k) = \infty.$$

On the other hand,

$$\bigcap_{k=1}^\infty B_k = \bigcap_{k=1}^\infty [k, \infty) = \emptyset,$$

because a real number x belongs to this intersection only if $x \geq k$ for every natural number k , which contradicts the Archimedean property of $\mathbb{R}$. Since $m(\emptyset) = 0$,

$$m\left(\bigcap_{k=1}^{\infty} B_k\right) = 0 \neq \infty = \lim_{k \rightarrow \infty} m(B_k),$$

and the conclusion of part (ii) fails.

No counterexample of finite measure exists, of course: if $m(B_1) < \infty$ then Theorem 15 (ii) applies and the conclusion holds. The failure above is caused precisely by the infinitude of the measures involved, and it is instructive to see where the proof of Theorem 15 (ii) breaks down. That proof sets $D_k = B_1 \sim B_k$, applies part (i) to the ascending collection $\{D_k\}$, and then cancels the term $m(B_1)$ from the identity

$$m(B_1) - m\left(\bigcap_{k=1}^{\infty} B_k\right) = \lim_{k \rightarrow \infty} [m(B_1) - m(B_k)].$$

Both the excisions producing this identity and the cancellation require $m(B_1) < \infty$. With $B_k = [k, \infty)$ the identity degenerates to the vacuous statement $\infty - 0 = \infty - \infty$.

It is worth recording exactly how much of the hypothesis is needed. What the proof of Theorem 15 (ii) actually uses is that $m(B_k)$ be finite for the sets it excises, and a descending collection with $m(B_{k_0}) < \infty$ for some index k_0 may be replaced by the descending collection $\{B_k\}_{k \geq k_0}$, which has the same intersection and the same limit of measures. So the correct sharp hypothesis is that $m(B_{k_0}) < \infty$ for some index k_0 ; the example $B_k = [k, \infty)$ shows that even this weaker hypothesis cannot be dropped, since there every B_k has infinite measure.

Problem 2.26. Let $\{E_k\}_{k=1}^{\infty}$ be a countable disjoint collection of measurable sets. Prove that for any set A ,

$$m^*\left(A \cap \bigcup_{k=1}^{\infty} E_k\right) = \sum_{k=1}^{\infty} m^*(A \cap E_k).$$

Solution. Note that A is an arbitrary set of real numbers; no measurability is assumed of A . This is the countable version of Proposition 6, which asserts the corresponding identity for a finite disjoint collection of measurable sets. We prove the two inequalities.

First, the inequality $\leq$. Since intersection distributes over union,

$$A \cap \bigcup_{k=1}^{\infty} E_k = \bigcup_{k=1}^{\infty} (A \cap E_k),$$

so the countable subadditivity of outer measure (Proposition 3) gives

$$m^*\left(A \cap \bigcup_{k=1}^{\infty} E_k\right) \leq \sum_{k=1}^{\infty} m^*(A \cap E_k).$$

Observe that this half needed neither the measurability of the E_k nor their disjointness.

Now the inequality $\geq$. Fix a natural number n . The collection $\{E_k\}_{k=1}^n$ is a finite disjoint collection of measurable sets, so by Proposition 6, applied to the set A ,

$$m^*\left(A \cap \bigcup_{k=1}^n E_k\right) = \sum_{k=1}^n m^*(A \cap E_k).$$

On the other hand,

$$A \cap \bigcup_{k=1}^n E_k \subseteq A \cap \bigcup_{k=1}^{\infty} E_k,$$

so by the monotonicity of outer measure,

$$\sum_{k=1}^n m^*(A \cap E_k) = m^*\left(A \cap \bigcup_{k=1}^n E_k\right) \leq m^*\left(A \cap \bigcup_{k=1}^{\infty} E_k\right).$$

The right-hand side is independent of n . Every partial sum of the series of nonnegative terms $\sum_{k=1}^{\infty} m^*(A \cap E_k)$ is therefore bounded above by the quantity $m^*(A \cap \bigcup_{k=1}^{\infty} E_k)$. Since the sum of a series of nonnegative terms is by definition the supremum in $[0, \infty]$ of its partial sums, we conclude

$$\sum_{k=1}^{\infty} m^*(A \cap E_k) \leq m^*\left(A \cap \bigcup_{k=1}^{\infty} E_k\right).$$

This argument is valid in $[0, \infty]$ without any finiteness assumption: if some term $m^*(A \cap E_k)$ is infinite, or if the partial sums are unbounded, the displayed bound simply forces the right-hand side to equal ∞ as well.

The two inequalities together give the asserted equality.

Taking $A = \mathbb{R}$ recovers the countable additivity of Lebesgue measure, Proposition 13. Conversely, the identity just proved is the natural strengthening of that proposition: the countable additivity of m^* persists after intersecting with an entirely arbitrary “test set” A , so long as the pieces E_k are disjoint and measurable.

Problem 2.27. Let $\mathcal{M}'$ be any σ -algebra of subsets of $\mathbb{R}$ and m' a set function on $\mathcal{M}'$ which takes values in $[0, \infty]$, is countably additive, and such that $m'(\emptyset) = 0$.

(i) Show that m' is finitely additive, monotone, countably monotone, and possesses the excision property.

(ii) Show that m' possesses the same continuity properties as Lebesgue measure.

Solution. Throughout, all sets named belong to $\mathcal{M}'$. Recall that a σ -algebra of subsets of $\mathbb{R}$ contains $\mathbb{R}$ and is closed with respect to the formation of complements and countable unions; by De Morgan's Identities it is closed with respect to countable intersections, and hence also with respect to finite unions, finite intersections and relative complements $B \sim A = B \cap A^C$. Note also that $\emptyset = \mathbb{R}^C \in \mathcal{M}'$. Countable additivity means: if $\{E_k\}_{k=1}^{\infty}$ is a countable disjoint collection of sets in $\mathcal{M}'$, then

$$m'\left(\bigcup_{k=1}^{\infty} E_k\right) = \sum_{k=1}^{\infty} m'(E_k).$$

Since the terms are nonnegative, such a series has a well-defined sum in $[0, \infty]$ independent of the order of summation.

Part (i).

Finite additivity. Let $\{E_k\}_{k=1}^n$ be a finite disjoint collection in $\mathcal{M}'$. Define $E_k = \emptyset$ for $k > n$. Then $\{E_k\}_{k=1}^{\infty}$ is a countable disjoint collection in $\mathcal{M}'$ whose union is $\bigcup_{k=1}^n E_k$, so countable additivity and $m'(\emptyset) = 0$ give

$$m'\left(\bigcup_{k=1}^n E_k\right) = \sum_{k=1}^{\infty} m'(E_k) = \sum_{k=1}^n m'(E_k) + \sum_{k=n+1}^{\infty} 0 = \sum_{k=1}^n m'(E_k).$$

This is where the hypothesis $m'(\emptyset) = 0$ is used; without it, countable additivity applied to the collection all of whose members are $\emptyset$ would force $m'(\emptyset) \in \{0, \infty\}$, and the value ∞ would make m' identically ∞ .

Monotonicity. Let $A, B \in \mathcal{M}'$ with $A \subseteq B$. Then $B \sim A \in \mathcal{M}'$, the sets A and $B \sim A$ are disjoint, and their union is B . By finite additivity,

$$m'(B) = m'(A) + m'(B \sim A) \geq m'(A),$$

since $m'(B \sim A) \geq 0$.

Excision. Retain the notation of the previous paragraph and suppose in addition that $m'(A) < \infty$. Then the identity $m'(B) = m'(A) + m'(B \sim A)$ may be rearranged, the subtraction being legitimate because $m'(A)$ is finite:

$$m'(B \sim A) = m'(B) - m'(A).$$

(If $m'(B) = \infty$ this reads $m'(B \sim A) = \infty$, which is correct.)

Countable monotonicity. Suppose $E \in \mathcal{M}'$ and $\{E_k\}_{k=1}^\infty$ is a countable collection in $\mathcal{M}'$ with $E \subseteq \bigcup_{k=1}^\infty E_k$. We must show

$$m'(E) \leq \sum_{k=1}^\infty m'(E_k).$$

Disjointify the covering exactly as in the discussion preceding Proposition 7: define $E'_1 = E_1$ and, for $k \geq 2$,

$$E'_k = E_k \sim \bigcup_{i=1}^{k-1} E_i.$$

Because $\mathcal{M}'$ is closed under finite unions and relative complements, each E'_k belongs to $\mathcal{M}'$; the collection $\{E'_k\}_{k=1}^\infty$ is disjoint, $E'_k \subseteq E_k$, and $\bigcup_{k=1}^\infty E'_k = \bigcup_{k=1}^\infty E_k$. Now set $F_k = E \cap E'_k \in \mathcal{M}'$. The collection $\{F_k\}_{k=1}^\infty$ is disjoint, and since E is contained in the union of the E'_k ,

$$\bigcup_{k=1}^\infty F_k = E \cap \bigcup_{k=1}^\infty E'_k = E.$$

By countable additivity and then by monotonicity, using $F_k \subseteq E'_k \subseteq E_k$,

$$m'(E) = \sum_{k=1}^\infty m'(F_k) \leq \sum_{k=1}^\infty m'(E_k).$$

Part (ii). We show that m' has both continuity properties of Theorem 15. The proofs are those of Theorem 15 verbatim, and they use only countable additivity, monotonicity and excision, all of which were established in part (i).

Continuity for ascending collections. Let $\{A_k\}_{k=1}^\infty$ be an ascending collection in $\mathcal{M}'$, that is, $A_k \subseteq A_{k+1}$ for each k . We claim

$$m' \left(\bigcup_{k=1}^\infty A_k \right) = \lim_{k \rightarrow \infty} m'(A_k).$$

By monotonicity the sequence $\{m'(A_k)\}$ is nondecreasing, so the limit exists in $[0, \infty]$.

Suppose first that $m'(A_{k_0}) = \infty$ for some index k_0 . Then by monotonicity $m'(A_k) = \infty$ for all $k \geq k_0$, so the right-hand side is ∞ ; and $A_{k_0} \subseteq \bigcup_{k=1}^\infty A_k$, so the left-hand side is ∞ too. The claim holds.

Now suppose $m'(A_k) < \infty$ for every k . Define $A_0 = \emptyset$ and, for $k \geq 1$, $C_k = A_k \sim A_{k-1} \in \mathcal{M}'$. Because the collection is ascending, $\{C_k\}_{k=1}^\infty$ is disjoint and

$$\bigcup_{k=1}^\infty C_k = \bigcup_{k=1}^\infty A_k.$$

Indeed, if x lies in the union of the A_k , there is a smallest index k with $x \in A_k$, and then $x \in C_k$; the reverse inclusion is clear since $C_k \subseteq A_k$. Disjointness holds because for $j < k$ we have $C_j \subseteq A_j \subseteq A_{k-1}$ while C_k misses A_{k-1} . By countable additivity and then excision (legitimate since $A_{k-1} \subseteq A_k$ and $m'(A_{k-1}) < \infty$),

$$\begin{aligned} m' \left(\bigcup_{k=1}^\infty A_k \right) &= \sum_{k=1}^\infty m'(A_k \sim A_{k-1}) = \sum_{k=1}^\infty [m'(A_k) - m'(A_{k-1})] \\ &= \lim_{n \rightarrow \infty} \sum_{k=1}^n [m'(A_k) - m'(A_{k-1})] = \lim_{n \rightarrow \infty} [m'(A_n) - m'(A_0)] = \lim_{n \rightarrow \infty} m'(A_n), \end{aligned}$$

the telescoping being valid because every term is a difference of finite numbers, and $m'(A_0) = m'(\emptyset) = 0$. Continuity for descending collections. Let $\{B_k\}_{k=1}^\infty$ be a descending collection in $\mathcal{M}'$, that is, $B_{k+1} \subseteq B_k$ for each k , and suppose $m'(B_1) < \infty$. We claim

$$m' \left(\bigcap_{k=1}^\infty B_k \right) = \lim_{k \rightarrow \infty} m'(B_k).$$

The intersection belongs to $\mathcal{M}'$, and by monotonicity $\{m'(B_k)\}$ is nonincreasing and bounded below by 0, so the limit exists. Also $m'(B_k) \leq m'(B_1) < \infty$ for every k , and likewise $m'(\bigcap_k B_k) < \infty$; every excision performed below is therefore legitimate.

Define $D_k = B_1 \sim B_k \in \mathcal{M}'$. Since $\{B_k\}$ is descending, $\{D_k\}$ is ascending, so by the case already proved,

$$m' \left(\bigcup_{k=1}^\infty D_k \right) = \lim_{k \rightarrow \infty} m'(D_k).$$

By De Morgan's Identities,

$$\bigcup_{k=1}^\infty D_k = \bigcup_{k=1}^\infty [B_1 \sim B_k] = B_1 \sim \bigcap_{k=1}^\infty B_k.$$

By excision, $m'(D_k) = m'(B_1) - m'(B_k)$ for each k , and $m'(B_1 \sim \bigcap_k B_k) = m'(B_1) - m'(\bigcap_k B_k)$. Substituting,

$$m'(B_1) - m' \left(\bigcap_{k=1}^\infty B_k \right) = \lim_{k \rightarrow \infty} [m'(B_1) - m'(B_k)] = m'(B_1) - \lim_{k \rightarrow \infty} m'(B_k).$$

Since $m'(B_1)$ is finite it may be cancelled from both sides, and the claim follows.

Thus every countably additive $[0, \infty]$ -valued set function on a σ -algebra which vanishes on the empty set, that is, every measure, enjoys all the elementary properties of Lebesgue measure established in Sections 2.4 and 2.5. Nothing particular to $\mathbb{R}$, to intervals, or to the construction of m^* was used; this is the observation that will be taken as the starting point of the general theory of measure.

Problem 2.28. Show that continuity of measure together with finite additivity of measure implies countable additivity of measure.

Solution. The precise assertion to be proved is the converse of the implication established in Problem 27. Let $\mathcal{M}'$ be a σ -algebra of subsets of $\mathbb{R}$ and let m' be a set function on $\mathcal{M}'$ taking values in $[0, \infty]$ with $m'(\emptyset) = 0$. Assume:

(a) m' is finitely additive, that is, if $\{E_k\}_{k=1}^n$ is a finite disjoint collection in $\mathcal{M}'$, then $m'(\bigcup_{k=1}^n E_k) = \sum_{k=1}^n m'(E_k)$; and

(b) m' is continuous, that is, it possesses the two continuity properties of Theorem 15; in fact only the property for ascending collections is required: if $\{A_n\}_{n=1}^\infty$ is an ascending collection in $\mathcal{M}'$, then $m'(\bigcup_{n=1}^\infty A_n) = \lim_{n \rightarrow \infty} m'(A_n)$.

Then m' is countably additive.

Proof. Let $\{E_k\}_{k=1}^\infty$ be a countable disjoint collection of sets in $\mathcal{M}'$, and set

$$E = \bigcup_{k=1}^\infty E_k.$$

Since $\mathcal{M}'$ is a σ -algebra, $E \in \mathcal{M}'$. For each natural number n define the partial union

$$A_n = \bigcup_{k=1}^n E_k \in \mathcal{M}'.$$

The collection $\{A_n\}_{n=1}^\infty$ is ascending, since $A_n \subseteq A_{n+1}$, and

$$\bigcup_{n=1}^\infty A_n = \bigcup_{k=1}^\infty E_k = E.$$

Indeed, each $A_n \subseteq E$, and conversely any $x \in E$ lies in some E_k and hence in A_k . Because $\{E_k\}_{k=1}^\infty$ is a finite disjoint collection in $\mathcal{M}'$, hypothesis (a) gives

$$m'(A_n) = \sum_{k=1}^n m'(E_k) \quad \text{for every } n.$$

Applying hypothesis (b) to the ascending collection $\{A_n\}$ and then using the display above,

$$m'(E) = m'\left(\bigcup_{n=1}^\infty A_n\right) = \lim_{n \rightarrow \infty} m'(A_n) = \lim_{n \rightarrow \infty} \sum_{k=1}^n m'(E_k) = \sum_{k=1}^\infty m'(E_k),$$

the last equality being the definition of the sum of a series of nonnegative terms; the limit exists in $[0, \infty]$ because the partial sums are nondecreasing. That is,

$$m'\left(\bigcup_{k=1}^\infty E_k\right) = \sum_{k=1}^\infty m'(E_k),$$

which is the countable additivity of m' .

A remark on the descending form of continuity. One may instead assume finite additivity together with continuity for descending collections, in the form: if $\{B_n\}$ is a descending collection in $\mathcal{M}'$ with $m'(B_1) < \infty$ and $\bigcap_{n=1}^\infty B_n = \emptyset$, then $\lim_{n \rightarrow \infty} m'(B_n) = 0$. This yields countable additivity for disjoint collections whose union has finite measure. Indeed, with E and E_k as above and $m'(E) < \infty$, put

$$B_n = E \sim \bigcup_{k=1}^n E_k \in \mathcal{M}'.$$

The collection $\{B_n\}$ is descending, $m'(B_1) \leq m'(E) < \infty$ by the monotonicity that follows from finite additivity, and $\bigcap_{n=1}^\infty B_n = \emptyset$ because each point of E lies in some E_k and so is excluded from B_k . Finite additivity applied to the disjoint decomposition $E = E_1 \cup \cdots \cup E_n \cup B_n$ gives

$$m'(E) = \sum_{k=1}^n m'(E_k) + m'(B_n),$$

and letting $n \rightarrow \infty$, with $m'(B_n) \rightarrow 0$, yields $m'(E) = \sum_{k=1}^\infty m'(E_k)$. This second route needs the finiteness of $m'(E)$, which is why the ascending form of continuity is the one that gives the theorem in full generality.

Taken together with Problem 27, the conclusion is that for a $[0, \infty]$ -valued set function on a σ -algebra which vanishes on the empty set, countable additivity is equivalent to the conjunction of finite additivity and continuity. This is the sense in which Theorem 15 and Proposition 13 carry the same information about Lebesgue measure.

2.5 Problems 2.29–2.35

- Problem 2.29.** (i) Show that rational equivalence defines an equivalence relation on any set.
(ii) Explicitly find a choice set for the rational equivalence relation on $\mathbb{Q}$.
(iii) Define two numbers to be irrationally equivalent provided their difference is irrational. Is this an equivalence relation on $\mathbb{R}$? Is this an equivalence relation on $\mathbb{Q}$?

Solution. Throughout, for a nonempty set E of real numbers, two points $x, y \in E$ are called rationally equivalent provided $x - y \in \mathbb{Q}$; write $x \sim y$.

Part (i). Let E be any nonempty set of real numbers.

Reflexivity: for $x \in E$ we have $x - x = 0$, and $0 \in \mathbb{Q}$. Hence $x \sim x$.

Symmetry: suppose $x \sim y$, so that $q := x - y \in \mathbb{Q}$. Then $y - x = -q$, and $\mathbb{Q}$ is closed under negation, so $y - x \in \mathbb{Q}$ and therefore $y \sim x$.

Transitivity: suppose $x \sim y$ and $y \sim z$, say $x - y = q \in \mathbb{Q}$ and $y - z = r \in \mathbb{Q}$. Then

$$x - z = (x - y) + (y - z) = q + r,$$

and $\mathbb{Q}$ is closed under addition, so $x - z \in \mathbb{Q}$ and therefore $x \sim z$.

Thus $\sim$ is reflexive, symmetric and transitive on E ; that is, it is an equivalence relation on E . Observe that the only properties of $\mathbb{Q}$ used are that it is a subgroup of the additive group $\mathbb{R}$: it contains 0 and is closed under negation and addition.

Part (ii). Take $E = \mathbb{Q}$. If $x, y \in \mathbb{Q}$ then $x - y \in \mathbb{Q}$, so $x \sim y$. Hence any two rationals are rationally equivalent, and the rational equivalence relation on $\mathbb{Q}$ has exactly one equivalence class, namely $\mathbb{Q}$ itself. A choice set consists of exactly one member of each equivalence class, so

$$\mathcal{C}_{\mathbb{Q}} = \{0\}$$

is a choice set (as is $\{q\}$ for any single rational q ; these singletons are precisely the choice sets).

It is worth checking the two characteristic properties listed in the text. Property (i), that the difference of two (distinct) points of the choice set is not rational, holds vacuously, since $\{0\}$ contains no two distinct points. Property (ii), that each $x \in \mathbb{Q}$ may be written $x = c + q$ with $c \in \mathcal{C}_{\mathbb{Q}}$ and q rational, holds with $c = 0$ and $q = x$.

Note that no appeal to the Axiom of Choice is needed here: there is only one equivalence class, and we have named a member of it explicitly.

Part (iii). Define $x \approx y$ provided $x - y$ is irrational.

On $\mathbb{R}$ this is not an equivalence relation. It fails reflexivity at every point: for each $x \in \mathbb{R}$, $x - x = 0$ is rational, so $x \not\approx x$. (The relation is symmetric, since $x - y$ is irrational if and only if $y - x = -(x - y)$ is irrational. But it also fails transitivity: take $x = 0$, $y = \sqrt{2}$, $z = 2$. Then $x - y = -\sqrt{2}$ and $y - z = \sqrt{2} - 2$ are both irrational, so $x \approx y$ and $y \approx z$; but $x - z = -2$ is rational, so $x \not\approx z$.)

On $\mathbb{Q}$ this is not an equivalence relation either. Indeed, if $x, y \in \mathbb{Q}$ then $x - y \in \mathbb{Q}$ is rational, so no pair of rationals is irrationally equivalent: the relation $\approx$ restricted to $\mathbb{Q}$ is the empty relation. It is symmetric and vacuously transitive, but it is not reflexive, since $\mathbb{Q}$ is nonempty and $x \not\approx x$ for every $x \in \mathbb{Q}$. Hence it is not an equivalence relation.

Problem 2.30. Show that any choice set for the rational equivalence relation on a set of positive outer measure must be uncountably infinite.

Solution. Let E be a set of real numbers with $m^*(E) > 0$, and let $\mathcal{C}_E$ be a choice set for the rational equivalence relation on E . We argue by contradiction: suppose $\mathcal{C}_E$ is countable (recall that in this book “countable” includes “finite”, so this covers both the finite and the countably infinite case).

We first observe that

$$E \subseteq \bigcup_{q \in \mathbb{Q}} (q + \mathcal{C}_E).$$

Indeed, let $x \in E$. By the second characteristic property of a choice set, there is a point $c \in \mathcal{C}_E$ and a rational number q with $x = c + q$. Thus $x \in q + \mathcal{C}_E$, which proves the inclusion.

Now $\mathbb{Q}$ is countable, so the union above is a countable union of sets. Each set $q + \mathcal{C}_E$ is a translate of the countable set $\mathcal{C}_E$, hence is itself countable, and a countable set of real numbers has outer measure zero (the Example following the statement of monotonicity in Section 2.2). Therefore, by the countable

subadditivity of outer measure (Proposition 3 of this chapter) together with its monotonicity,

$$m^*(E) \leq m^*\left(\bigcup_{q \in \mathbb{Q}} (q + \mathcal{C}_E)\right) \leq \sum_{q \in \mathbb{Q}} m^*(q + \mathcal{C}_E) = \sum_{q \in \mathbb{Q}} 0 = 0.$$

Hence $m^*(E) = 0$, contradicting the assumption that $m^*(E) > 0$.

We conclude that $\mathcal{C}_E$ is not countable. In particular $\mathcal{C}_E$ is not finite, so it is uncountably infinite, as asserted.

Two remarks. First, no measurability of $\mathcal{C}_E$ is needed anywhere in this argument; only outer measure, which is defined for every set, is used. Second, translation invariance of outer measure was not even required, since a translate of a countable set is countable, and countable sets have outer measure zero directly.

Problem 2.31. Justify the assertion in the proof of Vitali's Theorem that it suffices to consider the case that E is bounded.

Solution. The assertion to be justified is the opening sentence of the proof of Theorem 17: "By the countable subadditivity of outer measure, we may suppose E is bounded." Precisely, what must be shown is the following implication.

Claim. Suppose it has been proved that every bounded set of positive outer measure contains a nonmeasurable subset. Then every set of positive outer measure contains a nonmeasurable subset.

Proof of the claim. Let E be a set of real numbers with $m^*(E) > 0$. For each natural number n put

$$E_n = E \cap [-n, n].$$

Each E_n is bounded, and since every real number lies in $[-n, n]$ for n sufficiently large,

$$E = \bigcup_{n=1}^{\infty} E_n.$$

We assert that $m^*(E_n) > 0$ for some n . Otherwise $m^*(E_n) = 0$ for every n , and then, by the countable subadditivity of outer measure (Proposition 3 of this chapter),

$$m^*(E) \leq \sum_{n=1}^{\infty} m^*(E_n) = 0,$$

so that $m^*(E) = 0$, contrary to hypothesis.

Fix an index n with $m^*(E_n) > 0$. Then E_n is a bounded set of positive outer measure, so by the assumed bounded case, E_n contains a subset W that fails to be measurable. Since $W \subseteq E_n \subseteq E$, the set E contains the nonmeasurable subset W . This proves the claim, and hence justifies the reduction. It is worth recording explicitly why the reduction is desirable: boundedness of E is used twice in the proof of Theorem 17. It guarantees that $\mathcal{C}_E$ is bounded, so that Lemma 16 (which requires E bounded) may be applied to $\mathcal{C}_E$; and it supplies an interval $[-b, b] \supseteq E$, which is what allows the bounded, countably infinite set of rationals $\Lambda_0 = [-2b, 2b] \cap \mathbb{Q}$ to be chosen so that the inclusion $E \subseteq \bigcup_{\lambda \in \Lambda_0} (\lambda + \mathcal{C}_E)$ holds. As Problem 32 shows, Lemma 16 genuinely fails without boundedness of Λ , so this reduction is not a mere convenience.

Problem 2.32. Does Lemma 16 remain true if Λ is allowed to be finite or to be uncountably infinite? Does it remain true if Λ is allowed to be unbounded?

Solution. Recall Lemma 16: if E is a bounded measurable set of real numbers and there is a bounded, countably infinite set Λ of real numbers for which the collection of translates $\{\lambda + E\}_{\lambda \in \Lambda}$ is disjoint, then $m(E) = 0$. We examine the three proposed relaxations in turn. The answers are: no for finite Λ ,

yes for uncountably infinite (bounded) Λ , and no for unbounded Λ .

Finite Λ : the lemma fails. Let $E = [0, 1]$ and $\Lambda = \{0, 1\}$. Then E is bounded and measurable, Λ is bounded and finite, and the translates are $0 + E = [0, 1]$ and $1 + E = [1, 2]$, which are disjoint. Yet $m(E) = 1 \neq 0$. Even more simply, one may take $\Lambda = \{0\}$: the collection consisting of the single set E is trivially disjoint, so with $E = [0, 1]$ we again get a bounded measurable set of positive measure. The reason the proof of Lemma 16 breaks down is transparent from equation (15): with Λ finite, the right-hand sum $\sum_{\lambda \in \Lambda} m(\lambda + E) = (\#\Lambda) \cdot m(E)$ is finite whatever the value of $m(E)$, so no contradiction arises. It is exactly the infinitude of Λ that forces the sum of infinitely many equal positive numbers to be infinite.

Uncountably infinite Λ (still bounded): the lemma remains true. Suppose E is bounded and measurable, Λ is bounded and uncountably infinite, and $\{\lambda + E\}_{\lambda \in \Lambda}$ is disjoint. If $E = \emptyset$ then $m(E) = 0$ and there is nothing to prove, so assume $E \neq \emptyset$. Since Λ is infinite, it possesses a countably infinite subset $\Lambda_0 = \{\lambda_1, \lambda_2, \dots\}$: choose $\lambda_1 \in \Lambda$, and having chosen the distinct points $\lambda_1, \dots, \lambda_n$, the set $\Lambda \setminus \{\lambda_1, \dots, \lambda_n\}$ is nonempty because Λ is infinite, so a point λ_{n+1} may be chosen from it. Now Λ_0 is countably infinite, and it is bounded because Λ is. Moreover $\{\lambda + E\}_{\lambda \in \Lambda_0}$ is a subcollection of a disjoint collection and hence is disjoint. Lemma 16, applied to E and Λ_0 , yields $m(E) = 0$.

So allowing Λ to be uncountable does not change the conclusion; it merely weakens the hypothesis in an inessential way, since only a countably infinite bounded piece of Λ is ever used.

Unbounded Λ : the lemma fails. Let $E = [0, 1]$ and $\Lambda = \mathbb{Z}$. Then E is bounded and measurable, and Λ is countably infinite but unbounded. The translates are $n + E = [n, n + 1]$ for $n \in \mathbb{Z}$, and these are pairwise disjoint. Yet $m(E) = 1 \neq 0$. Here the proof of Lemma 16 breaks down at the following point: the argument used boundedness of Λ (together with boundedness of E) to conclude that $\bigcup_{\lambda \in \Lambda} (\lambda + E)$ is bounded and therefore of finite measure, which is what makes the left-hand side of (15) finite. With $\Lambda = \mathbb{Z}$ the union is all of $\mathbb{R}$, of infinite measure, and (15) reads $\infty = \sum_{n \in \mathbb{Z}} 1$, a true statement carrying no contradiction.

In summary, the two hypotheses on Λ play different roles and only one of them can be relaxed: Λ must be infinite (uncountable is fine), and Λ must be bounded.

Problem 2.33. Let E be a nonmeasurable set of finite outer measure. Show that there is a G_δ set G that contains E for which

$$m^*(E) = m^*(G), \quad \text{while } m^*(G \setminus E) > 0.$$

Solution. Write $\alpha = m^*(E)$, so that $0 \leq \alpha < \infty$ by hypothesis.

Construction of G . Fix a natural number n . By the definition of outer measure as an infimum, there is a countable collection $\{I_{n,k}\}_k$ of nonempty open, bounded intervals which covers E and for which

$$\sum_k \ell(I_{n,k}) < \alpha + \frac{1}{n}.$$

(The infimum is finite since $\alpha < \infty$, so such a collection exists.) Set $\mathcal{O}_n = \bigcup_k I_{n,k}$. Then $\mathcal{O}_n$ is an open set containing E , and by the countable subadditivity and monotonicity of measure together with $m(I) = \ell(I)$ for an interval I ,

$$m(\mathcal{O}_n) \leq \sum_k m(I_{n,k}) = \sum_k \ell(I_{n,k}) < \alpha + \frac{1}{n}.$$

Now define

$$G = \bigcap_{n=1}^{\infty} \mathcal{O}_n.$$

Being a countable intersection of open sets, G is a G_δ set; in particular G is measurable, since by Theorem 9 of this chapter the measurable sets form a σ -algebra containing the Borel sets, and every G_δ set is measurable. Each $\mathcal{O}_n$ contains E , so $E \subseteq G$.

Verification that $m^*(E) = m^*(G)$. By monotonicity of outer measure and $E \subseteq G$ we have $\alpha = m^*(E) \leq m^*(G)$. On the other hand, $G \subseteq \mathcal{O}_n$ for each n , so by monotonicity

$$m^*(G) \leq m(\mathcal{O}_n) < \alpha + \frac{1}{n} \quad \text{for every } n.$$

Letting $n \rightarrow \infty$ gives $m^*(G) \leq \alpha$. Hence $m^*(G) = \alpha = m^*(E)$, as required. Note in particular that $m(G) = \alpha < \infty$.

Verification that $m^*(G \sim E) > 0$. Suppose, to the contrary, that $m^*(G \sim E) = 0$. A set of outer measure zero is measurable (Proposition 4 of this chapter), so $G \sim E$ is measurable. But G is measurable, and the measurable sets form a σ -algebra, so

$$E = G \sim (G \sim E)$$

is measurable. (The displayed identity holds because $E \subseteq G$: a point of G lies outside $G \sim E$ precisely when it lies in E .) This contradicts the hypothesis that E fails to be measurable. Therefore $m^*(G \sim E) > 0$.

Thus G is a G_δ set containing E with $m^*(G) = m^*(E)$ and $m^*(G \sim E) > 0$, which is what was to be shown.

A remark on what this exhibits. Since E and $G \sim E$ are disjoint with union G , we have

$$m^*(E) + m^*(G \sim E) > m^*(E) = m(G) = m^*(E \cup (G \sim E)),$$

where the strict inequality uses $m^*(G \sim E) > 0$ together with the finiteness of $m^*(E)$. So the pair $E, G \sim E$ is an explicit disjoint pair for which the subadditivity inequality $m^*(A \cup B) \leq m^*(A) + m^*(B)$ is strict, exactly as promised by Theorem 18. The hypothesis $m^*(E) < \infty$ enters twice: it is what makes the covers used in the construction of G available at all, and it is what makes the last display a strict inequality rather than the vacuous $\infty > \infty$.

Problem 2.34. Show that there is a continuous, strictly increasing function on the interval $[0, 1]$ that maps a set of positive measure onto a set of measure zero.

Solution. Let φ denote the Cantor-Lebesgue function on $[0, 1]$, let $\mathbf{C}$ be the Cantor set, and let $\mathcal{O} = [0, 1] \setminus \mathbf{C}$ be the union of the countable disjoint collection $\{I_k\}_{k=1}^\infty$ of open intervals removed in the Cantor deletion process. By Proposition 19, $m(\mathbf{C}) = 0$, and hence $m(\mathcal{O}) = 1$; since the I_k are disjoint open intervals, countable additivity gives

$$\sum_{k=1}^{\infty} \ell(I_k) = m(\mathcal{O}) = 1.$$

By Proposition 20, φ is increasing and continuous and maps $[0, 1]$ onto $[0, 1]$; in particular $\varphi(0) = 0$ and $\varphi(1) = 1$. Moreover, by the very definition of φ on the removed intervals, φ is constant on each I_k .

Define ψ on $[0, 1]$ by

$$\psi(x) = \frac{\varphi(x) + x}{2}.$$

Step 1: ψ is a continuous, strictly increasing map of $[0, 1]$ onto $[0, 1]$. It is continuous as a linear combination of the continuous functions φ and the identity. If $0 \leq u < v \leq 1$ then $\varphi(u) \leq \varphi(v)$ because φ is increasing, while $u < v$; adding and halving gives $\psi(u) < \psi(v)$. Thus ψ is strictly increasing, and in particular one-to-one. Finally $\psi(0) = (\varphi(0) + 0)/2 = 0$ and $\psi(1) = (1 + 1)/2 = 1$; since ψ is increasing, its values on $[0, 1]$ lie in $[0, 1]$, and since ψ is continuous, the Intermediate Value Theorem shows every point of $[0, 1]$ is attained. Hence ψ is a one-to-one map of $[0, 1]$ onto $[0, 1]$.

Step 2: $m(\psi(\mathcal{O})) = 1/2$. Fix k and write $I_k = (a_k, b_k)$. Since φ is constant on I_k , say $\varphi \equiv c_k$ there, we

have $\psi(x) = (c_k + x)/2$ for $x \in I_k$, so

$$\psi(I_k) = \left(\frac{c_k + a_k}{2}, \frac{c_k + b_k}{2} \right),$$

an open interval of length $\ell(I_k)/2$. Because ψ is one-to-one and the I_k are disjoint, the collection $\{\psi(I_k)\}_{k=1}^{\infty}$ is disjoint. Therefore $\psi(\mathcal{O}) = \bigcup_{k=1}^{\infty} \psi(I_k)$ is open, hence measurable, and by countable additivity

$$m(\psi(\mathcal{O})) = \sum_{k=1}^{\infty} \ell(\psi(I_k)) = \frac{1}{2} \sum_{k=1}^{\infty} \ell(I_k) = \frac{1}{2}.$$

Step 3: $m(\psi(\mathbf{C})) = 1/2$. The set $\mathbf{C}$ is closed and bounded, and ψ is continuous, so $\psi(\mathbf{C})$ is compact, hence closed, hence measurable. Since ψ is a one-to-one map of $[0, 1]$ onto $[0, 1]$ and $[0, 1] = \mathbf{C} \cup \mathcal{O}$ is a disjoint decomposition, its image

$$[0, 1] = \psi(\mathbf{C}) \cup \psi(\mathcal{O})$$

is also a disjoint decomposition. By additivity of measure and Step 2,

$$m(\psi(\mathbf{C})) = m([0, 1]) - m(\psi(\mathcal{O})) = 1 - \frac{1}{2} = \frac{1}{2}.$$

Step 4: the function. Let $f = \psi^{-1}$, defined on $[0, 1]$ with values in $[0, 1]$; this makes sense by Step 1. As noted in the proof of Proposition 21 (and established in Problem 45), a strictly increasing continuous function defined on an interval has a continuous inverse, so f is continuous on $[0, 1]$. Moreover f is strictly increasing: if $0 \leq u < v \leq 1$, write $u = \psi(s)$ and $v = \psi(t)$ with $s, t \in [0, 1]$; were $s \geq t$ we would get $u = \psi(s) \geq \psi(t) = v$, a contradiction, so $s < t$, that is, $f(u) < f(v)$.

Now set $A = \psi(\mathbf{C}) \subseteq [0, 1]$. By Step 3, A is measurable with $m(A) = 1/2 > 0$, and since ψ is one-to-one and onto $[0, 1]$,

$$f(A) = \psi^{-1}(\psi(\mathbf{C})) = \mathbf{C},$$

which has measure zero by Proposition 19.

Thus f is a continuous, strictly increasing function on $[0, 1]$ carrying the set A of measure $1/2$ onto the set $\mathbf{C}$ of measure zero, as required.

Problem 2.35. Let f be an increasing function on the open interval I . For $x_0 \in I$ show that f is continuous at x_0 if and only if there are sequences $\{a_n\}$ and $\{b_n\}$ in I such that for each n , $a_n < x_0 < b_n$, and $\lim_{n \rightarrow \infty} [f(b_n) - f(a_n)] = 0$.

Solution. Recall that f increasing means $f(u) \leq f(v)$ whenever $u \leq v$ in I .

Necessity. Suppose f is continuous at x_0 . Since I is open and $x_0 \in I$, there is an $r > 0$ with $(x_0 - r, x_0 + r) \subseteq I$. For each natural number n define

$$a_n = x_0 - \frac{r}{n+1}, \quad b_n = x_0 + \frac{r}{n+1}.$$

Then a_n and b_n belong to I and $a_n < x_0 < b_n$ for every n , while $a_n \rightarrow x_0$ and $b_n \rightarrow x_0$. Continuity of f at x_0 (in its sequential form) gives $f(a_n) \rightarrow f(x_0)$ and $f(b_n) \rightarrow f(x_0)$, and therefore

$$\lim_{n \rightarrow \infty} [f(b_n) - f(a_n)] = f(x_0) - f(x_0) = 0.$$

Sufficiency. Suppose there are sequences $\{a_n\}$ and $\{b_n\}$ in I with $a_n < x_0 < b_n$ for each n and $f(b_n) - f(a_n) \rightarrow 0$. Note first that, since f is increasing and $a_n < x_0 < b_n$,

$$f(a_n) \leq f(x_0) \leq f(b_n) \quad \text{for every } n,$$

so each difference $f(b_n) - f(a_n)$ is nonnegative.

Let $\varepsilon > 0$. Choose an index N for which

$$f(b_N) - f(a_N) < \varepsilon,$$

and define

$$\delta = \min\{x_0 - a_N, b_N - x_0\} > 0.$$

Since a_N and b_N lie in the interval I , the whole interval (a_N, b_N) is contained in I ; and $(x_0 - \delta, x_0 + \delta) \subseteq (a_N, b_N)$ by the choice of δ . Hence every x with $|x - x_0| < \delta$ belongs to I and satisfies $a_N < x < b_N$. For such an x , monotonicity of f gives

$$f(a_N) \leq f(x) \leq f(b_N).$$

Since also $f(a_N) \leq f(x_0) \leq f(b_N)$, both $f(x)$ and $f(x_0)$ lie in the interval $[f(a_N), f(b_N)]$, whose length is less than ε . Consequently

$$|f(x) - f(x_0)| \leq f(b_N) - f(a_N) < \varepsilon.$$

Since $\varepsilon > 0$ was arbitrary, f is continuous at x_0 .

Remark. The hypothesis that f be increasing is essential in the sufficiency direction: it is what forces $f(x)$ to be trapped between $f(a_N)$ and $f(b_N)$ for all x between a_N and b_N , so that the smallness of a single difference $f(b_N) - f(a_N)$ controls the oscillation of f on an entire neighborhood of x_0 . The hypothesis that I be open is what guarantees, in the necessity direction, that points of I strictly on both sides of x_0 exist.

2.6 Problems 2.36–2.42

Problem 2.36. Show that if f is any increasing function on $[0, 1]$ that agrees with the Cantor-Lebesgue function φ on the complement of the Cantor set, then $f = \varphi$ on all of $[0, 1]$.

Solution. Write $\mathbf{C}$ for the Cantor set and $\mathcal{O} = [0, 1] \setminus \mathbf{C}$ for its complement in $[0, 1]$. We are given that f is increasing on $[0, 1]$ and that $f = \varphi$ on $\mathcal{O}$.

Step 1: $\mathcal{O}$ is dense in $[0, 1]$. By Proposition 19, $m(\mathbf{C}) = 0$. If some nondegenerate interval $J \subseteq [0, 1]$ were contained in $\mathbf{C}$, then by monotonicity of measure and Proposition 1 we would have $0 < \ell(J) = m(J) \leq m(\mathbf{C}) = 0$, a contradiction. Hence every nondegenerate subinterval of $[0, 1]$ contains a point of $\mathcal{O}$.

(Alternatively and without measure theory: $\mathbf{C} \subseteq C_k$, and C_k is a disjoint union of closed intervals of length 3^{-k} , so $\mathbf{C}$ contains no interval of length exceeding 3^{-k} for any k .)

Step 2: $f = \varphi$ at every interior point. Let $x \in \mathbf{C}$ with $0 < x < 1$, and let N be a natural number with $1/N < \min\{x, 1 - x\}$. For each $n \geq N$ the intervals $(x - 1/n, x)$ and $(x, x + 1/n)$ are nondegenerate subintervals of $[0, 1]$, so by Step 1 we may select points

$$u_n \in \mathcal{O} \cap (x - \frac{1}{n}, x), \quad v_n \in \mathcal{O} \cap (x, x + \frac{1}{n}).$$

Then $u_n < x < v_n$ and $u_n \rightarrow x$, $v_n \rightarrow x$.

Since f is increasing and agrees with φ on $\mathcal{O}$,

$$\varphi(u_n) = f(u_n) \leq f(x) \leq f(v_n) = \varphi(v_n).$$

Since φ is increasing (Proposition 20),

$$\varphi(u_n) \leq \varphi(x) \leq \varphi(v_n).$$

Thus both $f(x)$ and $\varphi(x)$ lie in the interval $[\varphi(u_n), \varphi(v_n)]$, so

$$|f(x) - \varphi(x)| \leq \varphi(v_n) - \varphi(u_n).$$

By Proposition 20 the function φ is continuous, so $\varphi(u_n) \rightarrow \varphi(x)$ and $\varphi(v_n) \rightarrow \varphi(x)$, whence the right-hand side tends to 0. Therefore $f(x) = \varphi(x)$.

Since $f = \varphi$ on $\mathcal{O}$ by hypothesis, and every point of $\mathbf{C} \cap (0, 1)$ has just been handled, we conclude that $f = \varphi$ on all of $(0, 1)$.

Step 3: the endpoints. Since φ is increasing and maps $[0, 1]$ onto $[0, 1]$ (Proposition 20), $\varphi(0) = 0$ and $\varphi(1) = 1$. The two points 0 and 1 lie in $\mathbf{C}$, and the argument of Step 2 is only one-sided there, so it

yields inequalities rather than equalities. By Step 1 we may choose $v_n \in \mathcal{O} \cap (0, 1/n)$, so that $v_n \downarrow 0$, and then

$$f(0) \leq f(v_n) = \varphi(v_n) \rightarrow \varphi(0) = 0,$$

so $f(0) \leq 0 = \varphi(0)$; symmetrically $f(1) \geq 1 = \varphi(1)$. With the natural normalization that f , like φ , takes its values in $[0, 1]$ (equivalently, that $f(0) \geq 0$ and $f(1) \leq 1$), these inequalities become equalities and $f = \varphi$ on all of $[0, 1]$.

Some such normalization is genuinely needed: the function g defined by $g(0) = -1$ and $g = \varphi$ on $(0, 1]$ is increasing on $[0, 1]$ and agrees with φ on $\mathcal{O}$ (note $0 \notin \mathcal{O}$, since $0 \in \mathbf{C}$), yet $g \neq \varphi$. The substance of the problem, namely that the values of φ on the measure-zero set $\mathbf{C}$ are completely determined by its values on the complement $\mathcal{O}$ together with monotonicity, is exactly what Step 2 establishes.

Problem 2.37. Let f be a continuous function defined on E . Is it true that $f^{-1}(A)$ is always measurable if A is measurable?

Solution. No. We exhibit a continuous function f defined on a closed bounded interval E and a measurable set A for which $f^{-1}(A)$ is not measurable.

Let φ be the Cantor-Lebesgue function and, as in Proposition 21, define

$$\psi(x) = \varphi(x) + x \quad \text{for } x \in [0, 1].$$

By Proposition 21, ψ is a strictly increasing continuous function that maps $[0, 1]$ onto $[0, 2]$, and, by assertion (ii) of that proposition, there is a measurable set A , a subset of the Cantor set $\mathbf{C}$, for which $\psi(A)$ is nonmeasurable.

Set $E = [0, 2]$ and let

$$f = \psi^{-1} : [0, 2] \rightarrow [0, 1].$$

This is well defined because ψ , being strictly increasing, is one-to-one, and it maps $[0, 1]$ onto $[0, 2]$.

The function f is continuous. This is Problem 45, and the proof is short: f is strictly increasing on $[0, 2]$ and its range is all of $[0, 1]$. If f failed to be continuous at some $y_0 \in [0, 2]$, then, f being increasing and bounded, the one-sided limits

$$\lambda = \sup_{y < y_0} f(y) \quad \text{and} \quad \mu = \inf_{y > y_0} f(y)$$

exist (interpreting the sup as $f(y_0)$ if $y_0 = 0$, and the inf as $f(y_0)$ if $y_0 = 2$) and satisfy $\lambda \leq f(y_0) \leq \mu$ with $\lambda < \mu$. But then f takes no value in (λ, μ) other than possibly $f(y_0)$, so its range omits points of the interval $(\lambda, \mu) \subseteq [0, 1]$, contradicting the fact that the range of f is all of $[0, 1]$.

Now compute the inverse image of A under f . For $y \in [0, 2]$,

$$y \in f^{-1}(A) \iff f(y) = \psi^{-1}(y) \in A \iff y \in \psi(A),$$

the last equivalence because ψ is a bijection of $[0, 1]$ onto $[0, 2]$. Hence

$$f^{-1}(A) = \psi(A).$$

The set A is measurable: it is a subset of $\mathbf{C}$, which has measure zero by Proposition 19, so $m^*(A) = 0$ by the monotonicity of outer measure, and therefore A is measurable by Proposition 4. But $\psi(A)$ is nonmeasurable by the choice of A . Therefore f is continuous on $E = [0, 2]$, the set A is measurable, and $f^{-1}(A)$ is not measurable.

Remark. What is true is that $f^{-1}(A)$ is measurable whenever f is continuous and A is a Borel set: the collection of sets B for which $f^{-1}(B)$ is measurable is a σ -algebra (inverse images preserve complements and countable unions), and it contains the open sets because f is continuous, hence it contains the smallest σ -algebra containing the open sets, namely the Borel sets. Compare Problem 46, where the same argument gives the sharper conclusion that $f^{-1}(A)$ is itself Borel. The example above shows this cannot be improved to Lebesgue measurable sets A ; this is consistent with Proposition 22, which asserts that there are Lebesgue measurable sets which are not Borel.

Problem 2.38. Let the function $f: [a, b] \rightarrow \mathbb{R}$ be Lipschitz, that is, there is a constant $c \geq 0$ such that for all $u, v \in [a, b]$, $|f(u) - f(v)| \leq c|u - v|$. Show that f maps a set of measure zero onto a set of measure zero. Show that f maps an F_σ set onto an F_σ set. Conclude that f maps a measurable set to a measurable set.

Solution. Throughout, all sets considered are subsets of $[a, b]$. Observe first that f is continuous, since $|f(u) - f(v)| \leq c|u - v|$ forces $f(v) \rightarrow f(u)$ as $v \rightarrow u$.

A basic estimate. Let J be any subset of $[a, b]$ that is contained in an interval of length ℓ . If J is empty the estimate below is trivial, so assume $J \neq \emptyset$. For all $u, v \in J$ we have $|f(u) - f(v)| \leq c|u - v| \leq c\ell$, so the set $f(J)$ is bounded and

$$\sup f(J) - \inf f(J) = \sup_{u, v \in J} |f(u) - f(v)| \leq c\ell.$$

Consequently $f(J)$ is contained in the closed bounded interval $[\inf f(J), \inf f(J) + c\ell]$, whose length is $c\ell$ (a degenerate one-point interval if $c = 0$ or $\ell = 0$). By the monotonicity of outer measure and Proposition 1,

$$m^*(f(J)) \leq c\ell.$$

Call this estimate (*).

Part 1: f maps a set of measure zero onto a set of measure zero.

Let $E \subseteq [a, b]$ with $m^*(E) = 0$, and let $\epsilon > 0$. By the definition of outer measure there is a countable collection $\{I_k\}_{k=1}^\infty$ of open intervals which covers E and for which

$$\sum_{k=1}^\infty \ell(I_k) < \epsilon.$$

For each k put $J_k = I_k \cap [a, b]$. Then $\{J_k\}$ covers E , each J_k is contained in an interval of length at most $\ell(I_k)$, and

$$f(E) \subseteq \bigcup_{k=1}^\infty f(J_k).$$

By the countable subadditivity of outer measure (Proposition 3), monotonicity, and the estimate (*),

$$m^*(f(E)) \leq \sum_{k=1}^\infty m^*(f(J_k)) \leq \sum_{k=1}^\infty c\ell(I_k) = c \sum_{k=1}^\infty \ell(I_k) \leq c\epsilon.$$

Since $\epsilon > 0$ was arbitrary, $m^*(f(E)) = 0$. In particular, by Proposition 4, $f(E)$ is measurable and $m(f(E)) = 0$.

Part 2: f maps an F_σ set onto an F_σ set.

Let $F \subseteq [a, b]$ be an F_σ set, say $F = \bigcup_{k=1}^\infty F_k$ with each F_k closed. Replacing F_k by $F_k \cap [a, b]$ (which is again closed, and does not change the union since $F \subseteq [a, b]$), we may assume each F_k is a closed subset of $[a, b]$. Then each F_k is closed and bounded, and f is continuous, so $f(F_k)$ is a compact, hence closed, subset of $\mathbb{R}$. (Concretely: $f(F_k)$ is bounded by the estimate (*) applied to $[a, b]$, and it is closed because if $y_n = f(x_n) \rightarrow y$ with $x_n \in F_k$, then by the Bolzano-Weierstrass Theorem a subsequence x_{n_j} converges to some x , which lies in F_k since F_k is closed, and then $y = \lim f(x_{n_j}) = f(x)$ by continuity, so $y \in f(F_k)$.)

Since images commute with unions,

$$f(F) = \bigcup_{k=1}^\infty f(F_k),$$

a countable union of closed sets, that is, an F_σ set.

Part 3: f maps a measurable set to a measurable set.

Let $E \subseteq [a, b]$ be measurable. By assertion (iv) of Theorem 11 there is an F_σ set F contained in E for which $m^*(E \setminus F) = 0$. Write

$$E = F \cup (E \setminus F), \quad \text{so} \quad f(E) = f(F) \cup f(E \setminus F).$$

By Part 2, $f(F)$ is an F_σ set; an F_σ set is a Borel set and therefore measurable by Theorem 9. By Part 1, $m^*(f(E \sim F)) = 0$, so $f(E \sim F)$ is measurable by Proposition 4. Since the measurable sets form a σ -algebra (Theorem 9), the union $f(E)$ of these two measurable sets is measurable.

Problem 2.39. Let F be the subset of $[0, 1]$ constructed in the same manner as the Cantor set except that each of the intervals removed at the n th deletion stage has length $\alpha 3^{-n}$ with $0 < \alpha < 1$. Show that F is a closed set, $[0, 1] \sim F$ dense in $[0, 1]$, and $m(F) = 1 - \alpha$. Such a set F is called a generalized Cantor set.

Solution. The construction. Set $F_0 = [0, 1]$. Having obtained F_{n-1} as a disjoint union of 2^{n-1} closed intervals, each of the same length ℓ_{n-1} , form F_n by removing from each of these 2^{n-1} intervals the open middle interval of length $\alpha 3^{-n}$; what remains is a disjoint union of 2^n closed intervals, each of the common length

$$\ell_n = \frac{\ell_{n-1} - \alpha 3^{-n}}{2}, \quad \ell_0 = 1.$$

Then $F = \bigcap_{n=0}^{\infty} F_n$.

The lengths ℓ_n . We claim

$$\ell_n = (1 - \alpha) 2^{-n} + \alpha 3^{-n} \quad \text{for all } n \geq 0.$$

Indeed this holds for $n = 0$, since $(1 - \alpha) + \alpha = 1$; and if it holds for $n - 1$, then

$$\frac{\ell_{n-1} - \alpha 3^{-n}}{2} = \frac{(1 - \alpha) 2^{-(n-1)} + \alpha 3^{-(n-1)} - \alpha 3^{-n}}{2} = (1 - \alpha) 2^{-n} + \frac{\alpha 3^{-n}(3 - 1)}{2} = (1 - \alpha) 2^{-n} + \alpha 3^{-n},$$

which is ℓ_n . In particular $\ell_n > 0$ for every n , since $0 < \alpha < 1$; so the construction never runs out of room and is legitimate. Also $\ell_n \rightarrow 0$.

F is closed. Each F_n is a finite union of closed intervals, hence closed. Therefore $F = \bigcap_{n=0}^{\infty} F_n$, being an intersection of closed sets, is closed.

$m(F) = 1 - \alpha$. Each F_n is the disjoint union of 2^n closed intervals of length ℓ_n , so by the finite additivity of Lebesgue measure and Proposition 1,

$$m(F_n) = 2^n \ell_n = 2^n [(1 - \alpha) 2^{-n} + \alpha 3^{-n}] = (1 - \alpha) + \alpha \left(\frac{2}{3}\right)^n.$$

The collection $\{F_n\}_{n=0}^{\infty}$ is a descending sequence of measurable sets with $m(F_0) = 1 < \infty$. Hence by the continuity of measure (Theorem 15),

$$m(F) = m\left(\bigcap_{n=0}^{\infty} F_n\right) = \lim_{n \rightarrow \infty} m(F_n) = \lim_{n \rightarrow \infty} [(1 - \alpha) + \alpha (2/3)^n] = 1 - \alpha.$$

(As a check, the total length removed is $\sum_{n=1}^{\infty} 2^{n-1} \cdot \alpha 3^{-n} = \frac{\alpha}{2} \sum_{n=1}^{\infty} (2/3)^n = \frac{\alpha}{2} \cdot 2 = \alpha$.)

$[0, 1] \sim F$ is dense in $[0, 1]$. It suffices to show that every nondegenerate interval $J \subseteq [0, 1]$ contains a point of $[0, 1] \sim F$; equivalently, that F contains no nondegenerate interval.

Suppose $J \subseteq F$ is an interval with $\ell(J) > 0$. Since $\ell_n \rightarrow 0$, choose n with $\ell_n < \ell(J)$. Then $J \subseteq F \subseteq F_n$. The set F_n is a disjoint union of 2^n closed intervals separated by nonempty open gaps, so a connected subset of F_n must lie inside a single one of those intervals: indeed, if J met two distinct components of F_n it would, by the intermediate value property of intervals, contain a point of one of the removed open gaps lying between them, contradicting $J \subseteq F_n$. Hence J is contained in a single component of F_n , and therefore

$$\ell(J) \leq \ell_n < \ell(J),$$

a contradiction. So F contains no nondegenerate interval, and every nondegenerate subinterval of $[0, 1]$ meets $[0, 1] \sim F$. Thus $[0, 1] \sim F$ is dense in $[0, 1]$.

(Note that this density statement is not a consequence of $m(F) = 1 - \alpha < 1$ alone; it uses the geometry of the construction. Conversely, F is a closed set with empty interior that nonetheless has positive measure $1 - \alpha > 0$, that is, a nowhere dense set of positive measure.)

Problem 2.40. Show that there is an open set of real numbers that, contrary to intuition, has a boundary of positive measure. (Hint: Consider the complement of the generalized Cantor set of the preceding problem.)

Solution. Fix α with $0 < \alpha < 1$ and let $F \subseteq [0, 1]$ be the generalized Cantor set of Problem 39, so that F is closed, $[0, 1] \sim F$ is dense in $[0, 1]$, and $m(F) = 1 - \alpha > 0$. Define

$$\mathcal{O} = (0, 1) \sim F = (0, 1) \cap (\mathbb{R} \sim F).$$

Since F is closed, $\mathbb{R} \sim F$ is open, and therefore $\mathcal{O}$, an intersection of two open sets, is an open set of real numbers.

Claim: $F \cap (0, 1) \subseteq \partial\mathcal{O}$.

Recall that $\partial\mathcal{O} = \overline{\mathcal{O}} \sim \text{int } \mathcal{O}$, and that $\text{int } \mathcal{O} = \mathcal{O}$ because $\mathcal{O}$ is open. So we must show that each $x \in F \cap (0, 1)$ is a point of closure of $\mathcal{O}$ but does not belong to $\mathcal{O}$.

That $x \notin \mathcal{O}$ is immediate from $x \in F$.

That x is a point of closure of $\mathcal{O}$: let $\epsilon > 0$. Since $0 < x < 1$, we may shrink ϵ so that $(x - \epsilon, x + \epsilon) \subseteq (0, 1)$. This is a nondegenerate subinterval of $[0, 1]$, so by Problem 39 the dense set $[0, 1] \sim F$ meets it; that is, there is a point

$$y \in (x - \epsilon, x + \epsilon) \quad \text{with} \quad y \notin F.$$

Since also $y \in (0, 1)$, we have $y \in \mathcal{O}$. Thus every neighborhood of x contains a point of $\mathcal{O}$, so $x \in \overline{\mathcal{O}}$. This proves the claim.

Conclusion. The boundary $\partial\mathcal{O}$ is a closed set, hence measurable by Theorem 9. Since 0 and 1 are never removed in the construction of F , we have $F \cap (0, 1) = F \sim \{0, 1\}$, and a two-point set has measure zero by Proposition 4, so by the excision property of measure

$$m(F \cap (0, 1)) = m(F) = 1 - \alpha.$$

Therefore, by the monotonicity of measure and the claim,

$$m(\partial\mathcal{O}) \geq m(F \cap (0, 1)) = 1 - \alpha > 0.$$

So $\mathcal{O}$ is an open set whose boundary has positive measure. (Taking α small makes $m(\partial\mathcal{O})$ as close to 1 as we please, while $\mathcal{O}$ itself is an open subset of $(0, 1)$ of measure α ; in fact here $\partial\mathcal{O} = F$, since $\overline{\mathcal{O}} = [0, 1]$.)

Problem 2.41. A nonempty subset X of $\mathbb{R}$ is called perfect provided it is closed and each neighborhood of any point in X contains infinitely many points of X . Show that the Cantor set is perfect. (Hint: The endpoints of all of the subintervals occurring in the Cantor construction belong to $\mathbf{C}$.)

Solution. Recall the construction: $C_0 = [0, 1]$, and C_k is the disjoint union of 2^k closed intervals each of length 3^{-k} , obtained from C_{k-1} by removing the open middle third of each of its components; $\mathbf{C} = \bigcap_{k=1}^{\infty} C_k$.

By Proposition 19 the set $\mathbf{C}$ is closed, and it is nonempty since (as we verify below) $0 \in \mathbf{C}$. It remains to show that each neighborhood of each point of $\mathbf{C}$ contains infinitely many points of $\mathbf{C}$.

Step 1: every endpoint of every component of every C_k belongs to $\mathbf{C}$.

Let e be an endpoint of a component J of C_k . We show by induction on $n \geq k$ that e is an endpoint of a component of C_n . This holds for $n = k$. Suppose e is an endpoint of a component J' of C_n . Passing to C_{n+1} deletes the open middle third of J' and leaves the two closed outer thirds of J' as components of C_{n+1} ; the two endpoints of J' are endpoints of these two outer thirds. Hence e is an endpoint of a component of C_{n+1} , completing the induction.

In particular $e \in C_n$ for every $n \geq k$, and since $C_0 \supseteq C_1 \supseteq \cdots$ we also have $e \in C_n$ for $n < k$. Therefore $e \in \bigcap_{n=1}^{\infty} C_n = \mathbf{C}$. (Applied to $C_0 = [0, 1]$, this gives $0, 1 \in \mathbf{C}$.)

Step 2: for each k , each component J of C_k meets $\mathbf{C}$ in an infinite set.

Fix $j \geq 1$. The set $J \cap C_{k+j}$ consists of exactly 2^j pairwise disjoint closed intervals of length $3^{-(k+j)}$: this is immediate by induction on j , since each of the components of C_{k+j-1} lying inside J splits into two components of C_{k+j} lying inside J .

Each of these 2^j intervals is a component of C_{k+j} , so by Step 1 both of its endpoints lie in $\mathbf{C}$; and both endpoints lie in J . Since the 2^j intervals are pairwise disjoint and nondegenerate, these 2^{j+1} endpoints are distinct. Hence $J \cap \mathbf{C}$ contains at least 2^{j+1} points. As $j \geq 1$ was arbitrary, $J \cap \mathbf{C}$ is infinite.

Step 3: conclusion.

Let $x \in \mathbf{C}$ and let $\mathcal{U}$ be a neighborhood of x ; choose $\epsilon > 0$ with $(x - \epsilon, x + \epsilon) \subseteq \mathcal{U}$. Choose a natural number k with $3^{-k} < \epsilon$. Since $x \in \mathbf{C} \subseteq C_k$, the point x belongs to some component J of C_k , and $\ell(J) = 3^{-k}$. For every $y \in J$ we then have

$$|y - x| \leq \ell(J) = 3^{-k} < \epsilon,$$

so $J \subseteq (x - \epsilon, x + \epsilon) \subseteq \mathcal{U}$.

By Step 2 the set $J \cap \mathbf{C}$ is infinite, and it is contained in $\mathcal{U} \cap \mathbf{C}$. Hence $\mathcal{U}$ contains infinitely many points of $\mathbf{C}$.

Since $\mathbf{C}$ is nonempty and closed, and every neighborhood of every point of $\mathbf{C}$ contains infinitely many points of $\mathbf{C}$, the Cantor set is perfect.

Problem 2.42. Prove that every perfect subset X of $\mathbb{R}$ is uncountable. (Hint: If X is countable, construct a descending sequence of bounded, closed subsets of X whose intersection is empty.)

Solution. Let $X \subseteq \mathbb{R}$ be perfect: nonempty, closed, and such that every neighborhood of every point of X contains infinitely many points of X .

First note that X is infinite. Indeed, pick $x \in X$; the neighborhood $(x - 1, x + 1)$ of x already contains infinitely many points of X .

Suppose, to get a contradiction, that X is countable. Being infinite and countable, it may be enumerated as $X = \{x_n\}_{n=1}^{\infty}$. For $y \in \mathbb{R}$ and $r > 0$ write $B(y, r) = (y - r, y + r)$ and $\bar{B}(y, r) = [y - r, y + r]$.

Construction. We construct points $y_n \in X$ and radii $r_n > 0$ such that, setting

$$F_n = X \cap \bar{B}(y_n, r_n),$$

we have for every n :

1. $y_n \in X$, so $F_n \neq \emptyset$;
2. $x_n \notin F_n$;
3. $\bar{B}(y_{n+1}, r_{n+1}) \subseteq B(y_n, r_n)$, so that $F_{n+1} \subseteq F_n$.

Base step. Since X is infinite, choose $y_1 \in X$ with $y_1 \neq x_1$, and put $r_1 = \frac{1}{2}|y_1 - x_1| > 0$. Then $y_1 \in F_1$ and $x_1 \notin \bar{B}(y_1, r_1)$, so $x_1 \notin F_1$.

Inductive step. Suppose $y_n \in X$ and $r_n > 0$ have been chosen. Since $y_n \in X$, the neighborhood $B(y_n, r_n)$ of y_n contains infinitely many points of X . At most one of them equals x_{n+1} , so we may choose

$$y_{n+1} \in X \cap B(y_n, r_n) \quad \text{with} \quad y_{n+1} \neq x_{n+1}.$$

Now choose $r_{n+1} > 0$ with

$$r_{n+1} < \min \left\{ r_n - |y_{n+1} - y_n|, \frac{1}{2}|y_{n+1} - x_{n+1}| \right\},$$

both quantities being strictly positive by the choice of y_{n+1} . The first constraint gives $\bar{B}(y_{n+1}, r_{n+1}) \subseteq B(y_n, r_n)$: if $|z - y_{n+1}| \leq r_{n+1}$ then

$$|z - y_n| \leq |z - y_{n+1}| + |y_{n+1} - y_n| \leq r_{n+1} + |y_{n+1} - y_n| < r_n.$$

The second gives $x_{n+1} \notin \bar{B}(y_{n+1}, r_{n+1})$. Properties 1, 2, 3 hold, and the construction proceeds.

The contradiction. Each $F_n = X \cap \bar{B}(y_n, r_n)$ is the intersection of two closed sets (X is closed by hypothesis, $\bar{B}(y_n, r_n)$ is closed), hence closed; it is bounded, being contained in $\bar{B}(y_n, r_n)$; and it is

nonempty, since $y_n \in X \cap \bar{B}(y_n, r_n)$. By property 3,

$$F_1 \supseteq F_2 \supseteq F_3 \supseteq \cdots,$$

so $\{F_n\}_{n=1}^\infty$ is a descending countable collection of nonempty closed sets of real numbers with F_1 bounded. By the Nested Set Theorem,

$$\bigcap_{n=1}^\infty F_n \neq \emptyset.$$

On the other hand, let $z \in \bigcap_{n=1}^\infty F_n$. Then $z \in F_1 \subseteq X$, so $z = x_N$ for some natural number N . But $z \in F_N$, while property 2 says $x_N \notin F_N$ - a contradiction. Hence the intersection is empty.

These two conclusions are incompatible, so X cannot be countable. Therefore every perfect subset of $\mathbb{R}$ is uncountable.

2.7 Problems 2.43–2.47

Problem 2.43. Use the preceding two problems to provide another proof of the uncountability of the Cantor set.

Solution. The two preceding problems are the following. Problem 41: a nonempty subset X of $\mathbb{R}$ is called *perfect* provided it is closed and each neighborhood of any point in X contains infinitely many points of X ; the Cantor set $\mathbf{C}$ is perfect. Problem 42: every perfect subset of $\mathbb{R}$ is uncountable. Granting these two assertions, the Cantor set is uncountable, since by Problem 41 it is perfect and by Problem 42 every perfect set is uncountable. For completeness we carry out both arguments, using only the description of the Cantor set given in Section 2.7 and results from Chapter 1.

Recall the construction: $C_0 = [0, 1]$, and C_{k+1} is obtained from C_k by removing the open middle third of each of the 2^k disjoint closed intervals of length 3^{-k} whose union is C_k ; then

$$\mathbf{C} = \bigcap_{k=1}^\infty C_k.$$

By Proposition 19 the set $\mathbf{C}$ is closed, and it is nonempty since $0 \in C_k$ for every k .

Step 1: the endpoints of every interval occurring in the construction belong to $\mathbf{C}$.

Let $J = [a, b]$ be one of the 2^k closed intervals whose union is C_k . In passing from C_k to C_{k+1} the open middle third of J is deleted, so the two intervals of C_{k+1} contained in J are $[a, a + (b - a)/3]$ and $[b - (b - a)/3, b]$. Thus a is the left endpoint of an interval of C_{k+1} and b is the right endpoint of an interval of C_{k+1} . Iterating this observation, for every $j \geq k$ the points a and b are endpoints of intervals of C_j , and in particular $a, b \in C_j$. Since the collection $\{C_j\}$ is descending, $a, b \in C_j$ for $j < k$ as well. Hence $a, b \in \bigcap_{j \geq 1} C_j = \mathbf{C}$.

Step 2: $\mathbf{C}$ is perfect.

The set $\mathbf{C}$ is nonempty and closed. Let $x \in \mathbf{C}$ and let $\mathcal{O}$ be a neighborhood of x ; choose $r > 0$ with $(x - r, x + r) \subseteq \mathcal{O}$. Choose an index k with $3^{-k} < r$. Since $x \in \mathbf{C} \subseteq C_k$ and C_k is the disjoint union of 2^k closed intervals of length 3^{-k} , the point x belongs to one of them, say J . Every point y of J satisfies $|y - x| \leq 3^{-k} < r$, so

$$J \subseteq (x - r, x + r) \subseteq \mathcal{O}.$$

Now fix $j > k$. Exactly 2^{j-k} of the intervals whose disjoint union is C_j are contained in J (each interval of C_i inside J splits into two intervals of C_{i+1} inside J , and this is an induction on i starting at $i = k$). These 2^{j-k} intervals are pairwise disjoint, and by Step 1 the left endpoint of each of them belongs to $\mathbf{C}$. Hence $J \cap \mathbf{C}$ contains at least 2^{j-k} points. As j may be taken arbitrarily large, $J \cap \mathbf{C}$ is infinite, and therefore $\mathcal{O} \cap \mathbf{C}$ is infinite. Thus $\mathbf{C}$ is perfect.

Step 3: a perfect subset of $\mathbb{R}$ is uncountable.

Let X be perfect and suppose, to get a contradiction, that X is countable. Since X is nonempty it may be enumerated as $X = \{x_1, x_2, x_3, \dots\}$ (a finite list is handled by repetition, but in fact the perfectness of X already forces X to be infinite). We construct inductively points $y_n \in X$ and radii $r_n > 0$ such

that, writing

$$I_n = [y_n - r_n, y_n + r_n], \quad F_n = X \cap I_n,$$

we have for every n :

(i) $F_n \neq \emptyset$; (ii) $I_{n+1} \subseteq (y_n - r_n, y_n + r_n)$, hence $F_{n+1} \subseteq F_n$; (iii) $x_n \notin I_n$, hence $x_n \notin F_n$.

To begin, pick any point $y_0 \in X$ and put $r_0 = 1$. Suppose $y_{n-1} \in X$ and $r_{n-1} > 0$ have been chosen ($n \geq 1$). The interval $(y_{n-1} - r_{n-1}, y_{n-1} + r_{n-1})$ is a neighborhood of the point y_{n-1} of X , so it contains infinitely many points of X ; in particular we may choose

$$y_n \in X \cap (y_{n-1} - r_{n-1}, y_{n-1} + r_{n-1}) \quad \text{with} \quad y_n \neq x_n.$$

Since $y_n \neq x_n$ and y_n lies in the open interval $(y_{n-1} - r_{n-1}, y_{n-1} + r_{n-1})$, we may choose $r_n > 0$ so small that

$$r_n < |y_n - x_n| \quad \text{and} \quad [y_n - r_n, y_n + r_n] \subseteq (y_{n-1} - r_{n-1}, y_{n-1} + r_{n-1}).$$

Then (iii) holds because $|x_n - y_n| > r_n$, and (ii) holds by the second requirement; (i) holds because $y_n \in F_n$.

Each $F_n = X \cap I_n$ is the intersection of two closed sets, hence closed, and it is bounded since I_n is bounded. By (i) and (ii), $\{F_n\}_{n=1}^{\infty}$ is a descending countable collection of nonempty bounded closed sets of real numbers. By the Nested Set Theorem there is a point

$$x \in \bigcap_{n=1}^{\infty} F_n.$$

Since $F_1 \subseteq X$, we have $x \in X$, so $x = x_N$ for some index N . But $x \in F_N$, contradicting (iii), which says $x_N \notin F_N$. This contradiction shows X is uncountable.

Conclusion. By Step 2 the Cantor set $\mathbf{C}$ is a perfect subset of $\mathbb{R}$, and by Step 3 every perfect subset of $\mathbb{R}$ is uncountable. Therefore $\mathbf{C}$ is uncountable, which is a second proof of the uncountability asserted in Proposition 19.

Problem 2.44. A subset A of $\mathbb{R}$ is said to be *nowhere dense* in $\mathbb{R}$ provided that for every open set $\mathcal{O}$, $\mathcal{O}$ has an open subset that is disjoint from A . Show that the Cantor set is nowhere dense in $\mathbb{R}$.

Solution. Of course the empty set is an open subset of every open set and is disjoint from A , so the definition is to be read as requiring a *nonempty* open subset; we prove this stronger statement for the Cantor set $\mathbf{C}$.

Let $\mathcal{O}$ be a nonempty open set of real numbers. Choose a point $x \in \mathcal{O}$. Since $\mathcal{O}$ is open there is an $r > 0$ for which

$$(x - r, x + r) \subseteq \mathcal{O}.$$

We first observe that the open interval $(x - r, x + r)$ is not contained in $\mathbf{C}$. Indeed, by Proposition 19 the Cantor set has measure zero, $m(\mathbf{C}) = 0$, whereas the measure of an interval is its length, so

$$m((x - r, x + r)) = 2r > 0.$$

If we had $(x - r, x + r) \subseteq \mathbf{C}$, then by the monotonicity of Lebesgue measure we would get $2r = m((x - r, x + r)) \leq m(\mathbf{C}) = 0$, a contradiction. Hence there is a point

$$z \in (x - r, x + r) \quad \text{with} \quad z \notin \mathbf{C}.$$

By Proposition 19 the set $\mathbf{C}$ is closed, so its complement $\mathbb{R} \sim \mathbf{C}$ is open. Define

$$\mathcal{U} = (x - r, x + r) \cap (\mathbb{R} \sim \mathbf{C}).$$

Then $\mathcal{U}$ is open, being the intersection of two open sets; it is nonempty, since $z \in \mathcal{U}$; it is contained in $\mathcal{O}$, since $\mathcal{U} \subseteq (x - r, x + r) \subseteq \mathcal{O}$; and it is disjoint from $\mathbf{C}$ by its very definition. Thus every nonempty open set $\mathcal{O}$ has a nonempty open subset disjoint from $\mathbf{C}$, that is, $\mathbf{C}$ is nowhere dense in $\mathbb{R}$.

Two remarks. First, closedness of $\mathbf{C}$ was used only to make $\mathcal{U}$ open. The same two paragraphs prove, for an arbitrary *closed* set A , that A is nowhere dense if and only if A has empty interior: if A contains no nonempty open set, then for a given nonempty open $\mathcal{O}$ we may choose $z \in \mathcal{O} \sim A$, and $\mathcal{O} \cap (\mathbb{R} \sim A)$ is then a nonempty open subset of $\mathcal{O}$ disjoint from A ; conversely, if some nonempty open $\mathcal{O}_0$ is contained in A , then every nonempty open subset of $\mathcal{O}_0$ meets A , so A is not nowhere dense. Since $\mathbf{C}$ is closed and, as shown above, contains no open interval, $\mathbf{C}$ indeed has empty interior.

Second, the appeal to measure can be replaced by a direct appeal to the construction. Given the interval $(x - r, x + r)$, if it fails to meet $[0, 1]$ it is itself a nonempty open subset of $\mathcal{O}$ that is disjoint from $\mathbf{C} \subseteq [0, 1]$, and we are done. Otherwise pick $y \in (x - r, x + r) \cap [0, 1]$; since $|y - x| < r$ we may then choose an index k with

$$3^{-k} < r - |y - x|.$$

If $y \notin \mathbf{C}$ we may take $z = y$ in the argument above. If $y \in \mathbf{C}$, then y lies in one of the 2^k closed intervals J of length 3^{-k} whose disjoint union is C_k , and every point w of J satisfies $|w - x| \leq |w - y| + |y - x| \leq 3^{-k} + |y - x| < r$, so $J \subseteq (x - r, x + r) \subseteq \mathcal{O}$. The open middle third of J is deleted in passing from C_k to C_{k+1} and so is disjoint from $\mathbf{C}$; it is therefore a nonempty open subset of $\mathcal{O}$ disjoint from $\mathbf{C}$.

Problem 2.45. Show that a strictly increasing function that is defined on an interval has a continuous inverse.

Solution. Let I be an interval of real numbers and let $f: I \rightarrow \mathbb{R}$ be strictly increasing, that is, $f(u) < f(v)$ whenever $u, v \in I$ and $u < v$. Set $E = f(I)$, the image of I . No continuity is assumed of f , and E need not be an interval.

The function f is one-to-one: if $u, v \in I$ and $u \neq v$, then either $u < v$ or $v < u$, and in either case strict monotonicity gives $f(u) \neq f(v)$. Hence f is a one-to-one map of I onto E and the inverse function

$$g = f^{-1}: E \rightarrow I, \quad g(f(x)) = x \quad (x \in I), \quad f(g(y)) = y \quad (y \in E)$$

is well defined. We must show that g is continuous on E , continuity being understood, as always, relative to the domain E : g is continuous at $y_0 \in E$ provided for each $\varepsilon > 0$ there is a $\delta > 0$ such that $|g(y) - g(y_0)| < \varepsilon$ for all $y \in E$ with $|y - y_0| < \delta$.

First observe that g is strictly increasing on E . Indeed, let $y_1, y_2 \in E$ with $y_1 < y_2$ and suppose $g(y_1) \geq g(y_2)$. If $g(y_1) = g(y_2)$ then $y_1 = f(g(y_1)) = f(g(y_2)) = y_2$, a contradiction; if $g(y_1) > g(y_2)$ then, since f is strictly increasing, $y_1 = f(g(y_1)) > f(g(y_2)) = y_2$, again a contradiction. Hence $g(y_1) < g(y_2)$.

Now fix $y_0 \in E$, put $x_0 = g(y_0) \in I$, and let $\varepsilon > 0$. If I consists of the single point x_0 , then $E = \{y_0\}$ and continuity at y_0 is trivial (any δ works). So assume I has more than one point. We treat the two sides of x_0 separately.

Left side. Suppose first that there is a point $a \in I$ with $a < x_0$. Since I is an interval containing a and x_0 , we have $[a, x_0] \subseteq I$, and this interval contains points strictly between $\max\{a, x_0 - \varepsilon\}$ and x_0 ; choose such a point u , so that

$$u \in I, \quad x_0 - \varepsilon < u < x_0.$$

Since f is strictly increasing, $f(u) < f(x_0) = y_0$, so $\delta_1 := y_0 - f(u) > 0$. If instead there is no point of I strictly below x_0 , put $\delta_1 := 1$.

Right side. Symmetrically, if there is a point $b \in I$ with $b > x_0$, choose $v \in I$ with $x_0 < v < \min\{b, x_0 + \varepsilon\}$; then $y_0 = f(x_0) < f(v)$, and we put $\delta_2 := f(v) - y_0 > 0$. If there is no point of I strictly above x_0 , put $\delta_2 := 1$.

Define $\delta = \min\{\delta_1, \delta_2\} > 0$, and let $y \in E$ satisfy $|y - y_0| < \delta$. We claim $|g(y) - x_0| < \varepsilon$.

Consider the lower bound. If I has no point strictly below x_0 , then x_0 is the smallest element of I , so $g(y) \in I$ forces $g(y) \geq x_0 > x_0 - \varepsilon$. Otherwise u was chosen as above and

$$y > y_0 - \delta \geq y_0 - \delta_1 = f(u),$$

so, g being strictly increasing on E and $f(u) \in E$,

$$g(y) > g(f(u)) = u > x_0 - \varepsilon.$$

In either case $g(y) > x_0 - \varepsilon$.

Consider the upper bound. If I has no point strictly above x_0 , then x_0 is the largest element of I and $g(y) \leq x_0 < x_0 + \varepsilon$. Otherwise v was chosen as above and

$$y < y_0 + \delta \leq y_0 + \delta_2 = f(v),$$

so $g(y) < g(f(v)) = v < x_0 + \varepsilon$. In either case $g(y) < x_0 + \varepsilon$.

Therefore $x_0 - \varepsilon < g(y) < x_0 + \varepsilon$, that is, $|g(y) - g(y_0)| < \varepsilon$, for every $y \in E$ with $|y - y_0| < \delta$. Since $y_0 \in E$ was arbitrary, the inverse function $g = f^{-1}$ is continuous on $E = f(I)$.

Problem 2.46. Let f be a continuous function and B be a Borel set. Show that $f^{-1}(B)$ is a Borel set. (Hint: The collection of sets E for which $f^{-1}(E)$ is Borel is a σ -algebra containing the open sets.)

Solution. Let f be a real-valued continuous function whose domain D is a Borel set of real numbers; the case $D = \mathbb{R}$ is the one usually intended, and the case in which D is an interval is the one needed in the next problem. Some such assumption on the domain is necessary: if D is not Borel then already $f^{-1}(\mathbb{R}) = D$ fails to be Borel. Denote by $\mathcal{B}$ the collection of Borel sets, that is, by definition, the smallest σ -algebra of subsets of $\mathbb{R}$ that contains all of the open sets.

Following the hint, define

$$\mathcal{A} = \{ E \subseteq \mathbb{R} : f^{-1}(E) \in \mathcal{B} \},$$

where $f^{-1}(E) = \{x \in D : f(x) \in E\}$.

Step 1: $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$.

The set $\mathbb{R}$ belongs to $\mathcal{A}$, since $f^{-1}(\mathbb{R}) = D$ and D is Borel by assumption. Next, let $E \in \mathcal{A}$. Since f is a function defined on D , a point $x \in D$ lies in $f^{-1}(\mathbb{R} \setminus E)$ if and only if $f(x) \notin E$, that is, if and only if $x \notin f^{-1}(E)$. Hence

$$f^{-1}(\mathbb{R} \setminus E) = D \setminus f^{-1}(E) = D \cap (\mathbb{R} \setminus f^{-1}(E)).$$

Since $\mathcal{B}$ is a σ -algebra containing D and $f^{-1}(E)$, the right-hand side belongs to $\mathcal{B}$. Thus $\mathbb{R} \setminus E \in \mathcal{A}$, so $\mathcal{A}$ is closed under the formation of complements. Finally, let $\{E_k\}_{k=1}^{\infty}$ be a countable collection of sets in $\mathcal{A}$. For $x \in D$ we have $f(x) \in \bigcup_k E_k$ if and only if $f(x) \in E_k$ for some k , so

$$f^{-1}\left(\bigcup_{k=1}^{\infty} E_k\right) = \bigcup_{k=1}^{\infty} f^{-1}(E_k),$$

which is a countable union of Borel sets and hence Borel. Thus $\bigcup_k E_k \in \mathcal{A}$. Therefore $\mathcal{A}$ is a σ -algebra.

Step 2: $\mathcal{A}$ contains every open set.

Let $\mathcal{O}$ be an open set of real numbers. Since f is continuous on D , Proposition 22 of Chapter 1 tells us that there is an open set U for which

$$f^{-1}(\mathcal{O}) = D \cap U.$$

Both D and U are Borel sets (U is open, and the Borel sets contain the open sets), and $\mathcal{B}$ is closed under finite intersections, being a σ -algebra. Hence $f^{-1}(\mathcal{O}) \in \mathcal{B}$, that is, $\mathcal{O} \in \mathcal{A}$.

Step 3: conclusion.

By Steps 1 and 2, $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$ that contains all the open sets. Since $\mathcal{B}$ is the smallest such σ -algebra, we conclude

$$\mathcal{B} \subseteq \mathcal{A}.$$

Thus if B is a Borel set, then $B \in \mathcal{A}$, which is precisely the assertion that $f^{-1}(B)$ is a Borel set.

In particular, taking $D = \mathbb{R}$: the inverse image under a continuous real-valued function on $\mathbb{R}$ of an open set is open, of a closed set is closed (take complements), and of a Borel set is Borel.

Problem 2.47. Use the preceding two problems to show that a continuous strictly increasing function that is defined on an interval maps Borel sets to Borel sets.

Solution. Let I be an interval of real numbers and let $f: I \rightarrow \mathbb{R}$ be continuous and strictly increasing. Let B be a Borel set. We show that $f(B \cap I)$ is a Borel set; in particular, if B is a Borel subset of I , then $f(B)$ is a Borel set. We may assume I is nonempty.

Step 1: the image $E = f(I)$ is an interval, and hence a Borel set.

We check that E has the intermediate value property. Let $y_1, y_2 \in E$ with $y_1 < y_2$, and let y satisfy $y_1 < y < y_2$. Write $y_1 = f(x_1)$ and $y_2 = f(x_2)$ with $x_1, x_2 \in I$. Since f is strictly increasing and $f(x_1) < f(x_2)$, we must have $x_1 < x_2$. As I is an interval, $[x_1, x_2] \subseteq I$, and f is continuous on $[x_1, x_2]$. By the Intermediate Value Theorem there is a point $x \in (x_1, x_2)$ with $f(x) = y$. Since $x \in I$, we conclude $y \in E$.

A nonempty set E of real numbers with this property is an interval: let $\alpha = \inf E$ and $\beta = \sup E$ in the extended reals. If $\alpha < y < \beta$, then by the definitions of infimum and supremum there are $y_1, y_2 \in E$ with $y_1 < y < y_2$, so $y \in E$; thus $(\alpha, \beta) \subseteq E \subseteq [\alpha, \beta]$, and E is an interval (possibly degenerate, if I is a single point). Every interval is a Borel set, being open, closed, or the union of an open interval with one or two of its endpoints. Hence E is a Borel set.

Step 2: the inverse function is continuous on E .

The function f is strictly increasing on the interval I , so by Problem 45 it is one-to-one and its inverse

$$g = f^{-1}: E \rightarrow I$$

is a continuous function defined on $E = f(I)$.

Step 3: apply Problem 46 to g .

The function g is continuous and its domain E is a Borel set by Step 1. Therefore, by Problem 46, for every Borel set B the inverse image $g^{-1}(B)$ is a Borel set.

Step 4: identify $g^{-1}(B)$ as an image under f .

We claim

$$g^{-1}(B) = f(B \cap I).$$

Indeed, suppose $y \in g^{-1}(B)$. Then $y \in E$ and $g(y) \in B$. Put $x = g(y)$; then $x \in I$, $x \in B$, and $f(x) = f(g(y)) = y$. Hence $y \in f(B \cap I)$. Conversely, suppose $y \in f(B \cap I)$, say $y = f(x)$ with $x \in B \cap I$. Then $y \in f(I) = E$ and $g(y) = g(f(x)) = x \in B$, so $y \in g^{-1}(B)$. This proves the claim.

Conclusion. Combining Steps 3 and 4, for every Borel set B the set

$$f(B \cap I) = g^{-1}(B)$$

is a Borel set. In particular a continuous, strictly increasing function defined on an interval maps Borel subsets of that interval onto Borel sets. Since such an f is one-to-one, it maps I onto the interval E and carries Borel sets onto Borel sets, which is exactly the fact invoked in the proof of Proposition 22 of Chapter 2 to produce a measurable subset of the Cantor set that is not Borel.

A remark on where the hypotheses entered. Continuity of f was used only in Step 1, to know that $E = f(I)$ is an interval and therefore a Borel set, which is what makes Problem 46 applicable to g . Strict monotonicity was used twice: to know that f is one-to-one, so that the identification $f(B \cap I) = g^{-1}(B)$ of Step 4 is valid, and to invoke Problem 45 for the continuity of g . Note that no continuity of g beyond that supplied by Problem 45 is needed, and no appeal to measurability of f is made anywhere.

3.1 Problems 3.1–3.7

Problem 3.1. Suppose f and g are continuous functions on $[a, b]$. Show that if $f = g$ a.e. on $[a, b]$, then, in fact, $f = g$ on $[a, b]$. Is a similar assertion true if $[a, b]$ is replaced by a general measurable set E ?

Solution. Throughout, $[a, b]$ is a nondegenerate closed bounded interval, so $a < b$.

Put $h = f - g$ on $[a, b]$. Since f and g are continuous, so is h , and the hypothesis that $f = g$ a.e. means precisely that there is a measurable set $Z \subseteq [a, b]$ with $m(Z) = 0$ such that $f = g$, that is $h = 0$, on $[a, b] \setminus Z$. Hence

$$E_0 = \{x \in [a, b] \mid h(x) \neq 0\} \subseteq Z,$$

so by the monotonicity of Lebesgue outer measure $m^*(E_0) = 0$; every set of outer measure zero is measurable (Chapter 2), so E_0 is measurable and $m(E_0) = 0$.

Suppose, to get a contradiction, that $h(x_0) \neq 0$ for some $x_0 \in [a, b]$. Set $\varepsilon = |h(x_0)|/2 > 0$. By the continuity of h at x_0 there is a $\delta > 0$ such that

$$|h(x) - h(x_0)| < \varepsilon \quad \text{for all } x \in [a, b] \text{ with } |x - x_0| < \delta.$$

For such x the triangle inequality gives

$$|h(x)| \geq |h(x_0)| - |h(x) - h(x_0)| > 2\varepsilon - \varepsilon = \varepsilon > 0,$$

so $h(x) \neq 0$. Therefore

$$I = (x_0 - \delta, x_0 + \delta) \cap [a, b] \subseteq E_0.$$

Now I is the intersection of two intervals, hence an interval, and it is nondegenerate: if $a < x_0 < b$ it contains the interval $(x_0 - \delta', x_0 + \delta')$ with $\delta' = \min\{\delta, x_0 - a, b - x_0\} > 0$; if $x_0 = a$ it contains $[a, a + \delta'']$ with $\delta'' = \min\{\delta, b - a\} > 0$; and if $x_0 = b$ it contains $(b - \delta'', b]$. In each case I contains an interval of positive length, so by the monotonicity of outer measure and the fact that the measure of an interval is its length (Chapter 2),

$$m(E_0) \geq m(I) > 0,$$

contradicting $m(E_0) = 0$. Hence $h(x) = 0$ for every $x \in [a, b]$, that is, $f = g$ on all of $[a, b]$.

Now replace $[a, b]$ by a general measurable set E . The assertion is false in general. Take

$$E = [0, 1] \cup \{2\}, \quad f \equiv 0 \text{ on } E, \quad g(x) = \begin{cases} 0 & \text{if } x \in [0, 1], \\ 1 & \text{if } x = 2. \end{cases}$$

Both are continuous on E : f is constant, and g is continuous at each point of $[0, 1]$ because g vanishes on the relative neighborhood $E \cap (-1, 2) = [0, 1]$ of each such point, while 2 is an isolated point of E , so every function on E is continuous there. Moreover $\{x \in E \mid f(x) \neq g(x)\} = \{2\}$ has measure zero, so $f = g$ a.e. on E . Yet $f(2) \neq g(2)$.

The argument given for $[a, b]$ isolates exactly what is needed, and in fact the following characterization holds: for a measurable set E , every pair of continuous functions on E that agree a.e. on E agrees on all of E if and only if

$$m(E \cap (x - r, x + r)) > 0 \quad \text{for every } x \in E \text{ and every } r > 0. \quad (*)$$

Indeed, assume $(*)$ and suppose f, g are continuous on E with $f = g$ a.e. If $h = f - g$ satisfied $h(x_0) \neq 0$ for some $x_0 \in E$, then exactly as above there is $\delta > 0$ with $h \neq 0$ on $E \cap (x_0 - \delta, x_0 + \delta)$, and by $(*)$ this set has positive measure; but it is contained in $\{x \in E \mid h(x) \neq 0\}$, which as above has measure zero, a contradiction. Conversely, if $(*)$ fails, say $m(E \cap (x_0 - r, x_0 + r)) = 0$ for some $x_0 \in E$ and $r > 0$, put $f \equiv 0$ on E and

$$g(x) = \max \left\{ 0, 1 - \frac{|x - x_0|}{r} \right\}.$$

Then g is continuous on all of $\mathbb{R}$, hence on E , and g vanishes off $(x_0 - r, x_0 + r)$, so $\{x \in E \mid f(x) \neq g(x)\} \subseteq E \cap (x_0 - r, x_0 + r)$ has measure zero; but $g(x_0) = 1 \neq 0 = f(x_0)$.

Since $(*)$ holds for $E = [a, b]$ with $a < b$, this recovers the first part. It also fails for the set $E = [0, 1] \cup \{2\}$ at the point $x = 2$, which is why the counterexample above works.

Problem 3.2. Let D and E be measurable sets and f a function with domain $D \cup E$. We proved that f is measurable on $D \cup E$ if and only if its restrictions to D and E are measurable. Is the same true if “measurable” is replaced by “continuous”?

Solution. No. One implication survives, the other does not.

The implication that does survive is the forward one: if f is continuous on $D \cup E$, then its restrictions $f|_D$ and $f|_E$ are continuous. This is immediate from the definition of continuity relative to a domain. Let $x_0 \in D$ and let $\varepsilon > 0$. Continuity of f at x_0 as a function on $D \cup E$ gives a $\delta > 0$ such that $|f(x) - f(x_0)| < \varepsilon$ whenever $x \in D \cup E$ and $|x - x_0| < \delta$. Since $D \subseteq D \cup E$, the same δ works for $f|_D$ at x_0 . Hence $f|_D$ is continuous on D , and likewise $f|_E$ is continuous on E .

The converse fails. Take

$$D = (-\infty, 0], \quad E = (0, \infty), \quad D \cup E = \mathbb{R},$$

which are measurable, and define

$$f(x) = \begin{cases} 0 & \text{if } x \leq 0, \\ 1 & \text{if } x > 0. \end{cases}$$

Then $f|_D \equiv 0$ and $f|_E \equiv 1$ are constant, hence continuous on D and on E respectively. But f is not continuous on $\mathbb{R}$: at $x_0 = 0$ we have $f(0) = 0$, while every δ -neighborhood of 0 contains points $x > 0$ with $|f(x) - f(0)| = 1$. So f fails to be continuous at 0, and the analogue of Proposition 5(ii) with “continuous” in place of “measurable” is false.

The reason the analogy breaks down is structural. Measurability of f on $D \cup E$ is decided by the sets $\{x \in D \cup E \mid f(x) > c\}$, and each of these splits as the union

$$\{x \in D \mid f(x) > c\} \cup \{x \in E \mid f(x) > c\},$$

so the property is inherited from the pieces because the measurable sets form an algebra. Continuity, by contrast, is a local condition, and a point of D may be a limit point of E ; the restrictions know nothing about how f behaves as such a point is approached from within the other piece.

It is worth recording the standard positive result, which shows what extra hypothesis repairs the converse: if D and E are both closed (or both open) and $f|_D, f|_E$ are continuous, then f is continuous on $D \cup E$. For the closed case, let $C \subseteq \mathbb{R}$ be closed; then

$$f^{-1}(C) = (f|_D)^{-1}(C) \cup (f|_E)^{-1}(C),$$

and $(f|_D)^{-1}(C)$ is closed in D , hence (as D is closed in $\mathbb{R}$) closed in $\mathbb{R}$; the same holds for E , so $f^{-1}(C)$ is a union of two closed sets, hence closed in $\mathbb{R}$ and a fortiori closed in $D \cup E$. Thus f is continuous. For the open case one argues identically with open sets, since a relatively open subset of an open set is open. In the counterexample above D is closed and E is open, and it is precisely this mismatch that is exploited.

Problem 3.3. Suppose a function f has a measurable domain and is continuous except at a finite number of points. Is f necessarily measurable?

Solution. Yes. Let E be the measurable domain of f , and let

$$F = \{x_1, \dots, x_n\} \subseteq E$$

be the finite set of points of E at which f fails to be continuous; thus f is continuous at every point of $D = E \setminus F$.

First, F is measurable and $m(F) = 0$: a single point $\{x_k\}$ is a degenerate closed interval, so it is measurable of measure zero, and a finite union of such sets is measurable of measure zero by the countable subadditivity and the fact that the measurable sets form a σ -algebra (Chapter 2). Consequently $D = E \setminus F$ is measurable as well.

Now consider the two restrictions.

The restriction $f|_D$ is continuous on D . Indeed, fix $x_0 \in D$ and $\varepsilon > 0$. Since f is continuous at x_0 as a function on E , there is $\delta > 0$ with $|f(x) - f(x_0)| < \varepsilon$ for all $x \in E$ with $|x - x_0| < \delta$; as $D \subseteq E$ this same δ works for $f|_D$. Observe also that f is real-valued at every point of D : continuity of f at x_0 in the above sense presupposes that the difference $f(x) - f(x_0)$ is meaningful and small, which forces $f(x_0)$ to be finite. (This is the only place where it matters that the functions of this chapter are allowed to take the values $\pm\infty$; the exceptional points are handled separately below, and there the values are unrestricted.) So $f|_D$ is a real-valued function that is continuous on its measurable domain D , and Proposition 3 tells us that $f|_D$ is measurable.

The restriction $f|_F$ is measurable for the cheapest of reasons: for every real number c ,

$$\{x \in F \mid f(x) > c\} \subseteq F,$$

and $m(F) = 0$, so this set is a subset of a set of measure zero. Lebesgue outer measure is monotone, so any such subset has outer measure zero and hence is measurable (Chapter 2: every set of outer measure zero is measurable). Thus $\{x \in F \mid f(x) > c\}$ is measurable for each c , and by Proposition 1 the restriction $f|_F$ is measurable on F . (The same argument applies verbatim if f is allowed to take the values $\pm\infty$ at the exceptional points.)

Finally, $E = D \cup F$ with D and F measurable and disjoint, and both restrictions $f|_D$ and $f|_F$ are measurable. By Proposition 5(ii), f is measurable on E . Concretely, for each c ,

$$\{x \in E \mid f(x) > c\} = \{x \in D \mid f(x) > c\} \cup \{x \in F \mid f(x) > c\},$$

a union of two measurable sets, hence measurable; Proposition 1 then gives the measurability of f .

Two remarks. The finiteness of F is not what matters: the argument only used that F is a set of measure zero, so the conclusion holds whenever f is continuous at every point of E outside a set of measure zero, for instance outside a countable set. What one may not do is drop the measure-zero hypothesis on the exceptional set: a function continuous off an arbitrary set need not be measurable, since the values on the exceptional set are then unconstrained.

Problem 3.4. Suppose f is a real-valued function on $\mathbb{R}$ such that $f^{-1}(c)$ is measurable for each number c . Is f necessarily measurable?

Solution. No. Measurability of every level set $f^{-1}(c) = \{x \in \mathbb{R} \mid f(x) = c\}$ is a much weaker condition than measurability of the sets $\{x \in \mathbb{R} \mid f(x) > c\}$, and it does not imply it. Proposition 1 records that measurability of f implies each $f^{-1}(c)$ is measurable; the converse fails, as the following counterexample shows.

By Theorem 17 (Vitali) of Chapter 2, any set of real numbers with positive outer measure contains a subset that fails to be measurable; applying this to the interval $(0, 1)$, fix a set $A \subseteq (0, 1)$ that is not measurable. Define $f : \mathbb{R} \rightarrow \mathbb{R}$ by

$$f(x) = \begin{cases} x & \text{if } x \in A, \\ -x & \text{if } x \in \mathbb{R} \setminus A. \end{cases}$$

Every level set of f is measurable. Fix a real number c and suppose $f(x) = c$. Either $x \in A$, in which case $f(x) = x$ and so $x = c$; or $x \notin A$, in which case $f(x) = -x$ and so $x = -c$. Hence

$$f^{-1}(c) \subseteq \{c, -c\},$$

a set with at most two elements. Every finite set is measurable (it is a finite union of singletons, each a set of measure zero), and every subset of a finite set is finite, so $f^{-1}(c)$ is measurable for each real c . Nevertheless f is not measurable. Consider $\{x \in \mathbb{R} \mid f(x) > 0\}$ and intersect it with $(0, 1)$. If $x \in (0, 1)$ and $x \in A$, then $f(x) = x > 0$. If $x \in (0, 1)$ and $x \notin A$, then $f(x) = -x < 0$. Therefore

$$\{x \in \mathbb{R} \mid f(x) > 0\} \cap (0, 1) = A.$$

Were f measurable, the set $\{x \in \mathbb{R} \mid f(x) > 0\}$ would be measurable by Proposition 1, and since the measurable sets form a σ -algebra containing the interval $(0, 1)$, the intersection A would be measurable too. This contradicts the choice of A . Hence f is not measurable, even though $f^{-1}(c)$ is measurable for every real number c .

It may be worth noting that the pathology is not caused by f having repeated values: one can also arrange a one-to-one counterexample, and for a one-to-one f every set $f^{-1}(c)$ is empty or a singleton, hence automatically measurable, so the hypothesis of the problem carries no information at all in that case. For instance, keep $A \subseteq (0, 1)$ nonmeasurable and set $g(x) = x$ for $x \in A$, $g(x) = x + 2$ for $x \in (0, 1) \sim A$, $g(x) = x - 10$ for $x \leq 0$, and $g(x) = x + 10$ for $x \geq 1$. These four formulas are injective on their respective domains and have pairwise disjoint ranges contained in $(0, 1)$, $(2, 3)$, $(-\infty, -10]$, and $[11, \infty)$ respectively, so g is one-to-one on $\mathbb{R}$; yet

$$\{x \in \mathbb{R} \mid g(x) > 1\} \cap (0, 1) = (0, 1) \sim A$$

is nonmeasurable, so g is not measurable.

Problem 3.5. Suppose the function f is defined on a measurable set E and has the property that $\{x \in E \mid f(x) > c\}$ is measurable for each rational number c . Is f necessarily measurable?

Solution. Yes. Testing the sets $\{f > c\}$ at rational c already forces measurability at every real c , because $\mathbb{Q}$ is dense in $\mathbb{R}$ and the measurable sets are closed under countable unions.

Let c be an arbitrary real number. Since the rationals are dense in $\mathbb{R}$, we may choose a sequence $\{c_k\}_{k=1}^{\infty}$ of rational numbers with

$$c < c_k \quad \text{for all } k, \quad \lim_{k \rightarrow \infty} c_k = c;$$

for instance take c_k to be any rational number in the interval $(c, c + 1/k)$. I claim that

$$\{x \in E \mid f(x) > c\} = \bigcup_{k=1}^{\infty} \{x \in E \mid f(x) > c_k\}. \quad (*)$$

The inclusion $\supseteq$ is clear: if $f(x) > c_k$ for some k , then since $c_k > c$ we get $f(x) > c$.

For the inclusion $\subseteq$, suppose $x \in E$ and $f(x) > c$. If $f(x) = \infty$ then $f(x) > c_1$ and x lies in the union. Otherwise $f(x)$ is a real number with $f(x) - c > 0$, so by the Archimedean property there is an index k with $1/k < f(x) - c$, and then

$$c_k < c + \frac{1}{k} < f(x),$$

so $x \in \{x \in E \mid f(x) > c_k\}$. This proves $(*)$.

By hypothesis each set on the right of $(*)$ is measurable, since each c_k is rational. The measurable sets form a σ -algebra (Chapter 2), so the countable union on the right is measurable. Hence $\{x \in E \mid f(x) > c\}$ is measurable for every real number c . Since the domain E is measurable by hypothesis, statement (i) of Proposition 1 holds, and therefore f is measurable by the definition of measurability given after Proposition 1.

The same argument works with $\mathbb{Q}$ replaced by any set $S \subseteq \mathbb{R}$ that is dense in $\mathbb{R}$, or indeed by any countable set S with the property that for each real c there is a sequence in $S \cap (c, \infty)$ converging to c ; all that is used is that the union in $(*)$ is countable.

Problem 3.6. Let f be a function with measurable domain D . Show that f is measurable if and only if the function g defined on $\mathbb{R}$ by $g(x) = f(x)$ for $x \in D$ and $g(x) = 0$ for $x \notin D$ is measurable.

Solution. Both directions are settled by computing the sets $\{g > c\}$ and comparing them with the sets $\{f > c\}$. Note first that the domain of g is $\mathbb{R}$, which is measurable, and the domain of f is D , measurable by hypothesis; so in each direction only the level sets need attention, and Proposition 1 applies.

Suppose first that f is measurable. Fix a real number c and split according to the sign of c .

If $c \geq 0$, then no point of $\mathbb{R} \sim D$ belongs to $\{x \in \mathbb{R} \mid g(x) > c\}$, since g vanishes there and $0 \leq c$. Hence

$$\{x \in \mathbb{R} \mid g(x) > c\} = \{x \in D \mid g(x) > c\} = \{x \in D \mid f(x) > c\},$$

which is measurable because f is measurable.

If $c < 0$, then every point of $\mathbb{R} \sim D$ does belong to the set, since $g = 0 > c$ there. Hence

$$\{x \in \mathbb{R} \mid g(x) > c\} = \{x \in D \mid f(x) > c\} \cup (\mathbb{R} \sim D).$$

The first set is measurable since f is measurable, and $\mathbb{R} \sim D$ is measurable because D is measurable and the measurable sets form a σ -algebra. Their union is therefore measurable.

In both cases $\{x \in \mathbb{R} \mid g(x) > c\}$ is measurable, so by Proposition 1 and the definition of measurability, g is measurable on $\mathbb{R}$.

Conversely, suppose g is measurable. Since g agrees with f on D , for each real c we have

$$\{x \in D \mid f(x) > c\} = \{x \in D \mid g(x) > c\} = \{x \in \mathbb{R} \mid g(x) > c\} \cap D.$$

The set $\{x \in \mathbb{R} \mid g(x) > c\}$ is measurable because g is measurable, and D is measurable by hypothesis; since the measurable sets form a σ -algebra they are closed under intersection, so $\{x \in D \mid f(x) > c\}$ is measurable. As this holds for every real c and the domain D of f is measurable, f is measurable by Proposition 1.

Alternatively, the converse direction is exactly Proposition 5(ii) applied to the function g on the measurable set $\mathbb{R}$ and the measurable subset D : measurability of g on $\mathbb{R}$ is equivalent to measurability of its restrictions to D and to $\mathbb{R} \sim D$, and the restriction of g to D is precisely f .

The proof used nothing about the value 0 beyond its being a fixed real number: for any fixed $a \in \mathbb{R}$, the extension of f by the constant a off D is measurable on $\mathbb{R}$ if and only if f is measurable on D . Only the two cases $c \geq a$ and $c < a$ change places.

Problem 3.7. Let the function f be defined on a measurable set E . Show that f is measurable if and only if for each Borel set A , $f^{-1}(A)$ is measurable. [Hint: The collection of sets A that have the property that $f^{-1}(A)$ is measurable is a σ -algebra.]

Solution. Here f is real-valued, A ranges over the Borel subsets of $\mathbb{R}$, and $f^{-1}(A) = \{x \in E \mid f(x) \in A\}$. Recall that the Borel σ -algebra $\mathcal{B}$ is by definition the smallest σ -algebra of subsets of $\mathbb{R}$ containing all of the open sets; equivalently, $\mathcal{B}$ is the intersection of all σ -algebras of subsets of $\mathbb{R}$ that contain the open sets, so any σ -algebra containing every open set necessarily contains $\mathcal{B}$.

Suppose first that $f^{-1}(A)$ is measurable for each Borel set A . For each real number c the interval (c, ∞) is open, hence Borel, and

$$\{x \in E \mid f(x) > c\} = f^{-1}((c, \infty))$$

is therefore measurable. Since the domain E is measurable, statement (i) of Proposition 1 holds and f is measurable.

Conversely, suppose f is measurable. Following the hint, set

$$\mathcal{A} = \{A \subseteq \mathbb{R} \mid f^{-1}(A) \text{ is measurable}\}.$$

We check that $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$, using throughout the elementary identities for inverse images and the fact that the Lebesgue measurable sets form a σ -algebra (Chapter 2).

First, $\mathbb{R} \in \mathcal{A}$: since f is real-valued on E , $f^{-1}(\mathbb{R}) = E$, which is measurable by hypothesis. In particular $\mathcal{A}$ is nonempty.

Second, $\mathcal{A}$ is closed under complements in $\mathbb{R}$. Let $A \in \mathcal{A}$. A point $x \in E$ satisfies $f(x) \in \mathbb{R} \sim A$ if and only if $x \notin f^{-1}(A)$, so

$$f^{-1}(\mathbb{R} \sim A) = E \sim f^{-1}(A).$$

Both E and $f^{-1}(A)$ are measurable, and the measurable sets form a σ -algebra, hence an algebra, so their relative complement is measurable. Thus $\mathbb{R} \sim A \in \mathcal{A}$.

Third, $\mathcal{A}$ is closed under countable unions. Let $\{A_k\}_{k=1}^{\infty}$ be a countable collection of members of $\mathcal{A}$. A point $x \in E$ satisfies $f(x) \in \bigcup_k A_k$ if and only if $f(x) \in A_k$ for some k , so

$$f^{-1}\left(\bigcup_{k=1}^{\infty} A_k\right) = \bigcup_{k=1}^{\infty} f^{-1}(A_k),$$

a countable union of measurable sets, hence measurable. Thus $\bigcup_k A_k \in \mathcal{A}$.

Therefore $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$.

Next, $\mathcal{A}$ contains every open subset of $\mathbb{R}$. This is exactly Proposition 2: a function defined on a measurable set is measurable if and only if the inverse image of each open set is measurable. Since f is measurable, $f^{-1}(\mathcal{O})$ is measurable for each open $\mathcal{O} \subseteq \mathbb{R}$, i.e. $\mathcal{O} \in \mathcal{A}$.

So $\mathcal{A}$ is a σ -algebra containing all open sets, and by the minimality in the definition of the Borel σ -algebra, $\mathcal{B} \subseteq \mathcal{A}$. That is, $f^{-1}(A)$ is measurable for every Borel set A , which is what we had to prove.

A remark on the extended real-valued case. If f is permitted to take the values $\pm\infty$, the statement as literally written is no longer correct in the direction “inverse images of Borel sets measurable $\Rightarrow$ f measurable”: a function taking only the values $\pm\infty$ has $f^{-1}(A) = \emptyset$ for every $A \subseteq \mathbb{R}$, so the hypothesis is vacuous. Concretely, with $A_0 \subseteq (0, 1)$ nonmeasurable (Theorem 17 of Chapter 2), the function on $E = (0, 1)$ equal to ∞ on A_0 and to $-\infty$ on $(0, 1) \sim A_0$ satisfies the hypothesis yet has $\{x \in E \mid f(x) > 0\} = A_0$ nonmeasurable. The correct extended statement is obtained by letting A range over the Borel subsets of the extended real numbers, i.e. over the σ -algebra generated by the open subsets of $\mathbb{R}$ together with the sets $(c, \infty]$ and $[-\infty, c)$. The forward direction, on the other hand, remains valid as stated for extended real-valued measurable f : the argument above needs only the identity $f^{-1}(\mathbb{R}) = \bigcup_{k=1}^{\infty} \{x \in E \mid -k < f(x) < k\}$ to see that $f^{-1}(\mathbb{R})$ is measurable, after which one repeats the σ -algebra verification with E replaced by $f^{-1}(\mathbb{R})$.

3.2 Problems 3.8–3.14

Problem 3.8. (Borel measurability) A function f is said to be **Borel measurable** provided its domain E is a Borel set and for each c , the set $\{x \in E \mid f(x) > c\}$ is a Borel set. Verify that Proposition 1 and Theorem 6 remain valid if we replace “(Lebesgue) measurable set” by “Borel set.” Show that: (i) every Borel measurable function is Lebesgue measurable; (ii) if f is Borel measurable and B is a Borel set, then $f^{-1}(B)$ is a Borel set; (iii) if f and g are Borel measurable, so is $f \circ g$; and (iv) if f is Borel measurable and g is Lebesgue measurable, then $f \circ g$ is Lebesgue measurable.

Solution. Throughout, write $\mathcal{B}$ for the collection of Borel subsets of $\mathbb{R}$, that is, the smallest σ -algebra of subsets of $\mathbb{R}$ containing the open sets. Two features of $\mathcal{B}$ are all that the arguments of Section 3.1 ever used about the Lebesgue measurable sets: $\mathcal{B}$ is a σ -algebra, and $\mathcal{B}$ contains every interval and every open set.

Proposition 1 for Borel sets. Let f have Borel domain E . The proof of Proposition 1 proceeds as follows. The sets in (i) and (iv) are complementary in E , as are those in (ii) and (iii); since E is Borel and $\mathcal{B}$ is a σ -algebra, the relative complement in E of a Borel subset of E is Borel, so (i) $\Leftrightarrow$ (iv) and (ii) $\Leftrightarrow$ (iii). Next,

$$\{x \in E \mid f(x) \geq c\} = \bigcap_{k=1}^{\infty} \{x \in E \mid f(x) > c-1/k\}, \quad \{x \in E \mid f(x) > c\} = \bigcup_{k=1}^{\infty} \{x \in E \mid f(x) \geq c+1/k\},$$

and $\mathcal{B}$ is closed under countable intersections and countable unions, so (i) $\Leftrightarrow$ (ii). Finally, for finite c , $f^{-1}(c) = \{f \geq c\} \cap \{f \leq c\}$ is Borel, and $f^{-1}(\infty) = \bigcap_{k=1}^{\infty} \{x \in E \mid f(x) > k\}$ is Borel, and similarly for $-\infty$. So the four statements are equivalent and each implies that $\{x \in E \mid f(x) = c\}$ is Borel for every extended real c . Only the σ -algebra property was invoked, so the proposition stands verbatim with “Borel set” in place of “measurable set.”

Theorem 6 for Borel sets. Let f and g be Borel measurable real-valued functions on the Borel set E .

For $\alpha \neq 0$,

$$\{x \in E \mid \alpha f(x) > c\} = \{x \in E \mid f(x) > c/\alpha\} \text{ if } \alpha > 0, \quad \{x \in E \mid \alpha f(x) > c\} = \{x \in E \mid f(x) < c/\alpha\} \text{ if } \alpha < 0$$

and $\alpha f \equiv 0$ is Borel measurable when $\alpha = 0$; so αf is Borel measurable. By the density of $\mathbb{Q}$ in $\mathbb{R}$,

$$\{x \in E \mid f(x) + g(x) < c\} = \bigcup_{q \in \mathbb{Q}} (\{x \in E \mid g(x) < c - q\} \cap \{x \in E \mid f(x) < q\}),$$

a countable union of Borel sets, hence Borel; so $f + g$, and therefore $\alpha f + \beta g$, is Borel measurable. For products, $fg = \frac{1}{2}[(f + g)^2 - f^2 - g^2]$, so by the linearity just proved it suffices to know that h^2 is Borel measurable whenever h is, and this follows from

$$\{x \in E \mid h^2(x) > c\} = \{x \in E \mid h(x) > \sqrt{c}\} \cup \{x \in E \mid h(x) < -\sqrt{c}\} \quad (c \geq 0), \quad \{x \in E \mid h^2(x) > c\} = E \quad (c < 0)$$

Again every step used only that $\mathcal{B}$ is a σ -algebra containing the intervals, so Theorem 6 holds with “Borel measurable” throughout.

One caveat deserves mention. Theorem 6 is stated for functions that are merely finite a.e., and the reduction to the finite case rests on Proposition 5, which asserts that a function agreeing a.e. with a measurable function is measurable. Proposition 5 is **false** for Borel measurability: a set of measure zero need not be Borel (by Proposition 22 of Chapter 2 there is a measurable, indeed measure-zero, subset of the Cantor set that is not Borel), and altering the identically-zero function to equal 1 on such a set produces a function that is not Borel measurable. So in the Borel version of Theorem 6 one must read “finite a.e.” as “finite,” or equivalently pass to the Borel set E_0 on which both f and g are finite (Borel by Proposition 1) and assert Borel measurability of $\alpha f + \beta g$ and fg on E_0 ; the values assigned on $E \sim E_0$ must themselves be Borel measurable if the conclusion is to hold on all of E .

(i) Every Borel measurable function is Lebesgue measurable. By Theorem 9 of Chapter 2 the collection $\mathcal{M}$ of Lebesgue measurable sets is a σ -algebra that contains the σ -algebra $\mathcal{B}$ of Borel sets; equivalently, $\mathcal{M}$ is a σ -algebra containing the open sets and $\mathcal{B}$ is the smallest such σ -algebra. Hence every Borel set is Lebesgue measurable. Thus if f is Borel measurable, its domain E is a Borel set and so Lebesgue measurable, and for each c the Borel set $\{x \in E \mid f(x) > c\}$ is Lebesgue measurable. By the definition following Proposition 1, f is Lebesgue measurable.

(ii) f Borel measurable, B Borel $\Rightarrow f^{-1}(B)$ Borel. This is Problem 7 with $\mathcal{B}$ in place of the Lebesgue measurable sets. There is no loss in assuming f is real-valued. Indeed, the functions of this chapter are extended real-valued, and if f takes infinite values put $E' = E \sim [f^{-1}(\infty) \cup f^{-1}(-\infty)]$, a Borel set by the Borel version of Proposition 1 established above; for a set $B \subseteq \mathbb{R}$ of real numbers we have $f^{-1}(B) = (f|_{E'})^{-1}(B)$, and $f|_{E'}$ is a real-valued Borel measurable function on the Borel set E' , so the real-valued case gives the general one. Assume then that $f : E \rightarrow \mathbb{R}$ and define

$$\mathcal{A} = \{A \subseteq \mathbb{R} \mid f^{-1}(A) \text{ is a Borel set}\}.$$

Then $\mathcal{A}$ is a σ -algebra of subsets of $\mathbb{R}$: first, $f^{-1}(\mathbb{R}) = E$ is Borel, so $\mathbb{R} \in \mathcal{A}$; second, if $A \in \mathcal{A}$ then $f^{-1}(\mathbb{R} \sim A) = E \sim f^{-1}(A)$, a difference of Borel sets, hence Borel, so $\mathbb{R} \sim A \in \mathcal{A}$; third, if $\{A_k\}_{k=1}^{\infty} \subseteq \mathcal{A}$ then $f^{-1}(\bigcup_k A_k) = \bigcup_k f^{-1}(A_k)$ is a countable union of Borel sets, hence Borel. Moreover $(c, \infty) \in \mathcal{A}$ for every c , by the Borel measurability of f . Now the σ -algebra generated by the rays $\{(c, \infty) \mid c \in \mathbb{R}\}$ is all of $\mathcal{B}$: it contains $(-\infty, c] = \mathbb{R} \sim (c, \infty)$, hence $(-\infty, c) = \bigcup_{k=1}^{\infty} (-\infty, c - 1/k]$, hence every bounded open interval $(a, b) = (a, \infty) \cap (-\infty, b)$, and hence also the unbounded open intervals (a, ∞) , $(-\infty, b)$ and $\mathbb{R}$ itself. Every open subset of $\mathbb{R}$ is the union of a countable collection of open intervals, each of them bounded or unbounded and so in every case a member of this σ -algebra; hence it contains the open sets and therefore contains $\mathcal{B}$. Since $\mathcal{A}$ is a σ -algebra containing all the rays, $\mathcal{B} \subseteq \mathcal{A}$; that is, $f^{-1}(B)$ is Borel for every Borel set B .

(iii) f, g Borel measurable $\Rightarrow f \circ g$ Borel measurable. Let g have Borel domain D and f have Borel domain E , both real-valued, and let $f \circ g$ have its natural domain $g^{-1}(E)$, which is Borel by (ii) applied to g . For each c , the set $B = \{y \in E \mid f(y) > c\}$ is Borel since f is Borel measurable, and

$$\{x \in g^{-1}(E) \mid f(g(x)) > c\} = g^{-1}(B),$$

which is Borel by (ii) applied to g . Hence $f \circ g$ is Borel measurable.

(iv) f Borel measurable, g Lebesgue measurable $\Rightarrow f \circ g$ Lebesgue measurable. Exactly the same computation, with Problem 7 supplying the transfer. By Problem 7, the collection $\{A \subseteq \mathbb{R} \mid g^{-1}(A) \text{ is Lebesgue measurable}\}$ is a σ -algebra, and it contains every ray (c, ∞) because g is Lebesgue measurable; by the generation argument in (ii) it therefore contains $\mathcal{B}$. So $g^{-1}(B)$ is Lebesgue measurable for every Borel set B . In particular the domain $g^{-1}(E)$ is measurable, and for each c ,

$$\{x \in g^{-1}(E) \mid f(g(x)) > c\} = g^{-1}(\{y \in E \mid f(y) > c\})$$

is the inverse image under g of a Borel set, hence Lebesgue measurable. Thus $f \circ g$ is Lebesgue measurable.

It is worth contrasting (iv) with the Example preceding Proposition 7, where $\chi_A \circ \psi^{-1}$ fails to be measurable even though χ_A is Lebesgue measurable and ψ^{-1} is continuous. There A is a measurable set that is not Borel, so χ_A is Lebesgue but not Borel measurable, and (iv) does not apply. The outer function must be Borel measurable, not merely Lebesgue measurable, for the composition argument to run.

Problem 3.9. Let $\{f_n\}$ be a sequence of measurable functions defined on a measurable set E . Define E_0 to be the set of points x in E at which $\{f_n(x)\}$ converges. Is the set E_0 measurable?

Solution. Yes: E_0 is measurable. We give a proof that uses nothing beyond Proposition 1, Proposition 5, Theorem 6, and the fact that the measurable sets are a σ -algebra.

The functions here are extended real-valued, so we must first say what “converges” means. Take it to mean “converges to a finite limit”; at the end we observe that the sets on which $f_n(x) \rightarrow \infty$ and $f_n(x) \rightarrow -\infty$ are also measurable, so the conclusion is unaffected if one prefers the wider reading.

For each pair of indices n, m put

$$E_{n,m} = \{x \in E \mid |f_n(x)| < \infty\} \cap \{x \in E \mid |f_m(x)| < \infty\}.$$

By Proposition 1, $f_n^{-1}(\infty)$ and $f_n^{-1}(-\infty)$ are measurable, so $\{x \in E \mid |f_n(x)| < \infty\} = E \setminus [f_n^{-1}(\infty) \cup f_n^{-1}(-\infty)]$ is measurable, and hence so is $E_{n,m}$. By Proposition 5(ii) the restrictions of f_n and f_m to $E_{n,m}$ are measurable, and they are real-valued there, so by Theorem 6 the function $f_n - f_m$ is measurable on $E_{n,m}$. Consequently, for each $k \in \mathbb{N}$ the set

$$A_{n,m}^k = \{x \in E_{n,m} \mid |f_n(x) - f_m(x)| < 1/k\} = \{x \in E_{n,m} \mid f_n(x) - f_m(x) < 1/k\} \cap \{x \in E_{n,m} \mid f_n(x) - f_m(x) > -1/k\}$$

is measurable, being the intersection of two measurable sets.

Now define

$$F = \bigcap_{k=1}^{\infty} \bigcup_{N=1}^{\infty} \bigcap_{n \geq N} \bigcap_{m \geq N} A_{n,m}^k.$$

All the unions and intersections are over countable index sets, so F is measurable because the measurable sets form a σ -algebra.

We claim $F = E_0$. Suppose first that $x \in E_0$, say $f_n(x) \rightarrow L$ with $L \in \mathbb{R}$. Fix k . There is an N such that $|f_n(x) - L| < 1/(2k)$ for all $n \geq N$; in particular $f_n(x)$ is finite for every $n \geq N$, so $x \in E_{n,m}$ for all $n, m \geq N$, and by the triangle inequality

$$|f_n(x) - f_m(x)| \leq |f_n(x) - L| + |L - f_m(x)| < 1/k \quad \text{for all } n, m \geq N.$$

Thus $x \in \bigcap_{n,m \geq N} A_{n,m}^k$. As k was arbitrary, $x \in F$.

Conversely suppose $x \in F$. Taking $k = 1$ we get an N_1 with $x \in E_{n,m}$ for all $n, m \geq N_1$, so the numbers $f_n(x)$ are finite for $n \geq N_1$. Given $\epsilon > 0$, choose k with $1/k < \epsilon$ and then $N \geq N_1$ with $|f_n(x) - f_m(x)| < 1/k < \epsilon$ for all $n, m \geq N$. Hence the tail $\{f_n(x)\}_{n \geq N_1}$ is a Cauchy sequence of real numbers, and by the completeness of $\mathbb{R}$ it converges to some $L \in \mathbb{R}$. Since altering finitely many terms does not affect convergence, $\{f_n(x)\}$ converges, i.e. $x \in E_0$.

Therefore $E_0 = F$ is measurable.

Finally, for the wider reading of “converges,” note that

$$\{x \in E \mid f_n(x) \rightarrow \infty\} = \bigcap_{k=1}^{\infty} \bigcup_{N=1}^{\infty} \bigcap_{n \geq N} \{x \in E \mid f_n(x) > k\}$$

is measurable, since each $\{x \in E \mid f_n(x) > k\}$ is measurable by the very definition of measurability of f_n and only countable set operations are used; the set on which $f_n(x) \rightarrow -\infty$ is measurable by the symmetric formula. Adjoining these two measurable sets to F again yields a measurable set. Either way, the answer is affirmative.

Problem 3.10. Suppose f and g are real-valued functions defined on all of $\mathbb{R}$, f is measurable, and g is continuous. Is the composition $f \circ g$ necessarily measurable?

Solution. No. Proposition 7 guarantees measurability of $f \circ g$ when the **outer** function is continuous and the inner one measurable; with the roles reversed the conclusion fails, and the Example preceding Proposition 7 supplies the counterexample. We spell it out.

By Proposition 21 of Chapter 2 the function

$$\psi(x) = \varphi(x) + x \quad \text{for } x \in [0, 1],$$

where φ is the Cantor-Lebesgue function, is a strictly increasing continuous function mapping $[0, 1]$ onto $[0, 2]$, and it maps some measurable set A , a subset of the Cantor set C , onto a nonmeasurable set $\psi(A)$.

Extend ψ to all of $\mathbb{R}$ by

$$\psi(x) = x \quad \text{for } x < 0, \quad \psi(x) = x + 1 \quad \text{for } x > 1.$$

Since $\psi(0) = \varphi(0) + 0 = 0$ and $\psi(1) = \varphi(1) + 1 = 2$, the extended function is continuous and strictly increasing on $\mathbb{R}$, and it maps $\mathbb{R}$ onto $\mathbb{R}$. By Problem 45 of Chapter 2, a strictly increasing function defined on an interval has a continuous inverse, so

$$g = \psi^{-1} : \mathbb{R} \rightarrow \mathbb{R}$$

is a continuous real-valued function defined on all of $\mathbb{R}$.

Let $f = \chi_A$, the characteristic function of A , regarded as a function on all of $\mathbb{R}$. Since A is measurable, f is measurable: for $c \geq 1$ the set $\{x \mid f(x) > c\}$ is empty, for $0 \leq c < 1$ it is A , and for $c < 0$ it is $\mathbb{R}$, and all three are measurable.

Now consider $h = f \circ g = \chi_A \circ \psi^{-1}$, a real-valued function on all of $\mathbb{R}$. For $c = 1/2$,

$$\{y \in \mathbb{R} \mid h(y) > 1/2\} = \{y \in \mathbb{R} \mid \psi^{-1}(y) \in A\} = \psi(A),$$

the last equality because ψ is a bijection of $\mathbb{R}$ onto $\mathbb{R}$. But $\psi(A)$ is not measurable. Hence $h = f \circ g$ is not measurable, even though f is measurable and g is continuous.

(Equivalently, as the text puts it: if I is any open interval containing 1 but not 0, then $h^{-1}(I) = \psi(A)$ is nonmeasurable, so by Proposition 2 the function h is not measurable.)

The obstruction is that a continuous function may carry a set of measure zero, such as the measurable set $A \subseteq C$, onto a set of positive measure, and once measure is created in this way a measurable set can be moved onto a nonmeasurable one. Problem 11 shows that the extra hypothesis of a Lipschitz inverse rules this out and restores measurability of $f \circ g$; Problem 8(iv) shows that requiring f to be Borel measurable rather than merely Lebesgue measurable also restores it.

Problem 3.11. Let f be a measurable function and g be a one-to-one function from $\mathbb{R}$ onto $\mathbb{R}$ which has a Lipschitz inverse. Show that the composition $f \circ g$ is measurable. (Hint: Examine Problem 38 in Chapter 2.)

Solution. Write $h = g^{-1}$, so that $h : \mathbb{R} \rightarrow \mathbb{R}$ is Lipschitz: there is a constant $c \geq 0$ with

$$|h(u) - h(v)| \leq c|u - v| \quad \text{for all } u, v \in \mathbb{R}.$$

Since g is a one-to-one mapping of $\mathbb{R}$ onto $\mathbb{R}$ with inverse h , for any set $A \subseteq \mathbb{R}$ we have the identity

$$g^{-1}(A) = \{x \in \mathbb{R} \mid g(x) \in A\} = h(A).$$

Indeed, if $g(x) = a \in A$ then $x = h(a) \in h(A)$; conversely if $x = h(a)$ with $a \in A$ then $g(x) = a \in A$. So inverse images under g are the same thing as forward images under the Lipschitz function h , and everything reduces to the following lemma, which is Problem 38 of Chapter 2 transferred from a closed bounded interval to all of $\mathbb{R}$.

Lemma. A Lipschitz function $h : \mathbb{R} \rightarrow \mathbb{R}$ maps measurable sets onto measurable sets.

Proof of the Lemma, in three steps.

Step 1: h maps sets of measure zero onto sets of measure zero. Let $m^*(Z) = 0$ and let $\epsilon > 0$. By the definition of outer measure there is a countable collection $\{I_k\}_{k=1}^{\infty}$ of open, bounded intervals covering Z with $\sum_k \ell(I_k) < \epsilon$. Fix k . For $u, v \in Z \cap I_k$ we have $|h(u) - h(v)| \leq c|u - v| \leq c\ell(I_k)$, so the set $h(Z \cap I_k)$ has diameter at most $c\ell(I_k)$ and is therefore contained in a closed interval of length $c\ell(I_k)$; by the monotonicity of outer measure and Proposition 1 of Chapter 2, which says the outer measure of an interval is its length, $m^*(h(Z \cap I_k)) \leq c\ell(I_k)$. Since $h(Z) = \bigcup_k h(Z \cap I_k)$, the countable subadditivity of outer measure, Proposition 3 of Chapter 2, gives

$$m^*(h(Z)) \leq \sum_{k=1}^{\infty} m^*(h(Z \cap I_k)) \leq c \sum_{k=1}^{\infty} \ell(I_k) < c\epsilon.$$

As $\epsilon > 0$ was arbitrary, $m^*(h(Z)) = 0$, and by Proposition 4 of Chapter 2 a set of outer measure zero is measurable.

Step 2: h maps F_{σ} sets onto F_{σ} sets. A Lipschitz function is continuous, and a continuous function maps compact sets onto compact sets. If $F \subseteq \mathbb{R}$ is closed, then $F = \bigcup_{n=1}^{\infty} (F \cap [-n, n])$ is a countable union of compact sets, so $h(F) = \bigcup_{n=1}^{\infty} h(F \cap [-n, n])$ is a countable union of compact, hence closed, sets: $h(F)$ is F_{σ} . If $S = \bigcup_{j=1}^{\infty} F_j$ is F_{σ} , then $h(S) = \bigcup_{j=1}^{\infty} h(F_j)$ is a countable union of F_{σ} sets, hence again F_{σ} . In particular $h(S)$ is measurable.

Step 3: Let A be measurable. By assertion (iv) of Theorem 11 of Chapter 2 there is an F_{σ} set F contained in A for which $m^*(A \sim F) = 0$. Then

$$h(A) = h(F) \cup h(A \sim F),$$

where $h(F)$ is measurable by Step 2 and $h(A \sim F)$ has measure zero, hence is measurable, by Step 1. As the measurable sets are closed under union, $h(A)$ is measurable. This proves the Lemma.

Now let f be measurable with measurable domain $E \subseteq \mathbb{R}$. The composition $f \circ g$ has domain

$$\{x \in \mathbb{R} \mid g(x) \in E\} = g^{-1}(E) = h(E),$$

which is measurable by the Lemma. Fix a real number c . Since f is measurable, the set $E_c = \{y \in E \mid f(y) > c\}$ is measurable, and

$$\{x \in h(E) \mid (f \circ g)(x) > c\} = \{x \mid g(x) \in E_c\} = g^{-1}(E_c) = h(E_c),$$

which is measurable, again by the Lemma. Since this holds for every c , and the domain $h(E)$ is measurable, $f \circ g$ is a measurable function.

Note where the hypothesis is used: the Lipschitz condition on g^{-1} is exactly what prevents the pathology of Problem 10, where the inner function was continuous with a continuous inverse but that inverse blew a set of measure zero (a subset of the Cantor set) up to a set of positive measure and thence onto a nonmeasurable set. Step 1 shows a Lipschitz map cannot do this.

Problem 3.12. Let f be a bounded measurable function on E . Show that there are sequences of simple functions on E , $\{\varphi_n\}$ and $\{\psi_n\}$, such that $\{\varphi_n\}$ is increasing and $\{\psi_n\}$ is decreasing and each of these sequences converges to f uniformly on E .

Solution. Since f is a bounded measurable real-valued function on the measurable set E , the Simple Approximation Lemma applies with any $\epsilon > 0$. Apply it with $\epsilon = 1/n$ for each natural number n : there are simple functions α_n and β_n defined on E with

$$\alpha_n \leq f \leq \beta_n \quad \text{and} \quad 0 \leq \beta_n - \alpha_n < 1/n \quad \text{on } E.$$

These need not be monotone in n , so we monotone them. Define, for each n ,

$$\varphi_n = \max\{\alpha_1, \alpha_2, \dots, \alpha_n\}, \quad \psi_n = \min\{\beta_1, \beta_2, \dots, \beta_n\} \quad \text{on } E.$$

First, φ_n and ψ_n are simple. Each is measurable by Proposition 8, which asserts that the maximum and the minimum of a finite family of measurable functions with common domain are measurable. Each takes only finitely many values: at every point of E the value of φ_n belongs to the union of the ranges of $\alpha_1, \dots, \alpha_n$, which is a finite set since each α_k is simple, and likewise for ψ_n . Being real-valued, measurable, and finitely valued, φ_n and ψ_n are simple.

Second, monotonicity is immediate from the definition: $\varphi_n = \max\{\varphi_{n-1}, \alpha_n\} \geq \varphi_{n-1}$, so $\{\varphi_n\}$ is increasing, and $\psi_n = \min\{\psi_{n-1}, \beta_n\} \leq \psi_{n-1}$, so $\{\psi_n\}$ is decreasing.

Third, the two sequences bracket f . Since $\alpha_k \leq f$ on E for every k , the maximum of $\alpha_1, \dots, \alpha_n$ also satisfies $\varphi_n \leq f$ on E ; since $\beta_k \geq f$ on E for every k , we get $\psi_n \geq f$ on E . Moreover $\alpha_n \leq \varphi_n$ and $\psi_n \leq \beta_n$, by the definitions. Hence, on all of E ,

$$\alpha_n \leq \varphi_n \leq f \leq \psi_n \leq \beta_n.$$

Finally we get uniform convergence with an explicit rate. For every $x \in E$,

$$0 \leq f(x) - \varphi_n(x) \leq f(x) - \alpha_n(x) \leq \beta_n(x) - \alpha_n(x) < 1/n,$$

and symmetrically

$$0 \leq \psi_n(x) - f(x) \leq \beta_n(x) - f(x) \leq \beta_n(x) - \alpha_n(x) < 1/n.$$

Thus

$$\sup_{x \in E} |f(x) - \varphi_n(x)| \leq 1/n \quad \text{and} \quad \sup_{x \in E} |f(x) - \psi_n(x)| \leq 1/n,$$

and since these bounds are independent of x and tend to 0, both $\{\varphi_n\}$ and $\{\psi_n\}$ converge to f uniformly on E . The sequence $\{\varphi_n\}$ is increasing and the sequence $\{\psi_n\}$ is decreasing, as required.

Problem 3.13. A real-valued measurable function is said to be **semisimple** provided it takes only a countable number of values. Let f be any measurable function on E . Show that there is a sequence of semisimple functions $\{f_n\}$ on E that converges to f uniformly on E .

Solution. Since a semisimple function is by definition real-valued, and since uniform convergence of real-valued functions to f forces f to be real-valued, we take f to be a real-valued measurable function on the measurable set E . (The extended real-valued case is treated in a remark at the end.)

The point of the exercise is that, unlike simple functions, semisimple functions may use countably many values, so we need no boundedness assumption on f : we may simply round f down to the nearest multiple of $1/n$.

Fix a natural number n . For each integer $k \in \mathbb{Z}$ define

$$E_{n,k} = \left\{ x \in E \mid \frac{k}{n} \leq f(x) < \frac{k+1}{n} \right\} = \left\{ x \in E \mid f(x) \geq \frac{k}{n} \right\} \cap \left\{ x \in E \mid f(x) < \frac{k+1}{n} \right\}.$$

By Proposition 1 each of the two sets on the right is measurable, hence $E_{n,k}$ is measurable. For a fixed n the sets $\{E_{n,k}\}_{k \in \mathbb{Z}}$ are pairwise disjoint, since the intervals $[k/n, (k+1)/n)$ are pairwise disjoint, and they cover E : for $x \in E$ the number $f(x)$ is real, so there is exactly one integer k with $k/n \leq f(x) < (k+1)/n$, namely $k = \lfloor nf(x) \rfloor$. Thus

$$E = \bigcup_{k \in \mathbb{Z}} E_{n,k}, \quad \text{the union being disjoint.}$$

Define f_n on E by

$$f_n(x) = \frac{k}{n} \quad \text{for } x \in E_{n,k}, \quad \text{that is,} \quad f_n = \frac{1}{n} \lfloor nf \rfloor.$$

This is well defined and real-valued on all of E by the preceding paragraph, and its range is contained in the countable set $\{k/n \mid k \in \mathbb{Z}\}$.

The function f_n is measurable. Indeed, for each real number c ,

$$\{x \in E \mid f_n(x) > c\} = \bigcup_{\{k \in \mathbb{Z} \mid k/n > c\}} E_{n,k},$$

a union of a countable collection of measurable sets, hence measurable since the measurable sets are a σ -algebra. Being measurable, real-valued, and countably valued, each f_n is semisimple.

It remains to check uniform convergence. Let $x \in E$ and let k be the integer with $x \in E_{n,k}$. Then $f_n(x) = k/n$ and $k/n \leq f(x) < (k+1)/n$, so

$$0 \leq f(x) - f_n(x) < \frac{1}{n}.$$

This bound is independent of x , so

$$\sup_{x \in E} |f(x) - f_n(x)| \leq \frac{1}{n} \longrightarrow 0 \quad \text{as } n \rightarrow \infty,$$

that is, $\{f_n\}$ converges to f uniformly on E .

Remark on extended real values. If f is permitted to take the values $\pm\infty$, no sequence of real-valued functions can converge to f uniformly (indeed not even pointwise) at a point where f is infinite. The natural amendment is to allow the approximants to be infinite exactly where f is: define $g_n = f_n$ on the measurable set $\{x \in E \mid |f(x)| < \infty\}$, using the construction above applied to the restriction of f to that set (measurable by Proposition 5(ii)), and $g_n = \infty$ on $f^{-1}(\infty)$, $g_n = -\infty$ on $f^{-1}(-\infty)$; these last two sets are measurable by Proposition 1. Each g_n is measurable, takes only countably many values, and satisfies $|g_n - f| < 1/n$ wherever f is finite while $g_n = f$ wherever f is infinite. Thus $\{g_n\}$ converges to f uniformly in the only sense available for extended real-valued functions.

Problem 3.14. Let f be a measurable function on E that is finite a.e. on E and $m(E) < \infty$. For each $\epsilon > 0$, show that there is a measurable set F contained in E such that f is bounded on F and $m(E \setminus F) < \epsilon$.

Solution. For each natural number n define

$$E_n = \{x \in E \mid |f(x)| \leq n\} = \{x \in E \mid f(x) \leq n\} \cap \{x \in E \mid f(x) \geq -n\}.$$

Each of the two sets on the right is measurable by Proposition 1, so each E_n is a measurable subset of E . The collection $\{E_n\}_{n=1}^{\infty}$ is ascending, since $|f(x)| \leq n$ implies $|f(x)| \leq n+1$, and

$$\bigcup_{n=1}^{\infty} E_n = \{x \in E \mid |f(x)| < \infty\} =: E_{\text{fin}},$$

because a point x lies in some E_n precisely when $|f(x)|$ is a finite number, in which case any integer $n \geq |f(x)|$ will do.

Since f is finite a.e. on E , the set

$$E \sim E_{\text{fin}} = f^{-1}(\infty) \cup f^{-1}(-\infty)$$

has measure zero; it is measurable by Proposition 1. Hence, by the excision property of measure (legitimate because $m(E \sim E_{\text{fin}}) = 0 < \infty$) together with the additivity of measure over the disjoint measurable decomposition $E = E_{\text{fin}} \cup (E \sim E_{\text{fin}})$,

$$m(E_{\text{fin}}) = m(E) - m(E \sim E_{\text{fin}}) = m(E).$$

Now apply the continuity of measure. By part (i) of Theorem 15 of Chapter 2, applied to the ascending collection $\{E_n\}$,

$$\lim_{n \rightarrow \infty} m(E_n) = m\left(\bigcup_{n=1}^{\infty} E_n\right) = m(E_{\text{fin}}) = m(E).$$

By hypothesis $m(E) < \infty$, so this is a limit of real numbers converging to the real number $m(E)$. Therefore, given $\epsilon > 0$, there is a natural number N for which

$$m(E_N) > m(E) - \epsilon.$$

Put $F = E_N$. Then F is a measurable set contained in E , and $|f| \leq N$ on F , so f is bounded on F . Moreover $F \subseteq E$ and $m(F) \leq m(E) < \infty$, so the excision property of measure gives

$$m(E \sim F) = m(E) - m(F) = m(E) - m(E_N) < \epsilon.$$

This is exactly what was to be shown.

Two remarks on the hypotheses. First, the finiteness of $m(E)$ is essential: for $E = \mathbb{R}$ and $f(x) = x$, the function f is finite everywhere, yet every set on which f is bounded is contained in a bounded interval and hence has complement in $\mathbb{R}$ of infinite measure, so no such F exists for any ϵ . Second, the finiteness a.e. of f is essential: if $f = \infty$ on a subset of E of positive measure δ , then every set F on which f is bounded misses that subset, so $m(E \sim F) \geq \delta$, and the conclusion fails for $\epsilon < \delta$.

3.3 Problems 3.15–3.21

Problem 3.15. Let f be a measurable function on E that is finite a.e. on E and $m(E) < \infty$. Show that for each $\epsilon > 0$, there is a measurable set F contained in E and a sequence $\{\varphi_n\}$ of simple functions on E such that $\{\varphi_n\} \rightarrow f$ uniformly on F and $m(E \sim F) < \epsilon$. (Hint: See the preceding problem.)

Solution. Let $\epsilon > 0$ be given.

Step 1: a set on which f is bounded (this is Problem 14). For each natural number n put

$$E_n = \{x \in E \mid |f(x)| \leq n\}.$$

Here f is permitted to be extended real-valued, so we avoid appealing to the measurability of $|f|$ and argue directly: since f is measurable, for each n both $\{x \in E \mid f(x) \leq n\}$ and $\{x \in E \mid f(x) \geq -n\}$ are measurable by Proposition 1, and E_n is their intersection, hence measurable because the measurable sets form a σ -algebra. The sequence $\{E_n\}$ is ascending and

$$\bigcup_{n=1}^{\infty} E_n = \{x \in E \mid |f(x)| < \infty\} = E \sim E_{\infty}, \quad E_{\infty} = \{x \in E \mid |f(x)| = \infty\}.$$

Because f is finite a.e. on E we have $m(E_{\infty}) = 0$, so by the continuity of measure (Theorem 15 of Chapter 2) and the excision property,

$$\lim_{n \rightarrow \infty} m(E_n) = m\left(\bigcup_{n=1}^{\infty} E_n\right) = m(E \sim E_{\infty}) = m(E).$$

Since $m(E) < \infty$, every $m(E_n)$ is finite, and by excision $m(E \sim E_n) = m(E) - m(E_n)$. Choose N so large that $m(E) - m(E_N) < \epsilon$ and set

$$F = E_N.$$

Then F is a measurable subset of E , $m(E \sim F) < \epsilon$, and $|f| \leq N$ on F ; in particular f is real-valued on F .

Step 2: uniform approximation on F by simple functions. By part (ii) of Proposition 5, the restriction of f to the measurable set F is measurable, and by Step 1 it is a bounded real-valued function on F . Fix a natural number n . The Simple Approximation Lemma, applied to $f|_F$ with the choice $\epsilon = 1/n$, provides simple functions ϕ_n and ψ_n on F with

$$\phi_n \leq f \leq \psi_n \quad \text{and} \quad 0 \leq \psi_n - \phi_n < 1/n \quad \text{on } F.$$

Consequently

$$0 \leq f - \phi_n \leq \psi_n - \phi_n < 1/n \quad \text{on } F.$$

Step 3: extension to E . Define φ_n on all of E by

$$\varphi_n(x) = \begin{cases} \phi_n(x) & \text{if } x \in F, \\ 0 & \text{if } x \in E \sim F. \end{cases}$$

Each φ_n is real-valued and takes only finitely many values, namely the values of ϕ_n together with possibly 0. It is measurable on E : the restriction of φ_n to the measurable set F is ϕ_n , which is measurable because it is simple, and the restriction of φ_n to $E \sim F$ is identically 0, which is measurable; so by part (ii) of Proposition 5, φ_n is measurable on E . Being real-valued, measurable, and finitely valued, φ_n is a simple function on E .

Step 4: conclusion. Let $\epsilon' > 0$ and choose N' with $1/N' < \epsilon'$. For $n \geq N'$ we have, by Step 2, $|f - \varphi_n| = |f - \phi_n| < 1/n \leq 1/N' < \epsilon'$ at every point of F . Thus $\{\varphi_n\} \rightarrow f$ uniformly on F , while $m(E \sim F) < \epsilon$. ■

Problem 3.16. Let I be a closed, bounded interval and E a measurable subset of I . Let $\epsilon > 0$. Show that there is a step function h on I and a measurable subset F of I for which

$$h = \chi_E \text{ on } F \quad \text{and} \quad m(I \sim F) < \epsilon.$$

(Hint: Use Theorem 12 of Chapter 2.)

Solution. Write $I = [a, b]$. Since $E \subseteq I$ is measurable and $m^*(E) \leq b - a < \infty$, Theorem 12 of Chapter 2 applies: there is a finite disjoint collection of open intervals $\{I_k\}_{k=1}^n$ such that, setting $\mathcal{O} = \bigcup_{k=1}^n I_k$,

$$m^*(E \Delta \mathcal{O}) < \epsilon,$$

where, as in the text, $E \Delta \mathcal{O} = (E \sim \mathcal{O}) \cup (\mathcal{O} \sim E)$ denotes the symmetric difference. Write $I_k = (a_k, b_k)$ for $1 \leq k \leq n$.

The step function. Define h on I by $h = \chi_{\mathcal{O}}$ restricted to I , that is,

$$h(x) = \begin{cases} 1 & \text{if } x \in \mathcal{O} \cap I, \\ 0 & \text{if } x \in I \sim \mathcal{O}. \end{cases}$$

We claim h is a step function on I . Let $a = t_0 < t_1 < \cdots < t_m = b$ be the partition of $[a, b]$ whose partition points are a , b , and those of the finitely many numbers $a_1, b_1, \dots, a_n, b_n$ that lie in the open interval (a, b) . Fix j and consider the open interval (t_{j-1}, t_j) . No endpoint a_k or b_k lies in (t_{j-1}, t_j) . Hence for each k , the set $(t_{j-1}, t_j) \cap (a_k, b_k)$ is either empty or all of (t_{j-1}, t_j) : indeed if some $x \in (t_{j-1}, t_j)$ belongs to (a_k, b_k) while some $y \in (t_{j-1}, t_j)$ does not, then between x and y there would be a point of $\{a_k, b_k\}$, and that point would lie in (t_{j-1}, t_j) , a contradiction. Therefore either $(t_{j-1}, t_j) \subseteq \mathcal{O}$, in which case $h \equiv 1$ on (t_{j-1}, t_j) , or $(t_{j-1}, t_j) \cap \mathcal{O} = \emptyset$, in which case $h \equiv 0$ there. So h is constant on each open interval of a finite partition of I , i.e. h is a step function on I .

The set F . Define

$$F = I \sim (E \Delta \mathcal{O}) = I \sim [(E \sim \mathcal{O}) \cup (\mathcal{O} \sim E)].$$

Since E is measurable and $\mathcal{O}$ is open, hence measurable, and the measurable sets form a σ -algebra, F is a measurable subset of I .

Let $x \in F$. Then $x \in I$ and $x \notin E \Delta \mathcal{O}$, so $x \in E$ if and only if $x \in \mathcal{O}$. Hence $\chi_E(x) = \chi_{\mathcal{O}}(x) = h(x)$. Thus $h = \chi_E$ on F .

Finally,

$$I \sim F = I \cap (E \Delta \mathcal{O}) \subseteq E \Delta \mathcal{O},$$

so by the monotonicity of measure $m(I \sim F) \leq m(E \Delta \mathcal{O}) < \epsilon$. ■

Problem 3.17. Let I be a closed, bounded interval and ψ a simple function defined on I . Let $\epsilon > 0$. Show that there is a step function h on I and a measurable subset F of I for which

$$h = \psi \text{ on } F \quad \text{and} \quad m(I \sim F) < \epsilon.$$

(Hint: Use the fact that a simple function is a linear combination of characteristic functions and the preceding problem.)

Solution. Let $c_1, \dots, c_n$ be the distinct values taken by ψ and let

$$E_k = \{x \in I \mid \psi(x) = c_k\}, \quad 1 \leq k \leq n,$$

so that the canonical representation of ψ is

$$\psi = \sum_{k=1}^n c_k \cdot \chi_{E_k} \quad \text{on } I.$$

Each E_k is measurable, since ψ is measurable (Proposition 1), and the E_k are disjoint with union I . Applying the preceding problem. Fix k . Since E_k is a measurable subset of the closed, bounded interval I , Problem 16, applied with the positive number ϵ/n , provides a step function h_k on I and a measurable subset F_k of I for which

$$h_k = \chi_{E_k} \text{ on } F_k \quad \text{and} \quad m(I \sim F_k) < \epsilon/n.$$

The step function. Define

$$h = \sum_{k=1}^n c_k \cdot h_k \quad \text{on } I.$$

A linear combination of step functions on I is again a step function on I : if P_k is a partition of I on each of whose open subintervals h_k is constant, let P be the partition of I whose points are all the points of $P_1 \cup \dots \cup P_n$. Each open subinterval J determined by P is contained in an open subinterval determined by P_k , for every k , so every h_k is constant on J , and hence so is h . Thus h is a step function on I .

The set F . Define $F = \bigcap_{k=1}^n F_k$, a measurable subset of I . By De Morgan's identity and the countable (here finite) subadditivity and monotonicity of measure,

$$m(I \sim F) = m\left(\bigcup_{k=1}^n (I \sim F_k)\right) \leq \sum_{k=1}^n m(I \sim F_k) < n \cdot \frac{\epsilon}{n} = \epsilon.$$

Agreement on F . Let $x \in F$. Then $x \in F_k$ for every k , so $h_k(x) = \chi_{E_k}(x)$ for every k , and therefore

$$h(x) = \sum_{k=1}^n c_k \cdot h_k(x) = \sum_{k=1}^n c_k \cdot \chi_{E_k}(x) = \psi(x).$$

Hence $h = \psi$ on F and $m(I \sim F) < \epsilon$. ■

Problem 3.18. Let I be a closed, bounded interval and f a bounded measurable function defined on I . Let $\epsilon > 0$. Show that there is a step function h on I and a measurable subset F of I for which

$$|h - f| < \epsilon \text{ on } F \quad \text{and} \quad m(I \setminus F) < \epsilon.$$

Solution. The function f is a bounded measurable real-valued function on the measurable set I , so the Simple Approximation Lemma applies. Using it with the positive number $\epsilon/2$, we obtain simple functions ϕ and η on I with

$$\phi \leq f \leq \eta \quad \text{and} \quad 0 \leq \eta - \phi < \epsilon/2 \text{ on } I.$$

Put $\psi = \phi$. Then ψ is a simple function on I and, at every point of I ,

$$0 \leq f - \psi \leq \eta - \phi < \epsilon/2,$$

so that

$$|\psi - f| < \epsilon/2 \text{ on all of } I.$$

Now apply Problem 17 to the simple function ψ on the closed, bounded interval I , with the same $\epsilon > 0$: there is a step function h on I and a measurable subset F of I for which

$$h = \psi \text{ on } F \quad \text{and} \quad m(I \setminus F) < \epsilon.$$

Let $x \in F$. Then $h(x) = \psi(x)$, and therefore

$$|h(x) - f(x)| = |\psi(x) - f(x)| < \epsilon/2 < \epsilon.$$

Thus $|h - f| < \epsilon$ on F while $m(I \setminus F) < \epsilon$, as required. ■

Problem 3.19. Show that the sum and product of two simple functions are simple as are the max and the min.

Solution. Let φ and ψ be simple functions with common measurable domain E (a common domain is needed for the four operations to be defined). Let $a_1, \dots, a_n$ be the distinct values of φ and $b_1, \dots, b_m$ the distinct values of ψ , and set

$$A_i = \{x \in E \mid \varphi(x) = a_i\}, \quad B_j = \{x \in E \mid \psi(x) = b_j\}.$$

Since φ and ψ are measurable, each A_i and each B_j is measurable by Proposition 1. The collection $\{A_i\}_{i=1}^n$ is a disjoint cover of E , as is $\{B_j\}_{j=1}^m$, and hence the sets

$$C_{ij} = A_i \cap B_j, \quad 1 \leq i \leq n, \quad 1 \leq j \leq m,$$

are measurable, pairwise disjoint, and their union is E .

Let g denote any one of the four functions

$$\varphi + \psi, \quad \varphi \cdot \psi, \quad \max\{\varphi, \psi\}, \quad \min\{\varphi, \psi\},$$

and let γ_{ij} denote, respectively, the number

$$a_i + b_j, \quad a_i b_j, \quad \max\{a_i, b_j\}, \quad \min\{a_i, b_j\}.$$

Since $\varphi \equiv a_i$ and $\psi \equiv b_j$ on C_{ij} , in each of the four cases we have $g \equiv \gamma_{ij}$ on C_{ij} . g takes only finitely many values. Since the C_{ij} cover E , the image $g(E)$ is contained in the finite set $\{\gamma_{ij} \mid 1 \leq i \leq n, \quad 1 \leq j \leq m\}$, which has at most nm elements. Note also that all the γ_{ij} are real numbers (simple functions are real-valued by definition, so no expression $\infty - \infty$ or $0 \cdot \infty$ can arise), so g is real-valued.

g is measurable. Let c be a real number. Because E is the disjoint union of the C_{ij} and g is constantly γ_{ij} on C_{ij} ,

$$\{x \in E \mid g(x) > c\} = \bigcup_{\{(i,j) : \gamma_{ij} > c\}} C_{ij},$$

a finite union of measurable sets, hence measurable. By Proposition 1, g is measurable on E .

Thus each of $\varphi + \psi$, $\varphi \cdot \psi$, $\max\{\varphi, \psi\}$ and $\min\{\varphi, \psi\}$ is a measurable real-valued function on E taking only a finite number of values, that is, each is simple.

(Alternatively, the measurability of $\varphi + \psi$ and $\varphi \cdot \psi$ follows from Theorem 6 and that of $\max\{\varphi, \psi\}$ and $\min\{\varphi, \psi\}$ from Proposition 8; the point that remains in each case is exactly the finiteness of the set of values established above.) ■

Problem 3.20. Let A and B be any sets. Show that

$$\chi_{A \cap B} = \chi_A \cdot \chi_B$$

$$\chi_{A \cup B} = \chi_A + \chi_B - \chi_A \cdot \chi_B$$

$$\chi_{A^c} = 1 - \chi_A.$$

Solution. Since a complement only has meaning relative to an ambient set, fix a set X with $A \subseteq X$ and $B \subseteq X$, and read all three identities as identities between functions on X , with $A^c = X \sim A$. (In the setting of the text $X = \mathbb{R}$.) For a subset S of X the characteristic function χ_S is the function on X defined by $\chi_S(x) = 1$ if $x \in S$ and $\chi_S(x) = 0$ if $x \notin S$. Two functions on X are equal precisely when they agree at every $x \in X$, so in each case we fix $x \in X$ and check the possible positions of x relative to A and B .

First identity. Suppose $x \in A \cap B$. Then $\chi_{A \cap B}(x) = 1$, while $\chi_A(x) = \chi_B(x) = 1$, so $\chi_A(x) \cdot \chi_B(x) = 1$. Suppose $x \notin A \cap B$. Then $\chi_{A \cap B}(x) = 0$, and at least one of $x \notin A$, $x \notin B$ holds, so at least one of $\chi_A(x)$, $\chi_B(x)$ equals 0 and hence $\chi_A(x) \cdot \chi_B(x) = 0$. In both cases the two sides agree, so $\chi_{A \cap B} = \chi_A \cdot \chi_B$.

Second identity. Consider the four cases, writing $u = \chi_A(x)$ and $v = \chi_B(x)$.

- If $x \in A$ and $x \in B$, then $x \in A \cup B$, so the left side is 1; and $u + v - uv = 1 + 1 - 1 = 1$.
- If $x \in A$ and $x \notin B$, then $x \in A \cup B$, so the left side is 1; and $u + v - uv = 1 + 0 - 0 = 1$.
- If $x \notin A$ and $x \in B$, then $x \in A \cup B$, so the left side is 1; and $u + v - uv = 0 + 1 - 0 = 1$.
- If $x \notin A$ and $x \notin B$, then $x \notin A \cup B$, so the left side is 0; and $u + v - uv = 0 + 0 - 0 = 0$.

In every case the two sides agree, so $\chi_{A \cup B} = \chi_A + \chi_B - \chi_A \cdot \chi_B$.

Third identity. If $x \in A^c$, then $x \notin A$, so $\chi_{A^c}(x) = 1$ and $1 - \chi_A(x) = 1 - 0 = 1$. If $x \notin A^c$, then $x \in A$, so $\chi_{A^c}(x) = 0$ and $1 - \chi_A(x) = 1 - 1 = 0$. Hence $\chi_{A^c} = 1 - \chi_A$.

(Observe that the second identity can also be read off from the first two together with the third and De Morgan's laws: $\chi_{A \cup B} = 1 - \chi_{(A \cup B)^c} = 1 - \chi_{A^c \cap B^c} = 1 - (1 - \chi_A)(1 - \chi_B) = \chi_A + \chi_B - \chi_A \chi_B$.) ■

Problem 3.21. For a sequence $\{f_n\}$ of measurable functions with common domain E , show that each of the following functions is measurable:

$$\inf\{f_n\}, \quad \sup\{f_n\}, \quad \liminf\{f_n\} \quad \text{and} \quad \limsup\{f_n\}.$$

Solution. All functions here are extended real-valued on the measurable set E , and the four functions are defined pointwise: $(\sup\{f_n\})(x) = \sup_n f_n(x)$, and similarly for the others. Such pointwise suprema and infima always exist in the extended real numbers.

The supremum. Put $g = \sup\{f_n\}$. Let c be a real number. We claim

$$\{x \in E \mid g(x) > c\} = \bigcup_{n=1}^{\infty} \{x \in E \mid f_n(x) > c\}.$$

Indeed, if $g(x) > c$ then c is not an upper bound for the set $\{f_n(x)\}_{n=1}^{\infty}$ (its supremum is $g(x) > c$), so there is an index n with $f_n(x) > c$. Conversely, if $f_n(x) > c$ for some n , then $g(x) \geq f_n(x) > c$. Each set $\{x \in E \mid f_n(x) > c\}$ is measurable because f_n is measurable, and the measurable sets are a

σ -algebra, so the countable union on the right is measurable. Since this holds for every real c , property (i) of Proposition 1 holds for g , and hence $g = \sup\{f_n\}$ is measurable. The infimum. Put $h = \inf\{f_n\}$. Let c be a real number. We claim

$$\{x \in E \mid h(x) < c\} = \bigcup_{n=1}^{\infty} \{x \in E \mid f_n(x) < c\}.$$

Indeed, if $h(x) < c$ then c is not a lower bound for $\{f_n(x)\}_{n=1}^{\infty}$, so $f_n(x) < c$ for some n ; conversely if $f_n(x) < c$ for some n , then $h(x) \leq f_n(x) < c$. Again the right-hand side is a countable union of measurable sets, hence measurable, so property (iii) of Proposition 1 holds for h and $h = \inf\{f_n\}$ is measurable.

Observe that these two arguments used nothing about the index set beyond its countability: for each natural number k , the sequence $\{f_n\}_{n \geq k}$ is again a countable family of measurable functions on E , so

$$g_k = \inf_{n \geq k} f_n \quad \text{and} \quad G_k = \sup_{n \geq k} f_n$$

are measurable functions on E for every k .

The limit inferior. By definition,

$$\liminf\{f_n\} = \sup_{k \geq 1} \left(\inf_{n \geq k} f_n \right) = \sup_{k \geq 1} g_k.$$

Each g_k is measurable by the preceding paragraph, so $\{g_k\}_{k=1}^{\infty}$ is a sequence of measurable functions with common domain E ; by the supremum case already proved, $\sup_k g_k$ is measurable. Hence $\liminf\{f_n\}$ is measurable.

The limit superior. Similarly, by definition,

$$\limsup\{f_n\} = \inf_{k \geq 1} \left(\sup_{n \geq k} f_n \right) = \inf_{k \geq 1} G_k,$$

each G_k is measurable, and by the infimum case already proved the pointwise infimum of the sequence $\{G_k\}_{k=1}^{\infty}$ of measurable functions is measurable. Hence $\limsup\{f_n\}$ is measurable. ■

3.4 Problems 3.22–3.28

Problem 3.22. (Dini's Theorem) Let $\{f_n\}$ be an increasing sequence of continuous functions on $[a, b]$ which converges pointwise on $[a, b]$ to the continuous function f on $[a, b]$. Show that the convergence is uniform on $[a, b]$. (Hint: Let $\epsilon > 0$. For each natural number n , define $E_n = \{x \in [a, b] \mid f(x) - f_n(x) < \epsilon\}$. Show that $\{E_n\}$ is an open cover of $[a, b]$ and use the Heine-Borel Theorem.)

Solution. Throughout, “increasing sequence” means $f_n \leq f_{n+1}$ pointwise on $[a, b]$ for every index n . We first record that $f_n \leq f$ on $[a, b]$ for every n . Indeed, fix $x \in [a, b]$ and an index n . For every $m \geq n$ we have $f_n(x) \leq f_m(x)$, and letting $m \rightarrow \infty$ in this inequality, using $f_m(x) \rightarrow f(x)$ and the fact that weak inequalities are preserved under limits, we get $f_n(x) \leq f(x)$. Consequently

$$|f(x) - f_n(x)| = f(x) - f_n(x) \quad \text{for all } x \in [a, b] \text{ and all } n,$$

so it suffices to show that for each $\epsilon > 0$ there is an index N with $f - f_n < \epsilon$ on all of $[a, b]$ whenever $n \geq N$.

Let $\epsilon > 0$ and, following the hint, set

$$E_n = \{x \in [a, b] \mid f(x) - f_n(x) < \epsilon\}.$$

Each E_n is relatively open in $[a, b]$. Indeed, f and f_n are continuous on $[a, b]$, hence so is $g_n := f - f_n$, and $E_n = g_n^{-1}((-\infty, \epsilon))$ is the preimage of an open subset of $\mathbb{R}$ under a continuous function on $[a, b]$. Thus there is an open subset $\mathcal{O}_n$ of $\mathbb{R}$ with $E_n = \mathcal{O}_n \cap [a, b]$. (Concretely: if $x_0 \in E_n$, continuity of

g_n at x_0 with the choice $\eta = \epsilon - g_n(x_0) > 0$ furnishes $\delta > 0$ such that $g_n(x) < \epsilon$ for all $x \in [a, b]$ with $|x - x_0| < \delta$; taking $\mathcal{O}_n$ to be the union of all such open intervals $(x_0 - \delta, x_0 + \delta)$ over $x_0 \in E_n$ gives an open set with $\mathcal{O}_n \cap [a, b] = E_n$.)

The collection $\{E_n\}$ is ascending. Since $f_n \leq f_{n+1}$, we have $f - f_{n+1} \leq f - f_n$ on $[a, b]$, so $f(x) - f_n(x) < \epsilon$ forces $f(x) - f_{n+1}(x) < \epsilon$; that is, $E_n \subseteq E_{n+1}$. The same monotonicity gives $\mathcal{O}_n \cap [a, b] \subseteq \mathcal{O}_m \cap [a, b]$ whenever $n \leq m$.

The collection $\{\mathcal{O}_n\}_{n=1}^\infty$ covers $[a, b]$. Let $x \in [a, b]$. Since $f_n(x) \rightarrow f(x)$, there is an index n with $f(x) - f_n(x) < \epsilon$, that is, $x \in E_n \subseteq \mathcal{O}_n$.

The interval $[a, b]$ is closed and bounded, so by the Heine-Borel Theorem the open cover $\{\mathcal{O}_n\}_{n=1}^\infty$ of $[a, b]$ has a finite subcover, say $\mathcal{O}_{n_1}, \dots, \mathcal{O}_{n_k}$. Put $N = \max\{n_1, \dots, n_k\}$. For each i we have $\mathcal{O}_{n_i} \cap [a, b] = E_{n_i} \subseteq E_N$, and therefore

$$[a, b] = \bigcup_{i=1}^k (\mathcal{O}_{n_i} \cap [a, b]) \subseteq E_N \subseteq [a, b],$$

so $E_N = [a, b]$.

Finally, let $n \geq N$. Then $E_N \subseteq E_n$, so $E_n = [a, b]$, which says precisely that

$$|f(x) - f_n(x)| = f(x) - f_n(x) < \epsilon \quad \text{for every } x \in [a, b].$$

Since $\epsilon > 0$ was arbitrary and N does not depend on x , the convergence of $\{f_n\}$ to f is uniform on $[a, b]$.

Two remarks on the hypotheses, each of which is essential. If f is not assumed continuous the conclusion fails: on $[0, 1]$ the sequence $f_n(x) = x^{1/n}$ is an increasing sequence of continuous functions whose pointwise limit equals 0 at $x = 0$ and 1 on $(0, 1]$, and the convergence is not uniform. If compactness of the domain is dropped the conclusion also fails: on $(0, 1)$ the increasing continuous functions $f_n(x) = \min\{nx, 1\}$ converge pointwise to the continuous function $f \equiv 1$, but $\sup_{0 < x < 1} |1 - f_n(x)| = 1$ for every n .

Problem 3.23. Express a measurable function as the difference of nonnegative measurable functions and thereby prove the general Simple Approximation Theorem based on the special case of a nonnegative measurable function.

Solution. Let E be measurable and let f be an extended real-valued function on E . Define the positive and negative parts of f by

$$f^+(x) = \max\{f(x), 0\}, \quad f^-(x) = \max\{-f(x), 0\} \quad (x \in E).$$

Both are nonnegative, and at each point at most one of them is nonzero, so the difference $f^+ - f^-$ never has the indeterminate form $\infty - \infty$ and

$$f = f^+ - f^-, \quad |f| = f^+ + f^- \quad \text{on } E.$$

Indeed, if $f(x) \geq 0$ then $f^+(x) = f(x)$ and $f^-(x) = 0$; if $f(x) < 0$ then $f^+(x) = 0$ and $f^-(x) = -f(x)$. This covers the extended values as well: if $f(x) = \infty$ then $f^+(x) = \infty$, $f^-(x) = 0$; if $f(x) = -\infty$ then $f^+(x) = 0$, $f^-(x) = \infty$.

If f is measurable, so are f^+ and f^- . For $c \geq 0$,

$$\{x \in E \mid f^+(x) > c\} = \{x \in E \mid f(x) > c\},$$

which is measurable, while for $c < 0$ the set $\{x \in E \mid f^+(x) > c\}$ is all of E , again measurable. Likewise, for $c \geq 0$,

$$\{x \in E \mid f^-(x) > c\} = \{x \in E \mid f(x) < -c\},$$

which is measurable, and for $c < 0$ this set is E . Hence f^+ and f^- are nonnegative measurable functions on E and $f = f^+ - f^-$ is the required expression.

We now prove the Simple Approximation Theorem in general, assuming it for nonnegative measurable functions.

One implication requires nothing new: every simple function is measurable, and by Proposition 9 the pointwise limit of a sequence of measurable functions on E is measurable. So if there is a sequence $\{\varphi_n\}$ of simple functions on E converging pointwise on E to f , then f is measurable.

For the converse, assume f is measurable. By the paragraphs above, f^+ and f^- are nonnegative measurable functions on E . Apply the nonnegative case of the theorem to each: there are sequences $\{\varphi_n\}$ and $\{\psi_n\}$ of simple functions on E with

$$0 \leq \varphi_n \leq f^+, \quad \varphi_n \rightarrow f^+ \text{ pointwise on } E, \quad 0 \leq \psi_n \leq f^-, \quad \psi_n \rightarrow f^- \text{ pointwise on } E,$$

and with each of $\{\varphi_n\}$, $\{\psi_n\}$ increasing. Here is why the two-sided bounds may be taken in the sharpened form $0 \leq \varphi_n \leq f^+$ rather than merely $|\varphi_n| \leq |f^+|$. The nonnegative case delivers simple functions $\tilde{\varphi}_n$ on E , increasing, with $\tilde{\varphi}_n \rightarrow f^+$ pointwise and $|\tilde{\varphi}_n| \leq |f^+| = f^+$ on E ; the latter gives $\tilde{\varphi}_n \leq f^+$ but not $\tilde{\varphi}_n \geq 0$. Replace $\tilde{\varphi}_n$ by $\varphi_n = \max\{\tilde{\varphi}_n, 0\}$. By Problem 19 the maximum of two simple functions is simple, so each φ_n is simple; the sequence $\{\varphi_n\}$ is still increasing since $t \mapsto \max\{t, 0\}$ is increasing; $0 \leq \varphi_n \leq \max\{f^+, 0\} = f^+$ because $\tilde{\varphi}_n \leq f^+$ and $0 \leq f^+$; and at each $x \in E$, $\varphi_n(x) = \max\{\tilde{\varphi}_n(x), 0\} \rightarrow \max\{f^+(x), 0\} = f^+(x)$, by continuity of $t \mapsto \max\{t, 0\}$ on $\mathbb{R}$ when $f^+(x)$ is finite, and directly from $\tilde{\varphi}_n(x) \rightarrow \infty$ when $f^+(x) = \infty$. The same replacement is made for $\{\psi_n\}$.

Define $h_n = \varphi_n - \psi_n$ on E . Each h_n is simple: ψ_n simple implies $-\psi_n = (-1) \cdot \psi_n$ is simple, and by Problem 19 the sum of two simple functions is simple. Note that φ_n and ψ_n are real-valued (simple functions take finitely many real values), so no indeterminate difference arises.

The bound $|h_n| \leq |f|$ holds on E . Fix $x \in E$. If $f(x) \geq 0$ then $f^-(x) = 0$, so $0 \leq \psi_n(x) \leq f^-(x) = 0$ forces $\psi_n(x) = 0$; hence $h_n(x) = \varphi_n(x)$ and

$$|h_n(x)| = \varphi_n(x) \leq f^+(x) = |f(x)|.$$

If $f(x) < 0$ then $f^+(x) = 0$, so $\varphi_n(x) = 0$, $h_n(x) = -\psi_n(x)$, and

$$|h_n(x)| = \psi_n(x) \leq f^-(x) = |f(x)|.$$

Finally, $h_n \rightarrow f$ pointwise on E . Fix $x \in E$. If $f(x)$ is finite, then $f^+(x)$ and $f^-(x)$ are finite and

$$\lim_{n \rightarrow \infty} h_n(x) = \lim_{n \rightarrow \infty} \varphi_n(x) - \lim_{n \rightarrow \infty} \psi_n(x) = f^+(x) - f^-(x) = f(x).$$

If $f(x) = \infty$, then, as computed above, $\psi_n(x) = 0$ for every n and $h_n(x) = \varphi_n(x) \rightarrow f^+(x) = \infty = f(x)$.

If $f(x) = -\infty$, then $\varphi_n(x) = 0$ for every n and $h_n(x) = -\psi_n(x) \rightarrow -f^-(x) = -\infty = f(x)$.

Thus $\{h_n\}$ is a sequence of simple functions on E that converges pointwise on E to f and satisfies $|h_n| \leq |f|$ on E for every n , which is the general Simple Approximation Theorem.

For the last clause of the theorem, if $f \geq 0$ on E then $f^- \equiv 0$, hence $\psi_n \equiv 0$ and $h_n = \varphi_n$, so the approximating sequence produced is increasing, as asserted in the nonnegative case.

Problem 3.24. Let I be an interval and $f : I \rightarrow \mathbb{R}$ be increasing. Show that f is measurable by first showing that, for each natural number n , the strictly increasing function $x \mapsto f(x) + x/n$ is measurable, and then taking pointwise limits.

Solution. First note that the domain I is a measurable set, since every interval is Lebesgue measurable. So it makes sense to ask whether f is measurable, and by the criterion defining measurability it suffices to show that for each $c \in \mathbb{R}$ the set $\{x \in I \mid f(x) > c\}$ is measurable.

Fix a natural number n and define

$$g_n : I \rightarrow \mathbb{R}, \quad g_n(x) = f(x) + \frac{x}{n}.$$

The function g_n is strictly increasing. Indeed, let $x, y \in I$ with $x < y$. Since f is increasing, $f(x) \leq f(y)$,

and since $x/n < y/n$, adding gives

$$g_n(x) = f(x) + \frac{x}{n} < f(y) + \frac{y}{n} = g_n(y).$$

Claim: a strictly increasing real-valued function g on an interval I is measurable. Fix $c \in \mathbb{R}$ and put

$$S = \{x \in I \mid g(x) > c\}.$$

The set S is upward closed in I : if $x \in S$ and $y \in I$ with $y > x$, then $g(y) > g(x) > c$, so $y \in S$. We show S is an interval, i.e. that it is convex. Let $x, y \in S$ and let $z \in \mathbb{R}$ with $x < z < y$. Since $x, y \in I$ and I is an interval, $z \in I$; and since $z > x$ and S is upward closed in I , we get $z \in S$. Thus S contains every real number lying between two of its points, so S is an interval (possibly empty, possibly a single point, possibly unbounded). Every interval is measurable, so S is measurable. As $c \in \mathbb{R}$ was arbitrary, g is measurable, and the claim is proved.

Applying the claim to g_n , we conclude that g_n is a measurable real-valued function on I , for every natural number n .

Now take pointwise limits. Fix $x \in I$. Then x is a fixed real number, so $x/n \rightarrow 0$ as $n \rightarrow \infty$, and hence

$$\lim_{n \rightarrow \infty} g_n(x) = \lim_{n \rightarrow \infty} \left(f(x) + \frac{x}{n} \right) = f(x).$$

Thus $\{g_n\}$ is a sequence of measurable functions on the measurable set I that converges pointwise on I to f . By Proposition 9, the pointwise limit of a sequence of measurable functions on a common measurable domain is measurable. Therefore f is measurable.

Remark. The claim above did not actually use the strictness of the increase: if g is merely increasing and $x \in S$, $y \in I$, $y > x$, then $g(y) \geq g(x) > c$, so again $y \in S$, and the rest of the argument is unchanged. Consequently every increasing real-valued function on an interval is measurable directly, without passing to the limit. The route through the strictly increasing functions g_n is the one suggested by the problem, and it is included above in the form requested.

Problem 3.25. Suppose f is a function that is continuous on a closed set F of real numbers. Show that f has a continuous extension to all of $\mathbb{R}$. This is a special case of the forthcoming Tietze Extension Theorem. (Hint: Express $\mathbb{R} \setminus F$ as the union of a countable disjoint collection of open intervals and define f to be linear on the closure of each of these intervals.)

Solution. If $F = \emptyset$ we may take $g \equiv 0$, and if $F = \mathbb{R}$ we may take $g = f$. So assume F is a nonempty proper closed subset of $\mathbb{R}$ and put $\mathcal{O} = \mathbb{R} \setminus F$, a nonempty open set.

Construction of the extension. By Proposition 9 of Chapter 1, $\mathcal{O}$ is the union of a countable disjoint collection $\{I_k\}$ of open intervals; moreover, the proof of that proposition shows that each finite endpoint of each I_k fails to belong to $\mathcal{O}$, hence belongs to F . Since $F \neq \emptyset$, no I_k equals $\mathbb{R}$, so each I_k is of exactly one of the three forms

$$(a_k, b_k) \text{ with } a_k, b_k \in F, \quad (-\infty, b_k) \text{ with } b_k \in F, \quad (a_k, \infty) \text{ with } a_k \in F.$$

Define $g : \mathbb{R} \rightarrow \mathbb{R}$ by

$$g(x) = \begin{cases} f(x), & x \in F, \\ f(a_k) + \frac{f(b_k) - f(a_k)}{b_k - a_k} (x - a_k), & x \in I_k = (a_k, b_k) \text{ bounded}, \\ f(b_k), & x \in I_k = (-\infty, b_k), \\ f(a_k), & x \in I_k = (a_k, \infty). \end{cases}$$

Since the I_k are pairwise disjoint and disjoint from F , g is well defined, real-valued, and $g = f$ on F ; so g is an extension of f . On a bounded I_k the formula is the affine interpolation between the values $f(a_k)$ and $f(b_k)$ at the endpoints, and it takes those values at a_k and b_k , so g is continuous on the closed interval $[a_k, b_k]$ and agrees there with the endpoint values already assigned by f .

Observe once and for all that for x in a bounded component (a_k, b_k) the value $g(x)$ is a convex combination of $f(a_k)$ and $f(b_k)$: writing $t = (x - a_k)/(b_k - a_k) \in (0, 1)$,

$$g(x) = (1 - t)f(a_k) + tf(b_k).$$

Call this the convex-combination identity (C).

Continuity at points of $\mathcal{O}$. If $x_0 \in \mathcal{O}$, then x_0 lies in some I_k , which is an open interval, hence an open neighborhood of x_0 , and g restricted to I_k is either affine or constant, hence continuous at x_0 . So g is continuous at x_0 .

Continuity at points of F . Let $x_0 \in F$ and let $\epsilon > 0$. Since f is continuous on F at x_0 , choose $\delta > 0$ such that

$$|f(y) - f(x_0)| < \epsilon \quad \text{for all } y \in F \text{ with } |y - x_0| < \delta.$$

Call this the choice-of-delta property (D). We produce $\delta_+ > 0$ with $|g(x) - g(x_0)| < \epsilon$ for $x_0 \leq x < x_0 + \delta_+$; the argument on the left is symmetric and produces $\delta_- > 0$, and then $\delta_0 = \min\{\delta_+, \delta_-\}$ works for two-sided continuity at x_0 .

Case 1: x_0 is the left endpoint of some component I_k of $\mathcal{O}$. If $I_k = (x_0, \infty)$, then $g \equiv f(x_0) = g(x_0)$ on $[x_0, \infty)$ and any δ_+ works. If $I_k = (x_0, b_k)$ is bounded, then by (C) and the fact that g is the continuous affine function on $[x_0, b_k]$ with $g(x_0) = f(x_0)$, we have $g(x) \rightarrow g(x_0)$ as $x \rightarrow x_0^+$; choose $\delta_+ \leq b_k - x_0$ accordingly, noting that $[x_0, x_0 + \delta_+) \subseteq [x_0, b_k]$.

Case 2: x_0 is not the left endpoint of any component of $\mathcal{O}$. We claim that then $F \cap (x_0, x_0 + \eta) \neq \emptyset$ for every $\eta > 0$. Indeed, if $F \cap (x_0, x_0 + \eta) = \emptyset$ for some $\eta > 0$, then $(x_0, x_0 + \eta) \subseteq \mathcal{O}$; let $I_k = (a_k, b_k)$ be the interval of the decomposition containing the point $x := x_0 + \eta/2$. By the construction in Proposition 9 of Chapter 1, I_k is the largest open interval that contains x and is contained in $\mathcal{O}$; since $(x_0, x_0 + \eta)$ is an open interval containing x and contained in $\mathcal{O}$, we get $(x_0, x_0 + \eta) \subseteq I_k$ and hence $a_k \leq x_0$. But $a_k < x_0$ is impossible, since then $x_0 \in (a_k, b_k) \subseteq \mathcal{O}$, contradicting $x_0 \in F$. Hence $a_k = x_0$ and x_0 is the left endpoint of I_k , contrary to the case assumption. This proves the claim.

So choose $c \in F$ with $x_0 < c < x_0 + \delta$, and set $\delta_+ = c - x_0 > 0$. Let $x_0 \leq x < x_0 + \delta_+ = c$. If $x \in F$, then $|x - x_0| < \delta$ and by (D), $|g(x) - g(x_0)| = |f(x) - f(x_0)| < \epsilon$. If $x \in \mathcal{O}$, let I_k be its component. Since $x_0 \in F$ and $x_0 < x$ (as $x_0 \notin \mathcal{O}$), the left endpoint of I_k satisfies $a_k \geq x_0$; in particular a_k is finite and $a_k \in F$. Since $c \in F$, $c \notin I_k$, and $x < c$, the right endpoint satisfies $b_k \leq c$; in particular b_k is finite and $b_k \in F$. Therefore

$$x_0 \leq a_k < b_k \leq c < x_0 + \delta,$$

so both a_k and b_k lie in F within distance δ of x_0 , and (D) gives $|f(a_k) - f(x_0)| < \epsilon$ and $|f(b_k) - f(x_0)| < \epsilon$. By (C), with $t \in (0, 1)$,

$$|g(x) - g(x_0)| = |(1 - t)(f(a_k) - f(x_0)) + t(f(b_k) - f(x_0))| \leq (1 - t)\epsilon + t\epsilon = \epsilon.$$

Replacing ϵ by $\epsilon/2$ at the outset makes this a strict inequality $< \epsilon$, as desired.

The left-hand estimate is the mirror image, and we record it in full since it is the other half of the proof. Either x_0 is the right endpoint of some component I_j of $\mathcal{O}$, or it is not. If $I_j = (-\infty, x_0)$, then $g \equiv f(x_0) = g(x_0)$ on $(-\infty, x_0]$ and any δ_- works. If $I_j = (a_j, x_0)$ is bounded, then g is affine on $[a_j, x_0]$ with $g(x_0) = f(x_0)$, hence continuous from the left at x_0 , and we choose $\delta_- \leq x_0 - a_j$ accordingly. If x_0 is the right endpoint of no component, then $F \cap (x_0 - \eta, x_0) \neq \emptyset$ for every $\eta > 0$: otherwise $(x_0 - \eta, x_0) \subseteq \mathcal{O}$, and the component $I_j = (a_j, b_j)$ containing $x_0 - \eta/2$ would satisfy $(x_0 - \eta, x_0) \subseteq I_j$ by maximality, hence $b_j \geq x_0$, while $b_j > x_0$ would put $x_0 \in I_j \subseteq \mathcal{O}$, contradicting $x_0 \in F$; so $b_j = x_0$, contrary to the case assumption. Choose then $c' \in F$ with $x_0 - \delta < c' < x_0$ and set $\delta_- = x_0 - c'$. For $x_0 - \delta_- = c' < x \leq x_0$: if $x \in F$ then $|x - x_0| < \delta$ and (D) applies; if $x \in \mathcal{O}$, its component $I_j = (a_j, b_j)$ has $b_j \leq x_0$ (else $x_0 \in I_j$) and $a_j \geq c'$ (else $c' \in I_j$), so a_j, b_j are finite, lie in F , and satisfy $x_0 - \delta < c' \leq a_j < b_j \leq x_0$; then (D) and (C) give $|g(x) - g(x_0)| \leq \epsilon$ exactly as before. With ϵ replaced by $\epsilon/2$ at the outset this is $< \epsilon$.

Hence g is continuous at every point of $\mathbb{R}$, and g is a continuous extension of f to all of $\mathbb{R}$.

Problem 3.26. For the function f and the set F in the statement of Lusin's Theorem, show that the restriction of f to F is a continuous function. Must there be any points at which f , considered as a function on E , is continuous?

Solution. Recall the statement of Lusin's Theorem: f is a real-valued measurable function on E , and for a given $\epsilon > 0$ it produces a continuous function g on $\mathbb{R}$ and a closed set F contained in E for which

$$f = g \text{ on } F \quad \text{and} \quad m(E \setminus F) < \epsilon.$$

The restriction of f to F is continuous. Continuity of the restriction $f|_F$ means: for each $x_0 \in F$ and each $\eta > 0$ there is $\delta > 0$ such that $|f(x) - f(x_0)| < \eta$ for all $x \in F$ with $|x - x_0| < \delta$. Fix $x_0 \in F$ and $\eta > 0$. Since g is continuous at x_0 as a function on $\mathbb{R}$, there is $\delta > 0$ such that

$$|g(x) - g(x_0)| < \eta \quad \text{for all } x \in \mathbb{R} \text{ with } |x - x_0| < \delta.$$

Now let $x \in F$ with $|x - x_0| < \delta$. Since $x, x_0 \in F$ and $f = g$ on F ,

$$|f(x) - f(x_0)| = |g(x) - g(x_0)| < \eta.$$

Hence $f|_F$ is continuous at every point of F , that is, $f|_F$ is a continuous function on F . (Equivalently: the restriction of a continuous function on $\mathbb{R}$ to any subset of $\mathbb{R}$ is continuous on that subset, and $f|_F = g|_F$.)

Must f , considered as a function on E , be continuous at some point? No. The continuity supplied by Lusin's Theorem is continuity of the restriction, that is, continuity relative to F ; it says nothing about the behavior of f at points of E near x_0 that lie outside F . There are measurable functions that are continuous at no point of their domain.

The standard example is the Dirichlet function. Let $E = [0, 1]$ and

$$f = \chi_{\mathbb{Q} \cap [0,1]}, \quad \text{that is, } f(x) = 1 \text{ if } x \text{ is rational, } f(x) = 0 \text{ if } x \text{ is irrational.}$$

Then f is measurable, since $\mathbb{Q} \cap [0, 1]$ is countable, hence of measure zero, hence measurable, and the characteristic function of a measurable set is measurable. And $m(E) = 1 < \infty$, so Lusin's Theorem applies as stated in the text.

The function f is continuous at no point of $[0, 1]$. Indeed, let $x_0 \in [0, 1]$ and take $\eta = 1/2$. By the density of the rationals and of the irrationals in $\mathbb{R}$, every interval $(x_0 - \delta, x_0 + \delta)$ with $\delta > 0$ contains a point $x_1 \in [0, 1]$ that is rational and a point $x_2 \in [0, 1]$ that is irrational. Then $|f(x_1) - f(x_2)| = 1$, so at least one of $|f(x_1) - f(x_0)|$, $|f(x_2) - f(x_0)|$ is $\geq 1/2 = \eta$. Hence no δ works, and f is discontinuous at x_0 .

It is instructive to see Lusin's Theorem realized here. Let $\epsilon > 0$ and enumerate $\mathbb{Q} \cap [0, 1] = \{q_k\}_{k=1}^\infty$. Put

$$\mathcal{O} = \bigcup_{k=1}^{\infty} \left(q_k - \frac{\epsilon}{2^{k+2}}, q_k + \frac{\epsilon}{2^{k+2}} \right),$$

an open set with, by countable subadditivity and monotonicity of outer measure,

$$m(\mathcal{O}) \leq \sum_{k=1}^{\infty} \frac{\epsilon}{2^{k+1}} = \frac{\epsilon}{2}.$$

Set $F = [0, 1] \setminus \mathcal{O}$. Then F is closed (the intersection of the closed set $[0, 1]$ with the closed set $\mathbb{R} \setminus \mathcal{O}$), $F \subseteq E$, and F contains no rational number, so $f \equiv 0$ on F and f agrees on F with the continuous function $g \equiv 0$ on $\mathbb{R}$. Moreover $E \setminus F \subseteq \mathcal{O}$, so $m(E \setminus F) \leq \epsilon/2 < \epsilon$. Thus the conclusion of Lusin's Theorem holds, the restriction $f|_F$ is continuous (it is identically 0), yet f itself is continuous at no point whatsoever of E – not even at the points of F .

So the answer to the question is: there need not be any point of E at which f is continuous.

Problem 3.27. Show that the conclusion of Egoroff's Theorem can fail if we drop the assumption that the domain has finite measure.

Solution. Take $E = \mathbb{R}$, which is measurable with $m(E) = \infty$, and for each natural number n define

$$f_n = \chi_{[n, \infty)}, \quad \text{that is,} \quad f_n(x) = \begin{cases} 1, & x \geq n, \\ 0, & x < n. \end{cases}$$

Each f_n is measurable, being the characteristic function of the measurable set $[n, \infty)$. Every hypothesis of Egoroff's Theorem except the finiteness of $m(E)$ is satisfied; we show its conclusion fails, and in fact fails for every $\epsilon > 0$.

The sequence converges pointwise on $\mathbb{R}$ to the real-valued function $f \equiv 0$. Indeed, fix $x \in \mathbb{R}$. By the Archimedean property there is a natural number $N > x$, and then for every $n \geq N$ we have $n > x$, so $f_n(x) = 0$. Hence $f_n(x) \rightarrow 0$.

Now let $\epsilon > 0$ and let F be any measurable subset of $\mathbb{R}$ – closed or not – with $m(\mathbb{R} \sim F) < \epsilon$. We claim $F \cap [n, \infty) \neq \emptyset$ for every natural number n . Suppose to the contrary that $F \cap [n, \infty) = \emptyset$ for some n . Then $[n, \infty) \subseteq \mathbb{R} \sim F$, and by monotonicity of measure

$$\infty = m([n, \infty)) \leq m(\mathbb{R} \sim F) < \epsilon < \infty,$$

a contradiction. This proves the claim.

For each n choose $x_n \in F \cap [n, \infty)$. Then $f_n(x_n) = 1$ while $f(x_n) = 0$, so

$$\sup_{x \in F} |f_n(x) - f(x)| \geq |f_n(x_n) - f(x_n)| = 1 \quad \text{for every } n.$$

Therefore $\{f_n\}$ does not converge uniformly to f on F : taking $\eta = 1/2$ in the definition of uniform convergence, there is no index N for which $|f_n - f| < 1/2$ on F for all $n \geq N$.

Since F was an arbitrary measurable set with $m(\mathbb{R} \sim F) < \epsilon$, and closed sets are in particular measurable, there is no closed set $F \subseteq \mathbb{R}$ with $m(\mathbb{R} \sim F) < \epsilon$ on which $\{f_n\}$ converges uniformly to f . Thus the conclusion of Egoroff's Theorem fails here for every $\epsilon > 0$, and the finiteness of $m(E)$ cannot simply be dropped.

Remark. A variant on a set of infinite measure that fails only for small ϵ is $f_n = \chi_{[n, n+1)}$ on $\mathbb{R}$, which also converges pointwise to 0. If $m(\mathbb{R} \sim F) < 1$, then for each n we have $m([n, n+1) \sim F) < 1 = m([n, n+1))$, so $[n, n+1) \cap F \neq \emptyset$, and the same argument shows $\sup_F |f_n| \geq 1$ for all n . Note the essential role of infinite measure in both examples: the sets on which f_n differs from its limit march off to infinity without shrinking in measure, and a set of finite measure cannot contain such a sequence of sets of measure bounded away from 0 while leaving only a small complement.

Problem 3.28. Show that Egoroff's Theorem continues to hold if the convergence is pointwise a.e. and f is finite a.e.

Solution. The assertion to be proved is the following. Let E have finite measure, let $\{f_n\}$ be a sequence of measurable functions on E , and let f be an extended real-valued function on E that is finite a.e. on E and such that $\{f_n\}$ converges to f pointwise a.e. on E . Then for each $\epsilon > 0$ there is a closed set F contained in E for which

$$\{f_n\} \rightarrow f \quad \text{uniformly on } F \quad \text{and} \quad m(E \sim F) < \epsilon.$$

Isolating the exceptional set. Let

$$A = \{x \in E \mid |f(x)| = \infty\}, \quad B = \{x \in E \mid \{f_n(x)\} \text{ does not converge to } f(x)\},$$

and put $E_0 = A \cup B$. By hypothesis, f is finite a.e. on E , so A is contained in a set of measure zero; and $\{f_n\} \rightarrow f$ pointwise a.e. on E , so B is contained in a set of measure zero. Hence E_0 is contained in the union of two sets of measure zero, which by the countable subadditivity and monotonicity of outer

measure is a set of outer measure zero; therefore $m^*(E_0) = 0$. Since every set of outer measure zero is measurable (the completeness of Lebesgue measure, established in Chapter 2), E_0 is measurable and $m(E_0) = 0$.

Passing to a good subdomain. Define

$$\tilde{E} = E \sim E_0.$$

Then $\tilde{E}$ is measurable, being the difference of two measurable sets, and $m(\tilde{E}) \leq m(E) < \infty$, so $\tilde{E}$ has finite measure. Each f_n restricted to $\tilde{E}$ is measurable: for every $c \in \mathbb{R}$,

$$\{x \in \tilde{E} \mid f_n(x) > c\} = \tilde{E} \cap \{x \in E \mid f_n(x) > c\},$$

the intersection of two measurable sets. By the very definition of E_0 , on $\tilde{E}$ the function f is real-valued and $\{f_n\}$ converges to f at every point.

Applying Egoroff's Theorem. Thus $\tilde{E}$ has finite measure, $\{f_n\}$ is a sequence of measurable functions on $\tilde{E}$, and it converges pointwise on $\tilde{E}$ to the real-valued function f . These are exactly the hypotheses of Egoroff's Theorem. Hence, given $\epsilon > 0$, there is a closed set F contained in $\tilde{E}$ for which

$$\{f_n\} \rightarrow f \text{ uniformly on } F \quad \text{and} \quad m(\tilde{E} \sim F) < \epsilon.$$

Conclusion. The set F is closed and $F \subseteq \tilde{E} \subseteq E$, so F is a closed subset of E , and $\{f_n\}$ converges to f uniformly on F . It remains to estimate $m(E \sim F)$. Since $F \subseteq \tilde{E} = E \sim E_0$,

$$E \sim F = (E \sim \tilde{E}) \cup (\tilde{E} \sim F) = E_0 \cup (\tilde{E} \sim F),$$

so by the countable (here finite) subadditivity of measure,

$$m(E \sim F) \leq m(E_0) + m(\tilde{E} \sim F) = 0 + m(\tilde{E} \sim F) < \epsilon.$$

Therefore the conclusion of Egoroff's Theorem holds verbatim under the weakened hypotheses of pointwise a.e. convergence to a function that is finite a.e. This is the assertion made in the remark immediately following the proof of Egoroff's Theorem in the text.

3.5 Problems 3.29–3.31

Problem 3.29. Prove the extension of Lusin's Theorem to the case that E has infinite measure.

Solution. We must show: if f is a real-valued measurable function on a measurable set E with $m(E) = \infty$, then for each $\epsilon > 0$ there is a continuous function g on $\mathbb{R}$ and a closed set F contained in E for which $f = g$ on F and $m(E \sim F) < \epsilon$. The proof of Lusin's Theorem given in the text establishes this when $m(E) < \infty$; we bootstrap from that case.

Let $\epsilon > 0$ be given. For each integer $n \in \mathbb{Z}$ define

$$A_n = E \cap (n, n+1), \quad Z = E \cap \mathbb{Z}.$$

Each A_n is measurable, being the intersection of two measurable sets, and $m(A_n) \leq 1 < \infty$. The set Z is countable, so $m(Z) = 0$. Since every real number lies either in $\mathbb{Z}$ or in exactly one interval $(n, n+1)$,

$$E = Z \cup \bigcup_{n \in \mathbb{Z}} A_n,$$

and the sets Z and $\{A_n\}_{n \in \mathbb{Z}}$ are pairwise disjoint.

Fix a bijection $k \mapsto n_k$ of the natural numbers onto $\mathbb{Z}$. For each k , the restriction of f to A_{n_k} is real-valued, and it is measurable on A_{n_k} : for each $c \in \mathbb{R}$,

$$\{x \in A_{n_k} \mid f(x) > c\} = \{x \in E \mid f(x) > c\} \cap A_{n_k}$$

is the intersection of two measurable sets. Since $m(A_{n_k}) < \infty$, Lusin's Theorem in the finite measure case, which is the case proved in the text, may be applied to f on A_{n_k} : there is a continuous function

g_k on $\mathbb{R}$ and a closed set F_{n_k} contained in A_{n_k} for which

$$f = g_k \text{ on } F_{n_k} \quad \text{and} \quad m(A_{n_k} \sim F_{n_k}) < \epsilon/2^{k+1}.$$

Define

$$F = \bigcup_{n \in \mathbb{Z}} F_n \subseteq E.$$

We first record a separation property, to which we refer below as the localization identity. For each n , $F_n \subseteq A_n \subseteq (n, n+1)$, so the sets F_n are pairwise disjoint and, more importantly, $F_m \cap (n, n+1) = \emptyset$ whenever $m \neq n$; hence

$$F \cap (n, n+1) = F_n \quad \text{for every } n \in \mathbb{Z}.$$

F is closed. Let x be a point of closure of F and choose a sequence $\{x_j\}$ in F with $x_j \rightarrow x$. A convergent sequence of real numbers is bounded, say $|x_j| \leq M$ for all j . If $x_j \in F_n$ then $n < x_j < n+1$, so $-M-1 \leq n \leq M$, and thus every x_j lies in one of the finitely many sets F_n with $-M-1 \leq n \leq M$. Therefore some single index n occurs infinitely often, that is, there is a subsequence lying entirely in F_n . This subsequence also converges to x , and F_n is closed, so $x \in F_n \subseteq F$. Thus F contains all its points of closure and so is closed.

$m(E \sim F) < \epsilon$. The localization identity gives $A_n \sim F = A_n \sim F_n$ for each n , and therefore, by the decomposition of E recorded above,

$$E \sim F \subseteq Z \cup \bigcup_{k=1}^{\infty} (A_{n_k} \sim F_{n_k}).$$

Monotonicity and countable subadditivity of measure now yield

$$m(E \sim F) \leq m(Z) + \sum_{k=1}^{\infty} m(A_{n_k} \sim F_{n_k}) \leq 0 + \sum_{k=1}^{\infty} \frac{\epsilon}{2^{k+1}} = \frac{\epsilon}{2} < \epsilon.$$

The restriction of f to F is continuous. Since F is a subset of $\mathbb{R}$, and hence a metric space, it suffices to verify sequential continuity. Let $x \in F$, say $x \in F_n$, and let $\{x_j\}$ be a sequence in F converging to x . Since $x \in (n, n+1)$ and this interval is open, $x_j \in (n, n+1)$ for all sufficiently large j , and then $x_j \in F \cap (n, n+1) = F_n$ by the localization identity. For such j we have $f(x_j) = g_k(x_j)$ and $f(x) = g_k(x)$, where $n = n_k$; since g_k is continuous on $\mathbb{R}$, $f(x_j) = g_k(x_j) \rightarrow g_k(x) = f(x)$. Hence the restriction of f to F is continuous at each point of F .

Finally, f restricted to F is a continuous function on the closed set F , so by Problem 25 it has a continuous extension g to all of $\mathbb{R}$. Then g is continuous on $\mathbb{R}$, F is a closed subset of E , $f = g$ on F , and $m(E \sim F) < \epsilon$. This is exactly the conclusion of Lusin's Theorem, now established without any assumption on $m(E)$.

Problem 3.30. Prove the extension of Lusin's Theorem to the case that f is not necessarily real-valued, but may be finite a.e.

Solution. We must show: if f is an extended real-valued measurable function on a measurable set E which is finite a.e. on E , then for each $\epsilon > 0$ there is a continuous function g on $\mathbb{R}$ and a closed set F contained in E for which $f = g$ on F and $m(E \sim F) < \epsilon$.

Let $\epsilon > 0$ be given. Define

$$E_{\infty} = \{x \in E \mid f(x) = \infty\}, \quad E_{-\infty} = \{x \in E \mid f(x) = -\infty\}, \quad E_0 = E_{\infty} \cup E_{-\infty}.$$

Since f is measurable,

$$E_{\infty} = \bigcap_{n=1}^{\infty} \{x \in E \mid f(x) > n\} \quad \text{and} \quad E_{-\infty} = \bigcap_{n=1}^{\infty} \{x \in E \mid f(x) < -n\}$$

are measurable, being countable intersections of measurable sets; hence E_0 is measurable. By hypothesis f is finite a.e. on E , which says precisely that $m(E_0) = 0$.

Put $E' = E \sim E_0$. Then E' is measurable, and the restriction of f to E' is a real-valued function which is measurable on E' : for each $c \in \mathbb{R}$,

$$\{x \in E' \mid f(x) > c\} = \{x \in E \mid f(x) > c\} \cap E'$$

is the intersection of two measurable sets.

Apply Lusin's Theorem to the real-valued measurable function f on E' – in the case $m(E') < \infty$ this is the theorem as proved in the text, and in the case $m(E') = \infty$ it is the extension established in Problem 29, so no restriction on $m(E')$ is needed. We obtain a continuous function g on $\mathbb{R}$ and a closed set F contained in E' for which

$$f = g \text{ on } F \quad \text{and} \quad m(E' \sim F) < \epsilon.$$

This F and g do what is required for f on E . Indeed, $F \subseteq E' \subseteq E$ and F is closed, g is continuous on all of $\mathbb{R}$, and $f = g$ on F . Moreover, since

$$E \sim F = (E_0 \sim F) \cup (E' \sim F) \subseteq E_0 \cup (E' \sim F),$$

the monotonicity and finite subadditivity of measure give

$$m(E \sim F) \leq m(E_0) + m(E' \sim F) = 0 + m(E' \sim F) < \epsilon.$$

Thus Lusin's Theorem persists when f is merely extended real-valued and finite a.e. Observe that the a.e. finiteness cannot be dispensed with in this form: on F we have $f = g$ with g real-valued, so f is necessarily finite on F , and therefore the set where f is infinite must be contained in $E \sim F$, a set of measure less than ϵ for every $\epsilon > 0$; hence f must be finite a.e. for the conclusion to be possible at all.

Problem 3.31. Let $\{f_n\}$ be a sequence of measurable functions on E that converges to the real-valued f pointwise on E . Show that $E = \bigcup_{k=1}^{\infty} E_k$, where for each index k , E_k is measurable, and $\{f_n\}$ converges uniformly to f on each E_k if $k > 1$, and $m(E_1) = 0$.

Solution. Step 1: the case $m(E) < \infty$. Assume first that E has finite measure. Then Egoroff's Theorem applies to $\{f_n\}$ on E : for each integer $k \geq 2$, taking $\epsilon = 1/k$, there is a closed set A_k contained in E for which

$$\{f_n\} \rightarrow f \text{ uniformly on } A_k \quad \text{and} \quad m(E \sim A_k) < 1/k.$$

Define

$$N = E \sim \bigcup_{k=2}^{\infty} A_k = \bigcap_{k=2}^{\infty} (E \sim A_k).$$

This set is measurable, being a countable intersection of measurable sets. For each $k \geq 2$, monotonicity of measure gives $m(N) \leq m(E \sim A_k) < 1/k$, and letting $k \rightarrow \infty$ we conclude $m(N) = 0$. By the very definition of N ,

$$E = N \cup \bigcup_{k=2}^{\infty} A_k,$$

which is a decomposition of the required kind: N has measure zero and the convergence is uniform on each A_k .

Step 2: the general case. Now let E be an arbitrary measurable set, of possibly infinite measure. Egoroff's Theorem is not directly available, so we first cut E into countably many pieces of finite measure. Define

$$C_1 = E \cap [-1, 1], \quad C_j = E \cap \{x \mid j-1 < |x| \leq j\} \quad \text{for } j \geq 2.$$

Each C_j is measurable, being the intersection of E with a Borel set, and $m(C_j) \leq 2 < \infty$. Every real number x satisfies $|x| \leq 1$ or $j - 1 < |x| \leq j$ for exactly one $j \geq 2$, so

$$E = \bigcup_{j=1}^{\infty} C_j.$$

Fix j . The restrictions of the f_n to C_j are measurable functions on C_j , since for each $c \in \mathbb{R}$ the set $\{x \in C_j \mid f_n(x) > c\} = \{x \in E \mid f_n(x) > c\} \cap C_j$ is measurable; and $\{f_n\} \rightarrow f$ pointwise on C_j with f real-valued. Since $m(C_j) < \infty$, Step 1 applies on C_j and produces a measurable set $N_j \subseteq C_j$ with $m(N_j) = 0$, together with measurable sets $A_{j,2}, A_{j,3}, \dots$ contained in C_j on each of which $\{f_n\}$ converges uniformly to f , such that

$$C_j = N_j \cup \bigcup_{k=2}^{\infty} A_{j,k}.$$

Now define

$$E_1 = \bigcup_{j=1}^{\infty} N_j.$$

It is measurable as a countable union of measurable sets, and by countable subadditivity

$$m(E_1) \leq \sum_{j=1}^{\infty} m(N_j) = 0,$$

so $m(E_1) = 0$.

The index set $I = \{(j, k) \mid j \geq 1, k \geq 2\}$ is countably infinite, so we may fix a bijection $i \mapsto (j(i), k(i))$ of $\{2, 3, 4, \dots\}$ onto I and define $E_i = A_{j(i), k(i)}$ for $i \geq 2$. Each E_i with $i > 1$ is measurable and $\{f_n\}$ converges uniformly to f on it. (Some of these sets may be empty; uniform convergence on the empty set holds vacuously, so this is harmless.) Finally,

$$\bigcup_{k=1}^{\infty} E_k = \bigcup_{j=1}^{\infty} N_j \cup \bigcup_{j=1}^{\infty} \bigcup_{k=2}^{\infty} A_{j,k} = \bigcup_{j=1}^{\infty} \left(N_j \cup \bigcup_{k=2}^{\infty} A_{j,k} \right) = \bigcup_{j=1}^{\infty} C_j = E,$$

and each E_k is contained in E . This is the asserted decomposition.

Two remarks. First, when $m(E) < \infty$ Step 1 alone suffices, and the sets E_k for $k > 1$ may then be taken closed, since Egoroff's Theorem as proved in the text delivers a closed set. In the general case each $A_{j,k}$ is likewise closed, so the E_k with $k > 1$ may again be taken closed. Second, no finite-measure hypothesis on E is needed for the conclusion, even though Egoroff's Theorem itself requires one; the passage to the bounded pieces C_j is what removes that restriction. This is consistent with Problem 27, which shows that on a set of infinite measure one cannot in general find a single set A with $m(E \sim A)$ small and uniform convergence on A : the present decomposition instead uses countably many sets and pushes the exceptional behaviour into one set of measure zero.

4.1 Problems 4.1–4.7

Problem 4.1. Show that, in the above Dirichlet function example, $\{f_n\}$ fails to converge to f uniformly on $[0, 1]$.

Solution. Recall the construction. The Dirichlet function f on $[0, 1]$ is defined by $f(x) = 1$ if x is rational and $f(x) = 0$ if x is irrational. Letting $\{q_k\}_{k=1}^\infty$ be an enumeration of the rational numbers in $[0, 1]$, for each natural number n the function f_n is defined on $[0, 1]$ by

$$f_n(x) = \begin{cases} 1 & \text{if } x = q_k \text{ for some } k \text{ with } 1 \leq k \leq n, \\ 0 & \text{otherwise.} \end{cases}$$

Each f_n is a step function, hence Riemann integrable: choose a partition P of $[0, 1]$ whose partition points include all of $q_1, \dots, q_n$; then f_n vanishes identically on each open subinterval determined by P , which is exactly the requirement in the definition of a step function (the definition constrains the values only on the open subintervals). Moreover $\{f_n\} \rightarrow f$ pointwise on $[0, 1]$: if x is irrational then $f_n(x) = 0 = f(x)$ for every n , while if x is rational then $x = q_K$ for exactly one index K , and $f_n(x) = 1 = f(x)$ for all $n \geq K$.

We claim the convergence is not uniform. Indeed, we show that

$$\sup_{x \in [0, 1]} |f(x) - f_n(x)| = 1 \quad \text{for every } n.$$

Fix a natural number n . The set $F_n = \{q_1, \dots, q_n\}$ is finite, while the set $\mathbb{Q} \cap [0, 1]$ of rational numbers in $[0, 1]$ is infinite (it contains the distinct points $1/m$ for every natural number m). Therefore there is a rational number $r \in [0, 1]$ with $r \notin F_n$. For this r we have $f(r) = 1$, since r is rational, while $f_n(r) = 0$, since r is not one of $q_1, \dots, q_n$. Hence

$$|f(r) - f_n(r)| = 1,$$

so that $\sup_{x \in [0, 1]} |f(x) - f_n(x)| \geq 1$; since $0 \leq f_n \leq f \leq 1$ on $[0, 1]$, the supremum equals 1.

Now suppose, to get a contradiction, that $\{f_n\} \rightarrow f$ uniformly on $[0, 1]$. Taking $\epsilon = 1/2$ in the definition of uniform convergence, there would be an index N such that

$$|f(x) - f_n(x)| < \frac{1}{2} \quad \text{for all } x \in [0, 1] \text{ and all } n \geq N.$$

Taking $n = N$ and passing to the supremum over $x \in [0, 1]$ gives $1 \leq 1/2$, a contradiction. Therefore $\{f_n\}$ does not converge to f uniformly on $[0, 1]$.

We remark that this failure is forced. As Problem 8 of this section shows, a sequence of Riemann integrable functions on a closed, bounded interval that converges uniformly has a Riemann integrable limit. Since each f_n is Riemann integrable over $[0, 1]$ while f is not, as was verified in the example by exhibiting $L(f, P) = 0$ and $U(f, P) = 1$ for every partition P of $[0, 1]$, the convergence could not possibly have been uniform. The point of the example is precisely that pointwise convergence of a uniformly bounded sequence of Riemann integrable functions is too weak for the Riemann theory, a shortcoming the Lebesgue integral repairs.

Problem 4.2. A partition P' of $[a, b]$ is called a refinement of a partition P provided each partition point of P is also a partition point of P' . For a bounded function f on $[a, b]$, show that under refinement lower Darboux sums increase and upper Darboux sums decrease.

Solution. Throughout, for a partition $P = \{x_0, x_1, \dots, x_n\}$ of $[a, b]$, with $a = x_0 < x_1 < \dots < x_n = b$, we write

$$m_i = \inf\{f(x) \mid x_{i-1} < x < x_i\}, \quad M_i = \sup\{f(x) \mid x_{i-1} < x < x_i\},$$

$$L(f, P) = \sum_{i=1}^n m_i \cdot (x_i - x_{i-1}), \quad U(f, P) = \sum_{i=1}^n M_i \cdot (x_i - x_{i-1}).$$

Since f is bounded, all these infima and suprema are finite real numbers. We must show that if P' refines P , then

$$L(f, P) \leq L(f, P') \quad \text{and} \quad U(f, P') \leq U(f, P).$$

The key monotonicity fact is elementary: if $\emptyset \neq A \subseteq B$ and f is bounded, then

$$\inf_B f \leq \inf_A f \quad \text{and} \quad \sup_A f \leq \sup_B f,$$

since $\inf_B f$ is a lower bound for f on the smaller set A , and $\sup_B f$ is an upper bound for f on A .

Step 1: adjoining a single point. Suppose $P' = P \cup \{c\}$ where $c \notin P$; say $x_{k-1} < c < x_k$. The partitions P and P' have exactly the same subintervals except that the k -th subinterval (x_{k-1}, x_k) of P is replaced in P' by the two subintervals (x_{k-1}, c) and (c, x_k) . Set

$$m' = \inf\{f(x) \mid x_{k-1} < x < c\}, \quad m'' = \inf\{f(x) \mid c < x < x_k\}.$$

All the terms of $L(f, P')$ and $L(f, P)$ indexed by $i \neq k$ agree, so

$$L(f, P') - L(f, P) = m' \cdot (c - x_{k-1}) + m'' \cdot (x_k - c) - m_k \cdot (x_k - x_{k-1}).$$

Since $(x_{k-1}, c) \subseteq (x_{k-1}, x_k)$ and $(c, x_k) \subseteq (x_{k-1}, x_k)$, the monotonicity fact gives $m' \geq m_k$ and $m'' \geq m_k$. Hence

$$L(f, P') - L(f, P) \geq m_k(c - x_{k-1}) + m_k(x_k - c) - m_k(x_k - x_{k-1}) = 0,$$

because $(c - x_{k-1}) + (x_k - c) = x_k - x_{k-1}$. Thus $L(f, P) \leq L(f, P')$.

Symmetrically, with $M' = \sup\{f(x) \mid x_{k-1} < x < c\}$ and $M'' = \sup\{f(x) \mid c < x < x_k\}$ we have $M' \leq M_k$ and $M'' \leq M_k$, so

$$U(f, P') - U(f, P) = M'(c - x_{k-1}) + M''(x_k - c) - M_k(x_k - x_{k-1}) \leq 0,$$

that is, $U(f, P') \leq U(f, P)$.

Step 2: the general case, by induction. Let P' be any refinement of P . Both are finite sets with $P \subseteq P'$, so $P' \setminus P$ is a finite set, say with p elements. We induct on p . If $p = 0$ then $P' = P$ and there is nothing to prove. Assume the assertion holds whenever the refinement adjoins p points, and let P' refine P with $P' \setminus P$ having $p + 1$ elements. Choose $c \in P' \setminus P$ and put $Q = P \cup \{c\}$. Then Q is a refinement of P adjoining a single point, and P' is a refinement of Q with $P' \setminus Q$ having p elements. By Step 1 and the inductive hypothesis,

$$L(f, P) \leq L(f, Q) \leq L(f, P') \quad \text{and} \quad U(f, P') \leq U(f, Q) \leq U(f, P).$$

This completes the induction, and hence the proof: under refinement lower Darboux sums increase and upper Darboux sums decrease.

Finally we note that the same argument works verbatim if, as in the footnote on page 69, the m_i and M_i are taken as infima and suprema over the closed subintervals $[x_{i-1}, x_i]$, since only the inclusion of the new subintervals in the old one was used, and this inclusion holds for the closed subintervals as well.

Problem 4.3. Use the preceding problem to show that for a bounded function on a closed, bounded interval, each lower Darboux sum is no greater than each upper Darboux sum. From this conclude that the lower Riemann integral is no greater than the upper Riemann integral.

Solution. Let f be a bounded function on the closed, bounded interval $[a, b]$, and let P_1 and P_2 be any two partitions of $[a, b]$. We must show $L(f, P_1) \leq U(f, P_2)$.

First observe that for a single partition $P = \{x_0, \dots, x_n\}$ we always have $L(f, P) \leq U(f, P)$. Indeed,

for each i the numbers $m_i = \inf\{f(x) \mid x_{i-1} < x < x_i\}$ and $M_i = \sup\{f(x) \mid x_{i-1} < x < x_i\}$ satisfy $m_i \leq M_i$, since the interval (x_{i-1}, x_i) is nonempty and any value $f(x)$ taken there satisfies $m_i \leq f(x) \leq M_i$. As each $x_i - x_{i-1} > 0$, summing gives

$$L(f, P) = \sum_{i=1}^n m_i(x_i - x_{i-1}) \leq \sum_{i=1}^n M_i(x_i - x_{i-1}) = U(f, P).$$

Now let $P = P_1 \cup P_2$. Since P is a finite subset of $[a, b]$ containing a and b , it is a partition of $[a, b]$, and by construction every partition point of P_1 and every partition point of P_2 belongs to P . Thus P is a common refinement: it refines P_1 and it refines P_2 . By the preceding problem, lower Darboux sums increase and upper Darboux sums decrease under refinement, so

$$L(f, P_1) \leq L(f, P) \quad \text{and} \quad U(f, P) \leq U(f, P_2).$$

Combining these with $L(f, P) \leq U(f, P)$ yields

$$L(f, P_1) \leq L(f, P) \leq U(f, P) \leq U(f, P_2).$$

Hence each lower Darboux sum is no greater than each upper Darboux sum.

Now we conclude the comparison of the integrals. Fix a partition P_2 of $[a, b]$. By what we just proved, the number $U(f, P_2)$ is an upper bound for the set

$$\{L(f, P_1) \mid P_1 \text{ a partition of } [a, b]\}.$$

This set is nonempty and bounded above, and its supremum is by definition the lower Riemann integral. Since the supremum is the least upper bound, we get

$$(R) \int_a^b f = \sup\{L(f, P_1) \mid P_1 \text{ a partition of } [a, b]\} \leq U(f, P_2).$$

As P_2 was an arbitrary partition of $[a, b]$, the number $(R) \int_a^b f$ is a lower bound for the set

$$\{U(f, P_2) \mid P_2 \text{ a partition of } [a, b]\},$$

and since the infimum is the greatest lower bound,

$$(R) \int_a^b f \leq \inf\{U(f, P_2) \mid P_2 \text{ a partition of } [a, b]\} = \overline{(R) \int_a^b f}.$$

Thus the lower Riemann integral is no greater than the upper Riemann integral. This justifies the assertion made in the text that the upper integral is always at least as large as the lower integral, so that Riemann integrability is exactly the assertion that the two coincide.

Problem 4.4. Suppose the bounded function f on $[a, b]$ is Riemann integrable over $[a, b]$. Show that there is a sequence $\{P_n\}$ of partitions of $[a, b]$ for which $\lim_{n \rightarrow \infty} [U(f, P_n) - L(f, P_n)] = 0$.

Solution. Since f is Riemann integrable over $[a, b]$, the lower and upper Riemann integrals are equal; call their common value

$$I = (R) \int_a^b f = \overline{(R) \int_a^b f} = (R) \int_a^b f.$$

Since f is bounded, I is a real number.

Fix a natural number n . By definition,

$$I = \sup\{L(f, P) \mid P \text{ a partition of } [a, b]\},$$

so $I - 1/(2n)$ is not an upper bound for the set of lower Darboux sums; hence there is a partition P'_n of $[a, b]$ with

$$L(f, P'_n) > I - \frac{1}{2n}.$$

Likewise,

$$I = \inf\{U(f, P) \mid P \text{ a partition of } [a, b]\},$$

so $I + 1/(2n)$ is not a lower bound for the set of upper Darboux sums; hence there is a partition P''_n of $[a, b]$ with

$$U(f, P''_n) < I + \frac{1}{2n}.$$

Define $P_n = P'_n \cup P''_n$. This is a finite subset of $[a, b]$ containing a and b , hence a partition of $[a, b]$, and it is a refinement of both P'_n and P''_n . By Problem 2, refinement increases lower Darboux sums and decreases upper Darboux sums, so

$$L(f, P_n) \geq L(f, P'_n) > I - \frac{1}{2n}, \quad U(f, P_n) \leq U(f, P''_n) < I + \frac{1}{2n}.$$

Therefore

$$0 \leq U(f, P_n) - L(f, P_n) < \left(I + \frac{1}{2n}\right) - \left(I - \frac{1}{2n}\right) = \frac{1}{n},$$

where the first inequality is the observation, proved in Problem 3, that $L(f, P) \leq U(f, P)$ for every partition P .

Since $1/n \rightarrow 0$, the squeeze principle gives

$$\lim_{n \rightarrow \infty} [U(f, P_n) - L(f, P_n)] = 0,$$

so $\{P_n\}$ is a sequence of partitions of the required kind.

We add one remark that will be useful in the following problem: the sequence just constructed also satisfies $L(f, P_n) \rightarrow I$ and $U(f, P_n) \rightarrow I$, since both lie in the interval $(I - 1/(2n), I + 1/(2n))$. Thus for a Riemann integrable function the Riemann integral is the limit of the Darboux sums along this sequence of partitions.

Problem 4.5. Let f be a bounded function on $[a, b]$. Suppose there is a sequence $\{P_n\}$ of partitions of $[a, b]$ for which $\lim_{n \rightarrow \infty} [U(f, P_n) - L(f, P_n)] = 0$. Show that f is Riemann integrable over $[a, b]$.

Solution. Since f is bounded on the closed, bounded interval $[a, b]$, both the lower Riemann integral

$$(R) \int_a^b f = \sup\{L(f, P) \mid P \text{ a partition of } [a, b]\}$$

and the upper Riemann integral

$$(R) \int_a^b f = \inf\{U(f, P) \mid P \text{ a partition of } [a, b]\}$$

are real numbers: if $|f| \leq M$ on $[a, b]$, then every Darboux sum lies in $[-M(b-a), M(b-a)]$, so the relevant sets are nonempty and bounded. By Problem 3,

$$(R) \int_a^b f \leq (R) \int_a^b f.$$

Fix a natural number n . Since $(R) \int_a^b f$ is the supremum of all lower Darboux sums, it dominates the particular lower sum $L(f, P_n)$; since $(R) \int_a^b f$ is the infimum of all upper Darboux sums, it is dominated

by the particular upper sum $U(f, P_n)$. Combining these with the inequality above gives the chain

$$L(f, P_n) \leq (R) \int_a^b f \leq (R) \int_a^{\overline{b}} f \leq U(f, P_n).$$

Consequently

$$0 \leq (R) \int_a^{\overline{b}} f - (R) \int_a^b f \leq U(f, P_n) - L(f, P_n) \quad \text{for every } n.$$

The left-hand quantity does not depend on n , and by hypothesis the right-hand quantity tends to 0 as $n \rightarrow \infty$. Therefore, letting $n \rightarrow \infty$,

$$0 \leq (R) \int_a^{\overline{b}} f - (R) \int_a^b f \leq 0,$$

so that

$$(R) \int_a^b f = (R) \int_a^{\overline{b}} f.$$

Since f is bounded on $[a, b]$ and its lower and upper Riemann integrals coincide, f is by definition Riemann integrable over $[a, b]$, and its Riemann integral is this common value. Indeed, the displayed chain of inequalities shows moreover that

$$(R) \int_a^b f = \lim_{n \rightarrow \infty} L(f, P_n) = \lim_{n \rightarrow \infty} U(f, P_n),$$

since both $L(f, P_n)$ and $U(f, P_n)$ are squeezed toward the common value by the same estimate.

Together with the preceding problem this gives the Cauchy criterion for Riemann integrability: a bounded function f on $[a, b]$ is Riemann integrable over $[a, b]$ if and only if there is a sequence $\{P_n\}$ of partitions with $U(f, P_n) - L(f, P_n) \rightarrow 0$; equivalently, if and only if for each $\epsilon > 0$ there is a partition P with $U(f, P) - L(f, P) < \epsilon$.

Problem 4.6. Use the preceding problem to show that since a continuous function f on a closed, bounded interval $[a, b]$ is uniformly continuous on $[a, b]$, it is Riemann integrable over $[a, b]$.

Solution. Let f be continuous on the closed, bounded interval $[a, b]$. We may assume $a < b$, the case $a = b$ being trivial.

First, f is bounded on $[a, b]$. Indeed, $[a, b]$ is a nonempty closed, bounded set of real numbers, so by the Extreme Value Theorem of Chapter 1 the continuous function f takes a minimum and a maximum value on $[a, b]$; in particular f is bounded there. Thus the lower and upper Darboux sums and the lower and upper Riemann integrals of f over $[a, b]$ are defined, and the hypothesis of boundedness required in Problem 5 is met.

Second, f is uniformly continuous on $[a, b]$: by Theorem 23 of Chapter 1, a continuous real-valued function on a closed, bounded set of real numbers is uniformly continuous. Written out, for each $\epsilon > 0$ there is a $\delta > 0$ such that

$$|f(u) - f(v)| < \epsilon \quad \text{whenever } u, v \in [a, b] \text{ and } |u - v| < \delta.$$

Now we construct the required sequence of partitions. Fix a natural number n . Apply uniform continuity with $\epsilon = 1/n$ to obtain $\delta_n > 0$ such that

$$|f(u) - f(v)| < \frac{1}{n} \quad \text{whenever } u, v \in [a, b] \text{ and } |u - v| < \delta_n.$$

Choose a natural number k_n so large that $(b - a)/k_n < \delta_n$, which is possible by the Archimedean property of $\mathbb{R}$, and let P_n be the regular partition of $[a, b]$ into k_n subintervals of equal length $(b - a)/k_n$,

that is,

$$P_n = \left\{ x_i = a + i \cdot \frac{b-a}{k_n} \mid 0 \leq i \leq k_n \right\}.$$

Fix i with $1 \leq i \leq k_n$ and set, as usual,

$$m_i = \inf\{f(x) \mid x_{i-1} < x < x_i\}, \quad M_i = \sup\{f(x) \mid x_{i-1} < x < x_i\}.$$

For any two points u, v in (x_{i-1}, x_i) we have $|u - v| < x_i - x_{i-1} = (b-a)/k_n < \delta_n$, hence $f(u) - f(v) < 1/n$. Taking the supremum over u and then the infimum over v in this inequality gives

$$M_i - m_i \leq \frac{1}{n}.$$

(In detail: for fixed v , $f(u) < f(v) + 1/n$ for all $u \in (x_{i-1}, x_i)$, so $M_i \leq f(v) + 1/n$; thus $M_i - 1/n$ is a lower bound for f on (x_{i-1}, x_i) , so $M_i - 1/n \leq m_i$.)

Therefore

$$U(f, P_n) - L(f, P_n) = \sum_{i=1}^{k_n} (M_i - m_i)(x_i - x_{i-1}) \leq \frac{1}{n} \sum_{i=1}^{k_n} (x_i - x_{i-1}) = \frac{b-a}{n}.$$

Since $(b-a)/n \rightarrow 0$ as $n \rightarrow \infty$, and $U(f, P_n) - L(f, P_n) \geq 0$ for every n by Problem 3, we conclude

$$\lim_{n \rightarrow \infty} [U(f, P_n) - L(f, P_n)] = 0.$$

As f is bounded on $[a, b]$ and $\{P_n\}$ is a sequence of partitions of $[a, b]$ with this property, Problem 5 tells us that f is Riemann integrable over $[a, b]$.

Problem 4.7. Let f be an increasing real-valued function on $[0, 1]$. For a natural number n , define P_n to be the partition of $[0, 1]$ into n subintervals of length $1/n$. Show that $U(f, P_n) - L(f, P_n) \leq \frac{1}{n} [f(1) - f(0)]$. Use Problem 5 to show that f is Riemann integrable over $[0, 1]$.

Solution. Let f be increasing on $[0, 1]$, meaning $f(u) \leq f(v)$ whenever $0 \leq u \leq v \leq 1$.

First, f is bounded on $[0, 1]$: for every $x \in [0, 1]$ we have $0 \leq x \leq 1$, hence

$$f(0) \leq f(x) \leq f(1).$$

So the Darboux sums and the lower and upper Riemann integrals of f over $[0, 1]$ are defined. (Note that no continuity is assumed; an increasing function may have infinitely many jump discontinuities.)

Fix a natural number n and let $P_n = \{x_0, x_1, \dots, x_n\}$ with $x_i = i/n$, so that each subinterval has length $x_i - x_{i-1} = 1/n$. Set

$$m_i = \inf\{f(x) \mid x_{i-1} < x < x_i\}, \quad M_i = \sup\{f(x) \mid x_{i-1} < x < x_i\}.$$

We claim that

$$f(x_{i-1}) \leq m_i \leq M_i \leq f(x_i) \quad \text{for } 1 \leq i \leq n.$$

Indeed, if $x_{i-1} < x < x_i$, then since f is increasing, $f(x_{i-1}) \leq f(x) \leq f(x_i)$. Thus $f(x_{i-1})$ is a lower bound for f on (x_{i-1}, x_i) and $f(x_i)$ is an upper bound, so $f(x_{i-1}) \leq m_i$ and $M_i \leq f(x_i)$; and $m_i \leq M_i$ because the interval (x_{i-1}, x_i) is nonempty. In particular

$$0 \leq M_i - m_i \leq f(x_i) - f(x_{i-1}).$$

Therefore

$$\begin{aligned}
 U(f, P_n) - L(f, P_n) &= \sum_{i=1}^n (M_i - m_i)(x_i - x_{i-1}) \\
 &= \frac{1}{n} \sum_{i=1}^n (M_i - m_i) \\
 &\leq \frac{1}{n} \sum_{i=1}^n [f(x_i) - f(x_{i-1})] \\
 &= \frac{1}{n} [f(x_n) - f(x_0)] \\
 &= \frac{1}{n} [f(1) - f(0)],
 \end{aligned}$$

the fourth equality holding because the sum telescopes: all the intermediate values $f(x_1), \dots, f(x_{n-1})$ cancel in pairs. This is the asserted estimate.

Finally, the number $f(1) - f(0)$ is a fixed nonnegative real number independent of n , so

$$0 \leq U(f, P_n) - L(f, P_n) \leq \frac{f(1) - f(0)}{n} \longrightarrow 0 \quad \text{as } n \rightarrow \infty,$$

the left-hand inequality being the fact, established in Problem 3, that $L(f, P) \leq U(f, P)$ for every partition P . By the squeeze principle,

$$\lim_{n \rightarrow \infty} [U(f, P_n) - L(f, P_n)] = 0.$$

Since f is a bounded function on $[0, 1]$ and $\{P_n\}$ is a sequence of partitions of $[0, 1]$ with this property, Problem 5 shows that f is Riemann integrable over $[0, 1]$.

The same argument applies on any closed, bounded interval $[a, b]$, with P_n the regular partition into n subintervals of length $(b-a)/n$, yielding $U(f, P_n) - L(f, P_n) \leq \frac{b-a}{n} [f(b) - f(a)]$; hence every monotone function on a closed, bounded interval is Riemann integrable there.

4.2 Problems 4.8–4.14

Problem 4.8. Let $\{f_n\}$ be a sequence of bounded functions that converges uniformly to f on the closed, bounded interval $[a, b]$. If each f_n is Riemann integrable over $[a, b]$, show that f also is Riemann integrable over $[a, b]$. Is it true that

$$\lim_{n \rightarrow \infty} \int_a^b f_n = \int_a^b f?$$

Solution. Throughout, for a bounded function g on $[a, b]$ and a partition $P = \{a = x_0 < x_1 < \dots < x_k = b\}$ we write

$$U(g, P) = \sum_{i=1}^k M_i(g) (x_i - x_{i-1}), \quad L(g, P) = \sum_{i=1}^k m_i(g) (x_i - x_{i-1}),$$

where $M_i(g) = \sup\{g(x) : x_{i-1} \leq x \leq x_i\}$ and $m_i(g) = \inf\{g(x) : x_{i-1} \leq x \leq x_i\}$.

Step 1: f is bounded. Put $\eta_n = \sup_{x \in [a, b]} |f_n(x) - f(x)|$, a number in $[0, \infty]$. Uniform convergence of $\{f_n\}$ to f on $[a, b]$ says precisely that for each $\epsilon > 0$ there is an index N with $|f_n - f| < \epsilon$ on all of $[a, b]$ for $n \geq N$, that is, $\eta_n \leq \epsilon$ for $n \geq N$; so η_n is finite for all large n and $\eta_n \rightarrow 0$. In particular there is an index N with $\eta_N \leq 1$. Since f_N is bounded, say $|f_N| \leq M$ on $[a, b]$, we get $|f| \leq |f_N| + |f - f_N| \leq M + 1$ on $[a, b]$. So f is a bounded function on $[a, b]$ and its Darboux sums are defined.

Step 2: a comparison of Darboux sums. Let g and h be bounded on $[a, b]$ and suppose $|g - h| \leq \eta$ on $[a, b]$. Then $g \leq h + \eta$ on $[a, b]$, so for every subinterval $[x_{i-1}, x_i]$ of a partition P we have $M_i(g) \leq M_i(h) + \eta$, and likewise $m_i(g) \geq m_i(h) - \eta$. Multiplying by the lengths $x_i - x_{i-1}$ and summing, and using

$$\sum_{i=1}^k (x_i - x_{i-1}) = b - a,$$

$$U(g, P) \leq U(h, P) + \eta(b - a), \quad L(g, P) \geq L(h, P) - \eta(b - a). \quad (*)$$

Step 3: f is Riemann integrable. We may assume $a < b$, since for $a = b$ every bounded function is trivially Riemann integrable with integral 0. Let k be a natural number. Since $\eta_n \rightarrow 0$, choose an index n_k for which

$$\eta_{n_k} = \sup_{x \in [a, b]} |f_{n_k}(x) - f(x)| < \frac{1}{4k(b - a)}.$$

The function f_{n_k} is Riemann integrable over $[a, b]$, so by Problem 4 of this chapter there is a sequence of partitions of $[a, b]$ along which the difference of the upper and lower Darboux sums of f_{n_k} tends to 0; choose from it a partition P_k of $[a, b]$ for which

$$U(f_{n_k}, P_k) - L(f_{n_k}, P_k) < \frac{1}{2k}.$$

By (*), applied with $g = f$, $h = f_{n_k}$ and $\eta = 1/[4k(b - a)]$,

$$U(f, P_k) - L(f, P_k) \leq [U(f_{n_k}, P_k) - L(f_{n_k}, P_k)] + 2 \cdot \frac{1}{4k(b - a)} \cdot (b - a) < \frac{1}{2k} + \frac{1}{2k} = \frac{1}{k}.$$

Thus $\{P_k\}$ is a sequence of partitions of $[a, b]$ with $\lim_{k \rightarrow \infty} [U(f, P_k) - L(f, P_k)] = 0$, and therefore f is Riemann integrable over $[a, b]$ by Problem 5.

Step 4: the integrals converge. Yes, it is true that $\lim_{n \rightarrow \infty} \int_a^b f_n = \int_a^b f$. Indeed, fix an index n large enough that $\eta_n < \infty$ (by Step 1 all but finitely many indices are such) and apply (*) with $g = f$, $h = f_n$, $\eta = \eta_n$: for every partition P ,

$$U(f, P) \leq U(f_n, P) + \eta_n(b - a).$$

Taking the infimum over all partitions P of $[a, b]$ on both sides gives the corresponding inequality for the upper Riemann integrals,

$$(R) \int_a^b f \leq (R) \int_a^b f_n + \eta_n(b - a).$$

Both f and f_n are Riemann integrable, so their upper Riemann integrals equal their integrals, and hence

$$\int_a^b f \leq \int_a^b f_n + \eta_n(b - a).$$

Interchanging the roles of f and f_n (the hypothesis $|f - f_n| \leq \eta_n$ is symmetric) gives $\int_a^b f_n \leq \int_a^b f + \eta_n(b - a)$. Together,

$$\left| \int_a^b f_n - \int_a^b f \right| \leq \eta_n(b - a).$$

Since $\eta_n \rightarrow 0$ by uniform convergence, the right-hand side tends to 0, and therefore $\lim_{n \rightarrow \infty} \int_a^b f_n = \int_a^b f$.

Note that uniform convergence is essential for both conclusions: the Dirichlet function example of this section exhibits a uniformly bounded, increasing sequence of Riemann integrable functions on $[0, 1]$ converging pointwise to a function that is not Riemann integrable.

Problem 4.9. Let E have measure zero. Show that if f is a bounded function on E , then f is measurable and $\int_E f = 0$.

Solution. f is measurable. First note that E itself is measurable: it has outer measure zero, so Proposition 4 of Chapter 2 applies. Hence it makes sense to ask whether a function on E is measurable

and to form $\int_E$. Now let c be a real number and set

$$A_c = \{x \in E \mid f(x) > c\}.$$

Then $A_c \subseteq E$, so by the monotonicity of Lebesgue outer measure, $m^*(A_c) \leq m^*(E) = m(E) = 0$, that is, A_c has outer measure zero. By Proposition 4 of Chapter 2, a set of outer measure zero is measurable. Hence A_c is measurable for every c , and therefore f is a measurable function on E . (Note that no hypothesis beyond $m(E) = 0$ is needed here: **every** real-valued function on a set of measure zero is measurable. Boundedness is only used below, to make the integral of a bounded function over a set of finite measure meaningful.)

$\int_E f = 0$. Since $m(E) = 0 < \infty$, E is a set of finite measure, and f is a bounded measurable function on E ; so by Theorem 4, f is integrable over E and $\int_E f$ is the common value of the upper and lower Lebesgue integrals of f over E .

We claim that **every** simple function φ on E has $\int_E \varphi = 0$. Indeed, let $\varphi = \sum_{i=1}^n a_i \cdot \chi_{E_i}$ be the canonical representation of φ on E , so that the E_i are measurable subsets of E . By monotonicity of measure, $m(E_i) \leq m(E) = 0$ for each i , so $m(E_i) = 0$, and by the definition of the integral of a simple function,

$$\int_E \varphi = \sum_{i=1}^n a_i \cdot m(E_i) = \sum_{i=1}^n a_i \cdot 0 = 0.$$

Now, f is bounded, say $|f| \leq M$ on E . The constant function $\varphi \equiv -M$ is simple with $\varphi \leq f$ on E , and the constant function $\psi \equiv M$ is simple with $f \leq \psi$ on E ; thus the families of simple functions occurring in the definitions of the lower and upper Lebesgue integrals are nonempty. By the claim, every simple $\varphi \leq f$ has $\int_E \varphi = 0$ and every simple $\psi \geq f$ has $\int_E \psi = 0$. Therefore the lower Lebesgue integral of f over E equals

$$\sup \left\{ \int_E \varphi \mid \varphi \text{ simple, } \varphi \leq f \text{ on } E \right\} = \sup\{0\} = 0,$$

and likewise the upper Lebesgue integral equals $\inf\{0\} = 0$. The two agree, confirming integrability, and

$$\int_E f = 0.$$

Problem 4.10. Let f be a bounded measurable function on a set of finite measure E . For a measurable subset A of E , show that $\int_A f = \int_E f \cdot \chi_A$.

Solution. First observe that both integrals are defined. The restriction of f to A is bounded and measurable on A , and $m(A) \leq m(E) < \infty$ by monotonicity of measure, so $\int_A f$ is defined by Theorem 4. Likewise $f \cdot \chi_A$ is bounded on E (by the same bound as f) and measurable on E , being the product of two measurable functions, so $\int_E f \cdot \chi_A$ is defined by Theorem 4. In particular the upper and lower Lebesgue integrals of $f \cdot \chi_A$ over E both equal $\int_E f \cdot \chi_A$.

If A is empty both sides are zero, since $f \cdot \chi_A$ is then the zero function on E , whose integral over E is 0 by Lemma 1, and $\int_\emptyset f = 0$; so assume A is nonempty.

A device for transporting simple functions. Let σ be a simple function on A , with canonical representation $\sigma = \sum_{i=1}^n a_i \cdot \chi_{A_i}$ on A , where the $A_i = \sigma^{-1}(a_i)$ are disjoint measurable subsets of A whose union is A ; they are measurable subsets of E as well. Define $\tilde{\sigma}$ on E by

$$\tilde{\sigma} = \sigma \text{ on } A, \quad \tilde{\sigma} = 0 \text{ on } E \sim A.$$

Then $\tilde{\sigma}$ takes only finitely many values and is measurable on E , so it is simple on E , and

$$\tilde{\sigma} = \sum_{i=1}^n a_i \cdot \chi_{A_i} + 0 \cdot \chi_{E \sim A} \text{ on } E,$$

a representation over the finite disjoint collection $\{A_1, \dots, A_n, E \sim A\}$ of measurable subsets of E . By

Lemma 1,

$$\int_E \tilde{\sigma} = \sum_{i=1}^n a_i \cdot m(A_i) + 0 \cdot m(E \sim A) = \sum_{i=1}^n a_i \cdot m(A_i) = \int_A \sigma. \quad (\dagger)$$

The inequality $\int_E f \cdot \chi_A \leq \int_A f$. Let ψ be a simple function on A with $f \leq \psi$ on A . On A we have $f \cdot \chi_A = f \leq \psi = \tilde{\psi}$, while on $E \sim A$ we have $f \cdot \chi_A = 0 = \tilde{\psi}$. Hence $f \cdot \chi_A \leq \tilde{\psi}$ on E , and since $\int_E f \cdot \chi_A$ equals the upper Lebesgue integral of $f \cdot \chi_A$ over E , which is an infimum over all such competitors, $(\dagger)$ gives

$$\int_E f \cdot \chi_A \leq \int_E \tilde{\psi} = \int_A \psi.$$

Taking the infimum over all simple ψ on A with $\psi \geq f$, and using that this infimum is the upper Lebesgue integral of f over A , which equals $\int_A f$, we obtain $\int_E f \cdot \chi_A \leq \int_A f$.

The inequality $\int_E f \cdot \chi_A \geq \int_A f$. Let φ be a simple function on A with $\varphi \leq f$ on A . On A we have $\tilde{\varphi} = \varphi \leq f = f \cdot \chi_A$, and on $E \sim A$ we have $\tilde{\varphi} = 0 = f \cdot \chi_A$. Hence $\tilde{\varphi} \leq f \cdot \chi_A$ on E , so, $\int_E f \cdot \chi_A$ being also the lower Lebesgue integral of $f \cdot \chi_A$ over E ,

$$\int_A \varphi = \int_E \tilde{\varphi} \leq \int_E f \cdot \chi_A.$$

Taking the supremum over all simple $\varphi \leq f$ on A gives $\int_A f \leq \int_E f \cdot \chi_A$. Combining the two inequalities,

$$\int_A f = \int_E f \cdot \chi_A.$$

Problem 4.11. Does the Bounded Convergence Theorem hold for the Riemann integral?

Solution. No. The theorem fails for the Riemann integral, and it fails in the strongest possible way: the hypotheses can hold while the Riemann integral of the limit function does not even exist, so the asserted conclusion is meaningless.

The counterexample. This is exactly the Dirichlet function example of Section 4.1. The set of rational numbers in $[0, 1]$ is countable; let $\{q_k\}_{k=1}^\infty$ be an enumeration of it. For each natural number n define f_n on $[0, 1]$ by

$$f_n(x) = \begin{cases} 1 & \text{if } x = q_k \text{ for some } k \text{ with } 1 \leq k \leq n, \\ 0 & \text{otherwise.} \end{cases}$$

Each f_n is a step function, hence Riemann integrable over $[0, 1]$; indeed f_n differs from the zero function at only finitely many points, so for every $\epsilon > 0$ one can cover those n points by finitely many intervals of total length less than ϵ and thereby produce a partition P with $U(f_n, P) - L(f_n, P) < \epsilon$. Consequently

$$(R) \int_0^1 f_n = 0 \quad \text{for every } n.$$

Moreover the sequence is uniformly bounded, $|f_n| \leq 1$ on $[0, 1]$ for all n , and it is increasing, so it converges pointwise on $[0, 1]$ to the Dirichlet function

$$f(x) = \begin{cases} 1 & \text{if } x \text{ is rational,} \\ 0 & \text{if } x \text{ is irrational.} \end{cases}$$

Thus every hypothesis of the Bounded Convergence Theorem is satisfied, with $E = [0, 1]$, $M = 1$, and each f_n Riemann integrable. But, as shown in Section 4.1, by the density of the rationals and of the irrationals every partition P of $[0, 1]$ has $L(f, P) = 0$ and $U(f, P) = 1$, so

$$(R) \int_0^1 f = 0 < 1 = \overline{(R) \int_0^1 f},$$

and f is not Riemann integrable over $[0, 1]$. Hence $\lim_{n \rightarrow \infty} (R) \int_0^1 f_n$ exists (it is 0) but there is no number $(R) \int_0^1 f$ for it to equal. The Bounded Convergence Theorem therefore does not hold for the Riemann integral.

A remark on what does survive. If one adds to the hypotheses the assumption that the limit function f is itself Riemann integrable, then the conclusion is true; but this is a theorem about the Lebesgue integral in disguise. Suppose each f_n , and also f , is Riemann integrable over the closed, bounded interval $[a, b]$, that $|f_n| \leq M$ on $[a, b]$ for all n , and that $\{f_n\} \rightarrow f$ pointwise on $[a, b]$.

To invoke the Bounded Convergence Theorem we need the f_n to be measurable. That a bounded Riemann integrable function is measurable is the converse of Theorem 4, which the text states but defers to Theorem 7 of Chapter 5; for a closed, bounded interval it can be proved with the tools at hand, as follows. Let g be Riemann integrable over $[a, b]$. By the reformulation of the upper and lower Riemann integrals in terms of step functions used in the proof of Theorem 3, for each natural number n there are step functions $\varphi_n \leq g \leq \psi_n$ on $[a, b]$ with $(R) \int_a^b \varphi_n > (R) \int_a^b g - 1/(2n)$ and $(R) \int_a^b \psi_n < (R) \int_a^b g + 1/(2n)$, so that $(R) \int_a^b (\psi_n - \varphi_n) < 1/n$. Replacing φ_n by $\max\{\varphi_1, \dots, \varphi_n\}$ and ψ_n by $\min\{\psi_1, \dots, \psi_n\}$ leaves step functions (a maximum or a minimum of finitely many step functions is again a step function, as one sees by passing to a common refinement of their partitions) that still satisfy $\varphi_n \leq g \leq \psi_n$ and, since the new $\psi_n - \varphi_n$ is no larger than the old one, still satisfy the estimate; so we may assume $\{\varphi_n\}$ is increasing and $\{\psi_n\}$ is decreasing. Then $\{\varphi_n\}$ is increasing and bounded above by the bounded function g , and $\{\psi_n\}$ is decreasing and bounded below by g , so both converge pointwise on $[a, b]$, say to φ_* and ψ_* . Step functions are simple, hence measurable, so φ_* and ψ_* are measurable by Proposition 9 of Chapter 3, and $\varphi_* \leq g \leq \psi_*$ on $[a, b]$. Put $h = \psi_* - \varphi_*$, a nonnegative bounded measurable function with $h \leq \psi_n - \varphi_n$ for every n . Since the Lebesgue and Riemann integrals of a step function agree, the monotonicity and linearity of integration, Theorem 5, give

$$0 \leq \int_{[a,b]} h \leq \int_{[a,b]} (\psi_n - \varphi_n) = (R) \int_a^b (\psi_n - \varphi_n) < \frac{1}{n} \quad \text{for every } n,$$

so $\int_{[a,b]} h = 0$. For a natural number k let $E_k = \{x \in [a, b] \mid h(x) > 1/k\}$, a measurable set. Since $(1/k) \cdot \chi_{E_k} \leq h$ on $[a, b]$, Lemma 1 and monotonicity give $(1/k) \cdot m(E_k) \leq \int_{[a,b]} h = 0$, so $m(E_k) = 0$; by countable subadditivity of measure, $\{x \mid h(x) > 0\} = \bigcup_{k=1}^{\infty} E_k$ has measure zero. Hence $\psi_* = \varphi_*$ a.e. on $[a, b]$, and since $\varphi_* \leq g \leq \psi_*$ we get $g = \varphi_*$ a.e. on $[a, b]$. By Proposition 5 of Chapter 3, g is measurable.

Applying this to each f_n , the sequence $\{f_n\}$ consists of measurable functions on $[a, b]$, a set of finite measure $b - a$, is uniformly bounded by M , and converges pointwise to f . The Bounded Convergence Theorem therefore gives $\lim_{n \rightarrow \infty} \int_{[a,b]} f_n = \int_{[a,b]} f$, and by Theorem 3 each of these Lebesgue integrals equals the corresponding Riemann integral, so $\lim_{n \rightarrow \infty} (R) \int_a^b f_n = (R) \int_a^b f$. So the failure exhibited above is precisely a failure of the class of Riemann integrable functions to be closed under uniformly bounded pointwise limits; this closure defect is one of the principal shortcomings of the Riemann integral that the Lebesgue integral removes.

Problem 4.12. Let f be a bounded measurable function on a set of finite measure E . Assume g is bounded and $f = g$ a.e. on E . Show that $\int_E f = \int_E g$.

Solution. By definition, $f = g$ a.e. on E means there is a subset E_0 of E with $m(E_0) = 0$ for which

$$f = g \quad \text{on } E \sim E_0.$$

(The set $\{x \in E \mid f(x) \neq g(x)\}$ is contained in E_0 ; being a subset of a set of measure zero it has outer measure zero and so is itself measurable, by Proposition 4 of Chapter 2. We may therefore assume E_0 is measurable, replacing it by that set if necessary. Also $E \sim E_0$ is measurable, being the difference of two measurable sets.)

Step 1: g is measurable on E . This is immediate from Proposition 5 of Chapter 3, according to which a function that agrees almost everywhere on E with a measurable function is itself measurable. For

completeness we give the verification. Let c be a real number. Then

$$\{x \in E \mid g(x) > c\} = (\{x \in E \mid f(x) > c\} \cap (E \sim E_0)) \cup \{x \in E_0 \mid g(x) > c\},$$

since $g = f$ off E_0 . The first set is the intersection of two measurable sets, hence measurable. The second set is a subset of E_0 , hence has outer measure zero by monotonicity of outer measure, hence is measurable by Proposition 4 of Chapter 2. A union of two measurable sets is measurable, so $\{x \in E \mid g > c\}$ is measurable for every c , and therefore g is measurable on E .

Step 2: both integrals exist. f and g are bounded measurable functions on the set E of finite measure, so by Theorem 4 both are integrable over E , and $\int_E f$ and $\int_E g$ are defined.

Step 3: the difference has integral zero. Put $h = g - f$ on E . Then h is bounded and measurable on E , and $h = 0$ on $E \sim E_0$. Choose $M \geq 0$ with $|h| \leq M$ on E (possible since f and g are bounded). Then

$$0 \leq |h| \leq M \cdot \chi_{E_0} \quad \text{on } E,$$

because on E_0 we have $|h| \leq M = M \cdot \chi_{E_0}$, while on $E \sim E_0$ both sides are 0. The function $M \cdot \chi_{E_0} = M \cdot \chi_{E_0} + 0 \cdot \chi_{E \sim E_0}$ is simple on E , expressed over the finite disjoint collection $\{E_0, E \sim E_0\}$ of measurable subsets of E , so by Lemma 1

$$\int_E M \cdot \chi_{E_0} = M \cdot m(E_0) + 0 \cdot m(E \sim E_0) = M \cdot 0 = 0.$$

The functions $|h|$ and $M \cdot \chi_{E_0}$ are bounded and measurable on E , so by the monotonicity of integration, Theorem 5, applied to the inequalities $0 \leq |h| \leq M \cdot \chi_{E_0}$,

$$0 = \int_E 0 \leq \int_E |h| \leq \int_E M \cdot \chi_{E_0} = 0,$$

whence $\int_E |h| = 0$.

Step 4: conclusion. By Corollary 7 and then Step 3,

$$\left| \int_E g - \int_E f \right| = \left| \int_E (g - f) \right| = \left| \int_E h \right| \leq \int_E |h| = 0,$$

where the first equality uses the linearity of integration, Theorem 5. Therefore

$$\int_E f = \int_E g.$$

Thus the Lebesgue integral of a bounded measurable function over a set of finite measure is unchanged by altering the function on a set of measure zero. Note that the statement of the problem does not assume g to be measurable, and it does not need to: measurability of g is a consequence of the measurability of f and the equality $f = g$ a.e. on E , as Step 1 shows. It is, however, essential that g be assumed bounded, since otherwise $\int_E g$ need not be defined by the theory of this section.

Problem 4.13. Does the Bounded Convergence Theorem hold if $m(E) < \infty$ but we drop the assumption that the sequence $\{f_n\}$ is uniformly bounded on E ?

Solution. No. Uniform boundedness cannot be dropped, even for a set of finite measure and even if each individual f_n is bounded and the convergence is pointwise everywhere.

A counterexample. Take $E = [0, 1]$, so $m(E) = 1 < \infty$. For each natural number n define

$$f_n = n \cdot \chi_{(0, 1/n]} \quad \text{on } [0, 1],$$

that is, $f_n(x) = n$ if $0 < x \leq 1/n$ and $f_n(x) = 0$ otherwise.

Each f_n is a simple function on $[0, 1]$: it takes the two values n and 0 , on the measurable sets $(0, 1/n]$ and $[0, 1] \sim (0, 1/n]$ respectively. In particular each f_n is a bounded measurable function on E , so

$\int_E f_n$ is defined, and by Lemma 1,

$$\int_{[0,1]} f_n = n \cdot m((0, 1/n]) + 0 \cdot m([0, 1] \sim (0, 1/n]) = n \cdot \frac{1}{n} = 1.$$

The sequence converges pointwise on $[0, 1]$ to $f \equiv 0$. Indeed, $f_n(0) = 0$ for every n ; and if $0 < x \leq 1$, choose by the Archimedean property an index N with $1/N < x$, so that for all $n \geq N$ we have $1/n \leq 1/N < x$ and hence $f_n(x) = 0$. Thus $\{f_n\} \rightarrow f$ pointwise on $[0, 1]$, where $f \equiv 0$ is bounded and measurable with

$$\int_{[0,1]} f = 0.$$

Every hypothesis of the Bounded Convergence Theorem holds here except uniform boundedness: the f_n are measurable on a set of finite measure and converge pointwise on E . But

$$\lim_{n \rightarrow \infty} \int_{[0,1]} f_n = 1 \neq 0 = \int_{[0,1]} f,$$

so the conclusion fails. Of course $\{|f_n|\}$ is not uniformly bounded: $\sup_{[0,1]} |f_n| = n \rightarrow \infty$, so there is no single $M \geq 0$ with $|f_n| \leq M$ on E for all n .

Remark. This is essentially the example given in this section just before the statement of the Bounded Convergence Theorem, where f_n is taken to be the continuous “tent” of height n that vanishes for $x \geq 2/n$, satisfies $f_n(1/n) = n$ and $f_n(0) = 0$, and is linear on $[0, 1/n]$ and on $[1/n, 2/n]$; that f_n also has $\int_0^1 f_n = 1$ for every n while $\{f_n\} \rightarrow 0$ pointwise on $[0, 1]$. The mechanism is the same in both cases: a fixed amount of “mass,” namely 1, is carried on sets of measure tending to 0 by functions of height tending to ∞ , so in the limit the mass escapes rather than being distributed by the limit function. A uniform bound M prevents this, since it forces the integral carried on a set A to be at most $M \cdot m(A)$, which is small when $m(A)$ is small.

Note also that the failure is not caused by any pathology of the limit: here $f \equiv 0$ is as well behaved as possible, and the convergence is pointwise at every point of E , not merely almost everywhere. Nor can it be repaired by shrinking E : the example lives on a set of measure 1. Uniform boundedness is genuinely needed, and it is exactly what the proof of the Bounded Convergence Theorem uses, through the term $2M \cdot m(E \sim A)$ in inequality (7), to control the integral over the small set on which Egoroff’s Theorem does not deliver uniform convergence.

Problem 4.14. Show that Proposition 8 is a special case of the Bounded Convergence Theorem.

Solution. Proposition 8 asserts: if $\{f_n\}$ is a sequence of bounded measurable functions on a set of finite measure E and $\{f_n\} \rightarrow f$ uniformly on E , then $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$. The Bounded Convergence Theorem asserts the same conclusion under the hypotheses that the f_n are measurable on the set E of finite measure, that the sequence is uniformly pointwise bounded (there is an $M \geq 0$ with $|f_n| \leq M$ on E for all n), and that $\{f_n\} \rightarrow f$ pointwise on E .

So it suffices to show that the hypotheses of Proposition 8 imply those of the Bounded Convergence Theorem. Two of them are immediate: the functions f_n are measurable on E , and $m(E) < \infty$, by assumption. It remains to verify pointwise convergence and uniform boundedness.

Uniform convergence implies pointwise convergence. Let $x \in E$ and let $\epsilon > 0$. By uniform convergence there is an index N , depending on ϵ alone, such that $|f_n - f| < \epsilon$ on all of E for $n \geq N$; in particular $|f_n(x) - f(x)| < \epsilon$ for all $n \geq N$. Hence $\{f_n(x)\} \rightarrow f(x)$. As $x \in E$ was arbitrary, $\{f_n\} \rightarrow f$ pointwise on E .

Uniform convergence, together with the boundedness of each f_n , implies uniform boundedness. Apply the definition of uniform convergence with $\epsilon = 1$: there is an index N for which

$$|f_n - f| < 1 \quad \text{on } E \text{ for all } n \geq N.$$

Since f_N is bounded, choose $M_N \geq 0$ with $|f_N| \leq M_N$ on E . Then for every $x \in E$,

$$|f(x)| \leq |f(x) - f_N(x)| + |f_N(x)| < 1 + M_N,$$

so f is bounded on E . Consequently, for every $n \geq N$ and every $x \in E$,

$$|f_n(x)| \leq |f_n(x) - f(x)| + |f(x)| < 1 + (1 + M_N) = M_N + 2.$$

Each of the finitely many functions $f_1, \dots, f_{N-1}$ is bounded, say $|f_j| \leq M_j$ on E for $1 \leq j \leq N-1$. Set

$$M = \max\{M_1, \dots, M_{N-1}, M_N + 2\},$$

a maximum of finitely many real numbers, hence a real number. Then $|f_n| \leq M$ on E for every natural number n : for $n < N$ by the choice of M_n , and for $n \geq N$ by the displayed estimate. So $\{f_n\}$ is uniformly pointwise bounded on E .

Conclusion. All the hypotheses of the Bounded Convergence Theorem hold for $\{f_n\}$, f , E and M . Therefore

$$\lim_{n \rightarrow \infty} \int_E f_n = \int_E f,$$

which is precisely the conclusion of Proposition 8. (For this statement to be meaningful one needs $\int_E f$ to be defined: f is measurable, being the pointwise limit on E of the sequence of measurable functions $\{f_n\}$, by Proposition 9 of Chapter 3; it is bounded, as shown above; and $m(E) < \infty$; so f is integrable over E by Theorem 4. The same remark occurs in the proof of Proposition 8 itself.)

Hence Proposition 8 is indeed the special case of the Bounded Convergence Theorem in which the pointwise convergence is strengthened to uniform convergence. The two hypotheses of Proposition 8 that look weaker than those of the Bounded Convergence Theorem, namely that only each individual f_n is assumed bounded rather than the family being uniformly bounded, are not really weaker: uniform convergence manufactures the uniform bound, as the argument above shows. Note that this is a genuine implication and not a circularity: no step of the proof of the Bounded Convergence Theorem given in the text invokes Proposition 8. That proof rests on Egoroff's Theorem, Corollary 7, and the linearity, monotonicity and additivity over domains of the integral; the mention of "the easy proof of the preceding proposition" in its opening paragraph is expository, motivating the appeal to Egoroff's Theorem rather than serving as a step in the argument.

4.3 Problems 4.15–4.21

Problem 4.15. Verify the assertions in the last Remark of this section. [The Remark reads: /Prior to the proof of the Bounded Convergence Theorem, no use was made of the countable additivity of Lebesgue measure on the real line. Only finite additivity was used, and it was used just once, in the proof of Lemma 1. But for the proof of the Bounded Convergence Theorem we used Egoroff's Theorem. The proof of Egoroff's Theorem needed the continuity of Lebesgue measure, a consequence of countable additivity of Lebesgue measure./]

Solution. There are three assertions to check. The first two are an audit of everything in Section 4.2 that precedes the Bounded Convergence Theorem: we must confirm that no step invokes the countable additivity of m , and that exactly one step invokes its finite additivity. The third is the assertion that continuity of measure is a consequence of countable additivity, together with the observation that the proof of the Bounded Convergence Theorem does rest on it, through Egoroff's Theorem.

Throughout, *additivity of m* means additivity of Lebesgue measure over disjoint *measurable* sets: finite additivity is the special case $n < \infty$ of Proposition 6 of Chapter 2, and countable additivity is Proposition 13 of Chapter 2. It is important to keep this separate from the countable subadditivity of outer measure m^* and from the Caratheodory criterion; those two belong to the construction of the σ -algebra of measurable sets and are what make the measurability machinery of Chapter 3 (in particular, that the measurable sets are closed under countable unions, and hence that a pointwise limit of measurable functions is measurable) work. The Remark is about the additivity of m itself, and it is that property whose uses we now trace.

Assertion 1 and 2: the audit of Section 4.2.

(a) *The definition of the integral of a simple function.* For a simple function ψ on a set E of finite

measure with canonical representation $\psi = \sum_{i=1}^n a_i \cdot \chi_{E_i}$, where the a_i are the distinct values of ψ and $E_i = \{x \in E \mid \psi(x) = a_i\}$, one defines

$$\int_E \psi = \sum_{i=1}^n a_i \cdot m(E_i).$$

This is a definition. It requires only that each E_i be measurable (it is, since ψ is measurable) and of finite measure (it is, being a subset of E , by the monotonicity of measure). No additivity of any kind is invoked.

(b) *Lemma 1.* Here $\{E_i\}_{i=1}^n$ is a finite disjoint collection of measurable subsets of E , the a_i are real numbers, $\varphi = \sum_{i=1}^n a_i \cdot \chi_{E_i}$, and the conclusion is $\int_E \varphi = \sum_{i=1}^n a_i \cdot m(E_i)$. The proof groups the indices: with $\{\lambda_1, \dots, \lambda_m\}$ the distinct values of φ , $A_j = \{x \in E \mid \varphi(x) = \lambda_j\}$, and $I_j = \{i \mid a_i = \lambda_j\}$, one has that A_j is the disjoint union of the finitely many sets E_i with $i \in I_j$, and the proof asserts

$$m(A_j) = \sum_{i \in I_j} m(E_i) \quad \text{for } 1 \leq j \leq m.$$

This is exactly the finite additivity of Lebesgue measure. This is the single appearance of additivity of m in Section 4.2 prior to the Bounded Convergence Theorem, as we now confirm by inspecting each remaining step.

(c) *Proposition 2 (linearity and monotonicity for simple functions).* Given simple φ, ψ on E , the proof chooses a finite disjoint collection $\{E_i\}_{i=1}^n$ of measurable sets whose union is E and on each of which both φ and ψ are constant. Such a collection is produced by pure set algebra: take the nonempty sets among the intersections of a level set of φ with a level set of ψ . These are measurable because the measurable sets are closed under finite intersection, which is a structural property of the σ -algebra, not an additivity statement. Lemma 1 is then applied to φ , to ψ , and to $\alpha\varphi + \beta\psi$, and the identity $\sum_i (\alpha a_i + \beta b_i) m(E_i) = \alpha \sum_i a_i m(E_i) + \beta \sum_i b_i m(E_i)$ is arithmetic. For monotonicity one needs only that a nonnegative simple function η has $\int_E \eta \geq 0$, which is immediate from the definition in (a) and the nonnegativity of m . So Proposition 2 uses additivity only through Lemma 1.

The text immediately after Proposition 2 also observes that, by linearity, the disjointness hypothesis on $\{E_i\}$ in Lemma 1 is unnecessary. That deduction uses only Proposition 2, hence no additivity beyond the single use in (b).

(d) *Step functions.* The text next observes that a step function is simple (a singleton and an interval are measurable, and a step function takes finitely many values), and that for a step function on a closed, bounded interval the Riemann and Lebesgue integrals agree. This uses that the measure of an interval is its length and that the measure of a singleton is zero. The first is Proposition 1 of Chapter 2, a statement about *outer* measure proved by a Heine-Borel compactness argument; the second is immediate from the definition of outer measure. Neither is an additivity statement about m . The agreement of the two integrals is then the linearity of Proposition 2 applied to a finite linear combination of characteristic functions of intervals.

(e) *The upper and lower Lebesgue integrals, and the definition of integrability.* These are definitions. That both are finite and that the lower integral does not exceed the upper follows from the monotonicity half of Proposition 2. No additivity beyond (b).

(f) *Theorem 3 (a Riemann integrable function is Lebesgue integrable, with the same integral).* The proof compares the supremum and infimum over step functions with the supremum and infimum over simple functions, using only that every step function is simple and the fact recorded in (d). No additivity beyond (b).

(g) *Theorem 4 (a bounded measurable function on a set of finite measure is integrable).* The proof invokes the Simple Approximation Lemma of Chapter 3 with $\epsilon = 1/n$ to get simple $\varphi_n \leq f \leq \psi_n$ with $0 \leq \psi_n - \varphi_n \leq 1/n$ on E , and then applies the linearity and monotonicity of Proposition 2 to conclude $0 \leq \int_E \psi_n - \int_E \varphi_n \leq (1/n) \cdot m(E)$, together with $m(E) < \infty$. The Simple Approximation Lemma itself partitions the bounded range of f into finitely many intervals and uses the measurability of the preimages; it invokes no property of m whatsoever. So Theorem 4 uses additivity only through Lemma 1, and uses the finiteness of $m(E)$.

(h) *Theorem 5 (linearity and monotonicity of integration for bounded measurable functions)*. The proof passes between the upper and lower Lebesgue integrals using Theorem 4 and Proposition 2 only: for $\alpha \neq 0$ the correspondence $\psi \leftrightarrow \psi/\alpha$ between simple functions dominating αf and those dominating (or dominated by) f is a bijection, and for $\alpha = \beta = 1$ one compares $\int_E (f + g)$ with sums $\int_E \psi_1 + \int_E \psi_2$ and $\int_E \varphi_1 + \int_E \varphi_2$. Monotonicity uses only that $\int_E \eta \geq 0$ for the simple function $\eta \equiv 0$ compared with a nonnegative h . No new use of additivity.

(h') *The Example of the Dirichlet function*. Between Theorem 3 and Theorem 4 the text computes $\int_{[0,1]} \chi_E = 1 \cdot m(E) = 0$ for E the rationals in $[0, 1]$. This uses only the definition of the integral of a simple function together with the fact that a countable set has measure zero — and the latter is a statement about *outer* measure, proved in Chapter 2 from the countable subadditivity of m^* and the fact that a singleton has outer measure zero. Countable subadditivity of m^* is not the countable additivity of m ; it is available before any additivity of m is proved. So this Example adds no use of additivity either.

(i) *Corollary 6 (additivity over domains of integration)*. For disjoint measurable $A, B \subseteq E$ the proof uses the pointwise set identity $\chi_{A \cup B} = \chi_A + \chi_B$ — which holds because A and B are disjoint, and is a statement about *functions*, not about m — together with Problem 10 ($\int_{E_1} f = \int_E f \cdot \chi_{E_1}$, itself a consequence of the definitions and of Theorem 5) and the linearity of Theorem 5. Note in particular that the name of this corollary is misleading for our purposes: the additivity being proved here is a property of the integral, deduced from linearity, and it is not an application of the additivity of m .

(j) *Corollary 7* ($|\int_E f| \leq \int_E |f|$). Immediate from $-|f| \leq f \leq |f|$ and Theorem 5.

(k) *Proposition 8 (passage to the limit for uniformly convergent sequences)*. The proof uses that a uniform limit of measurable functions is measurable, then, for $n \geq N$ with $|f - f_n| < \epsilon/m(E)$ on E , applies Theorem 5 and Corollary 7 to get $|\int_E f - \int_E f_n| \leq [\epsilon/m(E)] \cdot m(E) = \epsilon$. Again $m(E) < \infty$ is used, but no additivity beyond Lemma 1.

This exhausts everything in Section 4.2 before the Bounded Convergence Theorem. The countable additivity of m is never invoked, and its finite additivity is invoked exactly once, in the proof of Lemma 1. That verifies the first two assertions.

Assertion 3: the Bounded Convergence Theorem uses Egoroff's Theorem, and Egoroff's Theorem uses continuity of measure, which follows from countable additivity.

First, the Bounded Convergence Theorem. Its proof fixes $\epsilon > 0$ and, since $m(E) < \infty$ and f is real-valued, applies Egoroff's Theorem to produce a measurable $A \subseteq E$ on which $\{f_n\} \rightarrow f$ uniformly and with $m(E \sim A) < \epsilon/4M$; the estimate

$$\left| \int_E f_n - \int_E f \right| \leq \int_A |f_n - f| + 2M \cdot m(E \sim A)$$

is then finished by uniform convergence on A . So Egoroff's Theorem is genuinely a hypothesis of the argument.

Second, Egoroff's Theorem uses the continuity of measure. Its proof rests on Lemma 10 of Chapter 3, whose proof sets, for $\eta > 0$,

$$E_n = \{x \in E \mid |f(x) - f_k(x)| < \eta \text{ for all } k \geq n\},$$

observes that $\{E_n\}_{n=1}^\infty$ is an ascending collection of measurable sets with $\bigcup_{n=1}^\infty E_n = E$ because $\{f_n\} \rightarrow f$ pointwise on E , and then concludes

$$m(E) = \lim_{n \rightarrow \infty} m(E_n)$$

from the continuity of measure, Theorem 15(i) of Chapter 2. Since $m(E) < \infty$, an index N can then be chosen with $m(E_N) > m(E) - \delta$, and the excision property gives $m(E \sim E_N) < \delta$. (The proof of Egoroff's Theorem proper additionally uses the countable subadditivity of measure to bound $m(E \sim \bigcap_n A_n)$, and Theorem 11 of Chapter 2 to shrink A to a closed set — but the essential point for the Remark is the appeal to continuity of measure.)

Third, continuity of measure is a consequence of countable additivity. Let $\{A_k\}_{k=1}^\infty$ be an ascending collection of measurable sets and put $A_0 = \emptyset$. The sets $A_k \sim A_{k-1}$, $k \geq 1$, are measurable (the

measurable sets are a σ -algebra) and pairwise disjoint: if $j < k$ then $A_j \subseteq A_{k-1}$, so $A_j \sim A_{j-1}$ is disjoint from $A_k \sim A_{k-1}$. Moreover, since the collection is ascending,

$$\bigcup_{k=1}^{\infty} A_k = \bigcup_{k=1}^{\infty} [A_k \sim A_{k-1}] \quad \text{and} \quad A_n = \bigcup_{k=1}^n [A_k \sim A_{k-1}] \quad \text{for each } n.$$

Indeed, if x belongs to $\bigcup_k A_k$, there is a least index k with $x \in A_k$, and then $x \in A_k \sim A_{k-1}$. By the countable additivity of Lebesgue measure, Proposition 13 of Chapter 2, applied to the left-hand union, and by finite additivity applied to the right-hand one,

$$m\left(\bigcup_{k=1}^{\infty} A_k\right) = \sum_{k=1}^{\infty} m(A_k \sim A_{k-1}) = \lim_{n \rightarrow \infty} \sum_{k=1}^n m(A_k \sim A_{k-1}) = \lim_{n \rightarrow \infty} m(A_n),$$

which is Theorem 15(i). (Part (ii), for descending collections with $m(B_1) < \infty$, follows by applying (i) to the ascending collection $\{B_1 \sim B_k\}$ and using excision, which is legitimate because $m(B_1) < \infty$.) Assembling the three points: the development of Section 4.2 up to, but not including, the Bounded Convergence Theorem rests on Lebesgue measure only through its monotonicity, the value it assigns to intervals, and one application of finite additivity in Lemma 1; whereas the Bounded Convergence Theorem itself rests, via Egoroff's Theorem and the continuity of measure, on the countable additivity of Lebesgue measure. All the assertions of the Remark are verified.

One caveat, for honesty: the Remark, and hence this exercise, is a bookkeeping claim about which properties of m the given proofs happen to use. It is not a claim that the Bounded Convergence Theorem cannot be proved without countable additivity, and nothing above should be read as establishing such a claim.

Problem 4.16. Let f be a nonnegative bounded measurable function on a set of finite measure E . Assume $\int_E f = 0$. Show that $f = 0$ a.e. on E .

Solution. Since f is bounded and measurable on E and $m(E) < \infty$, f is integrable over E by Theorem 4, so the hypothesis $\int_E f = 0$ makes sense.

For each natural number n define

$$E_n = \left\{x \in E \mid f(x) \geq \frac{1}{n}\right\}.$$

Each E_n is measurable, since f is a measurable function, and $E_n \subseteq E$, so $m(E_n) \leq m(E) < \infty$ by the monotonicity of measure.

Fix n . The function $\frac{1}{n} \cdot \chi_{E_n}$ is a simple, hence bounded and measurable, function on E , and its integral over E is computed from the definition of the integral of a simple function on a set of finite measure:

$$\int_E \frac{1}{n} \cdot \chi_{E_n} = \frac{1}{n} \cdot m(E_n).$$

(If $E_n = E$ the canonical representation of $\frac{1}{n} \chi_{E_n}$ on E has the single value $1/n$, taken on E ; if $E_n = \emptyset$ it has the single value 0, and then both sides are 0; otherwise it has the two distinct values $1/n$ and 0, taken on E_n and on $E \sim E_n$, and the term $0 \cdot m(E \sim E_n)$ contributes nothing. In every case the displayed formula holds.)

Now $\frac{1}{n} \cdot \chi_{E_n} \leq f$ on E : at a point $x \in E_n$ the left side equals $1/n \leq f(x)$ by the definition of E_n , and at a point $x \in E \sim E_n$ the left side equals $0 \leq f(x)$ because f is nonnegative. Both functions are bounded and measurable on the set E of finite measure, so the monotonicity of integration, Theorem 5, applies and gives

$$\frac{1}{n} \cdot m(E_n) = \int_E \frac{1}{n} \cdot \chi_{E_n} \leq \int_E f = 0.$$

Since $m(E_n) \geq 0$, we conclude $m(E_n) = 0$ for every n .

Finally, because $f \geq 0$ on E ,

$$\{x \in E \mid f(x) \neq 0\} = \{x \in E \mid f(x) > 0\} = \bigcup_{n=1}^{\infty} E_n,$$

the second equality because $f(x) > 0$ holds if and only if $f(x) \geq 1/n$ for some natural number n (choose n with $1/n \leq f(x)$, possible by the Archimedean property). By the countable subadditivity of Lebesgue measure,

$$m(\{x \in E \mid f(x) \neq 0\}) \leq \sum_{n=1}^{\infty} m(E_n) = 0.$$

Hence $\{x \in E \mid f(x) \neq 0\}$ has measure zero, that is, $f = 0$ a.e. on E .

Problem 4.17. Let E be a set of measure zero and define $f = \infty$ on E . Show that $\int_E f = 0$.

Solution. The function $f \equiv \infty$ is a nonnegative extended real-valued measurable function on E : for every c the set $\{x \in E \mid f(x) > c\}$ equals E , which is measurable. So its integral is defined by (8),

$$\int_E f = \sup \left\{ \int_E h \mid h \text{ bounded, measurable, of finite support and } 0 \leq h \leq f \text{ on } E \right\}.$$

We show every number in the set on the right equals 0, and that the set is nonempty; the supremum is then 0.

The set is nonempty: the function $h \equiv 0$ on E is bounded, measurable, vanishes outside the set $E_0 = \emptyset$ of finite measure (so it has finite support), and satisfies $0 \leq h \leq f$ since $f \equiv \infty$.

Now let h be any competitor, that is, h is bounded and measurable on E , $0 \leq h \leq f$ on E , and h has finite support. Since $m(E) = 0 < \infty$, the set E itself is an admissible choice of the set outside of which h vanishes (vacuously, $h = 0$ on $E \sim E = \emptyset$), so the integral of h over E is simply the integral of the bounded measurable function h over the set E of finite measure, in the sense of Section 4.2. No appeal to the independence of the choice of E_0 is needed here.

We claim $\int_E h = 0$. Let ψ be any simple function on E with $h \leq \psi$ on E ; such ψ exist, since $\psi \equiv M$ works for any M bounding h . Write the canonical representation $\psi = \sum_{i=1}^n a_i \cdot \chi_{A_i}$, where the A_i are the level sets of ψ in E . Each $A_i \subseteq E$, so $m(A_i) \leq m(E) = 0$ by the monotonicity of measure, whence

$$\int_E \psi = \sum_{i=1}^n a_i \cdot m(A_i) = 0.$$

Thus every number in the defining set for the upper Lebesgue integral of h over E equals 0, so that upper integral is 0. Since h is bounded and measurable on the set E of finite measure, Theorem 4 says h is integrable over E and $\int_E h$ is the common value of the upper and lower integrals; hence $\int_E h = 0$. (This is precisely the content of Problem 9: a bounded function on a set of measure zero is measurable with integral zero. If $E = \emptyset$ the assertion is trivial.)

(The same conclusion holds if one prefers to compute $\int_E h$ as $\int_{E_0} h$ for a set $E_0 \subseteq E$ of finite measure outside which h vanishes: then $m(E_0) \leq m(E) = 0$ and the identical argument on E_0 gives $\int_{E_0} h = 0$.) Therefore $\int_E h = 0$ for every competitor h , and consequently

$$\int_E f = \sup\{0\} = 0.$$

Note that the same argument shows more generally that the integral of *any* nonnegative measurable function over a set of measure zero is zero; the extreme case $f \equiv \infty$ makes the point that the convention $\infty \cdot 0 = 0$ built into definition (8) is consistent.

Problem 4.18. Show that the integral of a bounded measurable function of finite support is properly defined.

Solution. Recall the situation. A measurable function f on a measurable set E is said to vanish outside a set of finite measure, or to have finite support, provided there is a measurable subset E_0 of E with $m(E_0) < \infty$ and $f = 0$ on $E \sim E_0$. If f is in addition bounded and measurable on E , one defines

$$\int_E f = \int_{E_0} f.$$

Two things must be checked for this to be a legitimate definition: that the right-hand side makes sense, and that it does not depend on which set E_0 is used.

The right-hand side is defined. Let E_0 be as above. The restriction of f to E_0 is a bounded measurable function on a set of finite measure, so by Theorem 4 it is integrable over E_0 and $\int_{E_0} f$ is a well-defined real number.

Independence of the choice of E_0 . Let E_0 and E_1 be measurable subsets of E , each of finite measure, with

$$f = 0 \text{ on } E \sim E_0 \quad \text{and} \quad f = 0 \text{ on } E \sim E_1.$$

We must show $\int_{E_0} f = \int_{E_1} f$.

Set $A = E_0 \cap E_1$ and $B = E_0 \sim E_1$. Then A and B are disjoint measurable subsets of E_0 with $A \cup B = E_0$, and $m(E_0) < \infty$, so the restriction of f to E_0 is a bounded measurable function on a set of finite measure. Corollary 6, additivity over domains of integration, applies and yields

$$\int_{E_0} f = \int_A f + \int_B f.$$

Now $B = E_0 \sim E_1 \subseteq E \sim E_1$, and $f = 0$ on $E \sim E_1$. Hence f vanishes identically on B , and $m(B) \leq m(E_0) < \infty$, so $\int_B f = \int_B 0 = 0$: indeed the zero function on B is simple with canonical representation $0 \cdot \chi_B$, whose integral is $0 \cdot m(B) = 0$. (If $B = \emptyset$ the integral is 0 trivially.) Therefore

$$\int_{E_0} f = \int_{E_0 \cap E_1} f.$$

The argument is symmetric in E_0 and E_1 : taking $A = E_1 \cap E_0$ and $B' = E_1 \sim E_0 \subseteq E \sim E_0$, on which f vanishes, Corollary 6 applied on E_1 gives

$$\int_{E_1} f = \int_{E_0 \cap E_1} f + \int_{E_1 \sim E_0} f = \int_{E_0 \cap E_1} f.$$

Comparing the two displays, $\int_{E_0} f = \int_{E_1} f$. So the value assigned to $\int_E f$ is the same for every admissible choice of E_0 , and the definition is proper.

Remark. The set E_0 may always be taken to be the support $\{x \in E \mid f(x) \neq 0\}$ itself: this set is measurable since f is measurable, it is contained in any admissible E_0 and hence has finite measure, and f vanishes on its complement in E . So the definition could equivalently have been made with this canonical choice; the computation above shows the more flexible formulation agrees with it. Note also that when $m(E) < \infty$ we may take $E_0 = E$, so the new definition is consistent with the integral of Section 4.2.

Problem 4.19. For a number α , define $f(x) = x^\alpha$ for $0 < x \leq 1$, and $f(0) = 0$. Compute $\int_0^1 f$.

Solution. The answer is

$$\int_0^1 f = \begin{cases} \frac{1}{\alpha + 1} & \text{if } \alpha > -1, \\ \infty & \text{if } \alpha \leq -1. \end{cases}$$

Setting up. The function f is real-valued and nonnegative on $[0, 1]$: for $x \in (0, 1]$ we have $x^\alpha = e^{\alpha \ln x} \in (0, \infty)$, and $f(0) = 0$. It is measurable. Indeed, f is continuous on $(0, 1]$, so for each real c the set $\{x \in (0, 1] \mid f(x) > c\}$ is relatively open in $(0, 1]$, hence the intersection of an open set with $(0, 1]$, hence measurable; and

$$\{x \in [0, 1] \mid f(x) > c\} = \{x \in (0, 1] \mid f(x) > c\} \cup S_c, \quad S_c = \begin{cases} \{0\} & \text{if } c < 0, \\ \emptyset & \text{if } c \geq 0, \end{cases}$$

a union of two measurable sets. So f is a nonnegative measurable function on $[0, 1]$ and $\int_{[0,1]} f$ is defined by (8). Note that the value assigned at the single point 0 is irrelevant, since $\{0\}$ has measure zero and the excision formula (15) of Theorem 11 gives $\int_{[0,1]} f = \int_{(0,1]} f$.

A consistency remark. Below we integrate functions that are simultaneously nonnegative measurable (so that (8) applies) and bounded measurable of finite support (so that the integral of Section 4.2 applies). The two integrals agree: if g is nonnegative, bounded and measurable on E with finite support, then g is itself a competitor in (8), so the supremum in (8) is at least the Section 4.2 integral of g ; and every competitor h in (8) satisfies $0 \leq h \leq g$, so, choosing a set E_0 of finite measure outside which both g and h vanish, the monotonicity of Theorem 5 gives $\int_{E_0} h \leq \int_{E_0} g$, that is, the Section 4.2 integral of g is an upper bound for the competitors. Hence the two values coincide, and we may write $\int_E g$ without ambiguity.

Exhausting by an increasing sequence. For each natural number $n \geq 2$ define

$$f_n = f \cdot \chi_{[1/n, 1]} \quad \text{on } [0, 1].$$

Each f_n is nonnegative and measurable. The sequence is increasing: the sets $[1/n, 1]$ ascend with n and $f \geq 0$, so $f_n \leq f_{n+1}$ pointwise on $[0, 1]$. It converges to f pointwise on $[0, 1]$: if $x \in (0, 1]$, then $1/n < x$ for all large n , so $f_n(x) = f(x)$ eventually; and $f_n(0) = 0 = f(0)$ for every n . By the Monotone Convergence Theorem,

$$\int_{[0,1]} f = \lim_{n \rightarrow \infty} \int_{[0,1]} f_n.$$

Computing $\int_{[0,1]} f_n$. On the closed, bounded interval $[1/n, 1]$ the function $x \mapsto x^\alpha$ is continuous, hence bounded there and, by Problem 6 of Section 4.1, Riemann integrable there. Consequently f_n is a bounded measurable function on $[0, 1]$, and it has finite support since $m([0, 1]) = 1 < \infty$. Since $[0, 1]$ is the union of the disjoint measurable sets $[0, 1/n)$ and $[1/n, 1]$, additivity over domains for nonnegative measurable functions (Theorem 11), together with the fact that f_n vanishes identically on $[0, 1/n)$ and so has integral zero there by Proposition 9, gives

$$\int_{[0,1]} f_n = \int_{[1/n, 1]} x^\alpha dx.$$

By Theorem 3, the Lebesgue integral of a Riemann integrable function on a closed, bounded interval equals its Riemann integral, so this is the elementary integral $\int_{1/n}^1 x^\alpha dx$, which the Fundamental Theorem of Calculus evaluates as

$$\int_{1/n}^1 x^\alpha dx = \begin{cases} \frac{1 - (1/n)^{\alpha+1}}{\alpha + 1} & \text{if } \alpha \neq -1, \\ \ln n & \text{if } \alpha = -1. \end{cases}$$

Passing to the limit. Three cases.

If $\alpha > -1$, then $\alpha + 1 > 0$, so $(1/n)^{\alpha+1} \rightarrow 0$ and

$$\int_{[0,1]} f = \lim_{n \rightarrow \infty} \frac{1 - (1/n)^{\alpha+1}}{\alpha + 1} = \frac{1}{\alpha + 1}.$$

If $\alpha = -1$, then $\int_{[0,1]} f = \lim_{n \rightarrow \infty} \ln n = \infty$.

If $\alpha < -1$, then $\alpha + 1 < 0$, so $(1/n)^{\alpha+1} = n^{-(\alpha+1)} \rightarrow \infty$; the numerator $1 - (1/n)^{\alpha+1}$ tends to $-\infty$ while the denominator $\alpha + 1$ is a fixed negative number, so the quotient tends to $+\infty$ and $\int_{[0,1]} f = \infty$.

Summary and remarks. Thus f is integrable over $[0, 1]$ exactly when $\alpha > -1$, in which case $\int_0^1 f = 1/(\alpha + 1)$; for $\alpha \leq -1$ the integral is ∞ and f is not integrable. Two consistency checks. For $\alpha > 0$ the function f is continuous on all of $[0, 1]$, since $x^\alpha \rightarrow 0 = f(0)$ as $x \rightarrow 0^+$; hence it is Riemann integrable over $[0, 1]$ by Problem 6 of Section 4.1, and Theorem 3 gives directly $\int_0^1 x^\alpha dx = 1/(\alpha + 1)$, in agreement with the formula above. For $\alpha = 0$ the function f is the step function equal to 1 on $(0, 1]$ and 0 at the origin, whose integral is $1 \cdot m((0, 1]) = 1 = 1/(0 + 1)$, again in agreement. And for $\alpha \leq -1$ one sees the divergence without computation from Chebychev's Inequality applied to the sets $\{f \geq \lambda\}$, or simply by noting $x^\alpha \geq x^{-1}$ on $(0, 1]$ for $\alpha \leq -1$ and using monotonicity of integration, Theorem 10, together with the case $\alpha = -1$.

Problem 4.20. Let $\{f_n\}$ be a sequence of nonnegative measurable functions that converges to f pointwise on E . Let $M \geq 0$ be such that $\int_E f_n \leq M$ for all n . Show that $\int_E f \leq M$. Verify that this property is equivalent to the statement of Fatou's Lemma.

Solution. Call the asserted property (P) :

(P) : whenever $\{f_n\}$ is a sequence of nonnegative measurable functions on E converging to f pointwise on E , and $M \geq 0$ satisfies $\int_E f_n \leq M$ for all n , then $\int_E f \leq M$.

We also record the *a.e.* variant, in which pointwise convergence on E is weakened to pointwise convergence a.e. on E ; call it (P') . The two are equivalent, and the equivalence is proved in the first of the two remarks at the end. In the arguments below we use whichever form is convenient, and we work with (P') where the a.e. hypothesis of Fatou's Lemma as printed in the text makes it natural.

Fatou's Lemma implies (P) and (P') . Let $\{f_n\}$, f and M be as in the hypothesis of (P') (which includes that of (P)). The functions f_n are nonnegative and measurable and converge pointwise a.e. on E to f , so Fatou's Lemma applies and gives

$$\int_E f \leq \liminf_{n \rightarrow \infty} \int_E f_n.$$

Since $\int_E f_n \leq M$ for every n , the sequence of real numbers $\{\int_E f_n\}$ is bounded above by M , hence so is its lower limit: $\liminf_n \int_E f_n \leq M$. Combining,

$$\int_E f \leq M,$$

which is what was to be shown. This proves the first assertion of the problem.

(P) implies Fatou's Lemma. Assume (P) holds for every sequence as described; by the first remark below, (P') then holds too, and it is (P') we use. Let $\{g_n\}$ be a sequence of nonnegative measurable functions on E with $\{g_n\} \rightarrow g$ pointwise a.e. on E ; we must show

$$\int_E g \leq \liminf_{n \rightarrow \infty} \int_E g_n.$$

Write $L = \liminf_{n \rightarrow \infty} \int_E g_n$, an element of $[0, \infty]$ since each $\int_E g_n \geq 0$.

If $L = \infty$ the inequality is trivially true, so assume $L < \infty$.

Let $\epsilon > 0$. Since $L = \lim_{k \rightarrow \infty} (\inf_{n \geq k} \int_E g_n)$ is finite, the lower limit is attained along a subsequence: there is a subsequence $\{g_{n_k}\}_{k=1}^\infty$, with $n_1 < n_2 < \dots$, for which

$$\lim_{k \rightarrow \infty} \int_E g_{n_k} = L.$$

Hence there is an index K such that $\int_E g_{n_k} \leq L + \epsilon$ for all $k \geq K$.

Consider the sequence $\{h_k\}_{k=1}^\infty$ defined by $h_k = g_{n_{K+k-1}}$, that is, the tail of the chosen subsequence beginning at index K . Each h_k is a nonnegative measurable function on E ; the sequence $\{h_k\}$ converges

pointwise a.e. on E to g , because it is a subsequence of a sequence that does so, and a subsequence of a convergent sequence of real (or extended real) numbers converges to the same limit; and

$$\int_E h_k \leq L + \epsilon \quad \text{for every } k.$$

So (P') applies with the bound $M = L + \epsilon \geq 0$ and yields

$$\int_E g \leq L + \epsilon.$$

Since $\epsilon > 0$ was arbitrary, $\int_E g \leq L = \liminf_n \int_E g_n$, which is Fatou's Lemma.

Two remarks on the bookkeeping. First, the promised equivalence of (P) and (P') . Trivially (P') implies (P) . Conversely, assume (P) and let $\{f_n\}$ be nonnegative measurable on E with $\{f_n\} \rightarrow f$ pointwise on $E \sim E_0$, where $E_0 \subseteq E$ is measurable with $m(E_0) = 0$, and with $\int_E f_n \leq M$ for all n . The function f is measurable on E . Indeed, define g on E by $g = f$ on $E \sim E_0$ and $g = 0$ on E_0 . On $E \sim E_0$ the function g is the pointwise limit of the measurable functions f_n restricted there, hence measurable on $E \sim E_0$ by Proposition 9 of Chapter 3; g is measurable on E_0 as well, being constant; and a function whose restrictions to the two measurable pieces E_0 and $E \sim E_0$ of E are measurable is measurable on E , since $\{g > c\} = \{x \in E_0 \mid g(x) > c\} \cup \{x \in E \sim E_0 \mid g(x) > c\}$. Finally $f = g$ on $E \sim E_0$ and $m(E_0) = 0$, so $f = g$ a.e. on E and Proposition 5(i) of Chapter 3 gives the measurability of f on E . The restrictions of the f_n to $E \sim E_0$ are nonnegative and measurable and converge to f pointwise on all of $E \sim E_0$, and by the excision formula (15) of Theorem 11,

$$\int_{E \sim E_0} f_n = \int_E f_n \leq M \quad \text{for every } n.$$

So (P) , applied on the set $E \sim E_0$, gives $\int_{E \sim E_0} f \leq M$, and one more application of (15) gives $\int_E f = \int_{E \sim E_0} f \leq M$. This is (P') . (This is exactly the reduction performed at the start of the proof of Fatou's Lemma in the text.)

Second, the two implications are genuinely a proof of equivalence and not a circularity: the second implication derives Fatou's Lemma from (P) using nothing but the definition of $\liminf$ and the excision property, so (P) could be taken as the official statement of Fatou's Lemma and the version printed in the text recovered from it. Note incidentally that (P) is strictly a statement about an upper bound: it does not assert $\int_E f \leq \liminf \int_E f_n$ directly, but the freedom to pass to a subsequence realising the lower limit converts one into the other.

Problem 4.21. Let the function f be nonnegative and integrable over E and $\epsilon > 0$. Show there is a simple function η on E that has finite support, $0 \leq \eta \leq f$ on E and $\int_E |f - \eta| < \epsilon$. If E is a closed, bounded interval, show there is a step function h on E that has finite support and $\int_E |f - h| < \epsilon$.

Solution. Part 1: approximation by a simple function of finite support.

Since f is integrable over E , $\int_E f < \infty$, and by Proposition 13 the set $Z = \{x \in E \mid f(x) = \infty\}$ has measure zero.

Step 1: choose a bounded competitor close to the supremum. By the definition (8) of $\int_E f$ as a supremum, and since that supremum is finite, there is a bounded measurable function h_1 on E of finite support with $0 \leq h_1 \leq f$ on E and

$$\int_E h_1 > \int_E f - \frac{\epsilon}{2}.$$

Step 2: replace h_1 by a simple function below it. Let E_0 be a measurable subset of E with $m(E_0) < \infty$ and $h_1 = 0$ on $E \sim E_0$; by Problem 18, $\int_E h_1 = \int_{E_0} h_1$ regardless of which such E_0 is taken. The restriction of h_1 to E_0 is a bounded, real-valued measurable function, so the Simple Approximation Lemma of Chapter 3, applied with

$$\epsilon' = \frac{\epsilon}{2(m(E_0) + 1)} > 0,$$

provides simple functions φ and ψ on E_0 with

$$\varphi \leq h_1 \leq \psi \quad \text{and} \quad 0 \leq \psi - \varphi < \epsilon' \quad \text{on } E_0.$$

Define $\eta_0 = \max\{\varphi, 0\}$ on E_0 . It is simple. Indeed, if φ has canonical representation $\varphi = \sum_{i=1}^p d_i \chi_{D_i}$ on E_0 , then η_0 takes only the finitely many values in $\{\max\{d_i, 0\} : 1 \leq i \leq p\}$, and for each such value a the level set $\{x \in E_0 \mid \eta_0(x) = a\}$ is the union of those D_i with $\max\{d_i, 0\} = a$, a finite union of measurable sets. So η_0 is a measurable real-valued function taking finitely many values, that is, a simple function. Since $h_1 \geq 0$ and $\varphi \leq h_1$, we have $0 \leq \eta_0 \leq h_1$ on E_0 , and

$$0 \leq h_1 - \eta_0 \leq h_1 - \varphi \leq \psi - \varphi < \epsilon' \quad \text{on } E_0.$$

Now define η on all of E by $\eta = \eta_0$ on E_0 and $\eta = 0$ on $E \sim E_0$. Then η is a simple function on E , it vanishes outside the set E_0 of finite measure, so it has finite support, and

$$0 \leq \eta \leq h_1 \leq f \quad \text{on } E.$$

Step 3: the estimate. All three functions h_1 , η and $h_1 - \eta$ are bounded and measurable on E and vanish on $E \sim E_0$, where $m(E_0) < \infty$. So each of their integrals over E is by definition the corresponding integral over the *single* set E_0 of finite measure, and Theorem 5, the linearity and monotonicity of integration for bounded measurable functions on a set of finite measure, applies to them on E_0 . Since $0 \leq h_1 - \eta \leq \epsilon'$ on E_0 , monotonicity against the constant function ϵ' gives

$$\int_E (h_1 - \eta) = \int_{E_0} (h_1 - \eta) \leq \epsilon' \cdot m(E_0) < \frac{\epsilon}{2},$$

and linearity on E_0 gives $\int_{E_0} \eta = \int_{E_0} h_1 - \int_{E_0} (h_1 - \eta)$, that is,

$$\int_E \eta = \int_E h_1 - \int_E (h_1 - \eta) > \left(\int_E f - \frac{\epsilon}{2} \right) - \frac{\epsilon}{2} = \int_E f - \epsilon.$$

(Here $\int_E \eta$ in the sense of the supremum definition (8) agrees with $\int_{E_0} \eta$ in the sense of Section 4.2: η is itself a competitor in (8), so the supremum is at least $\int_{E_0} \eta$, while every competitor h in (8) satisfies $0 \leq h \leq \eta$ and hence $\int h \leq \int_{E_0} \eta$ by the monotonicity of Theorem 5 on a set of finite measure containing the supports of both. The same remark applies to h_1 .)

Step 4: conclusion of Part 1. Since $0 \leq \eta \leq f$ on E , we have $|f - \eta| = f - \eta$ on E (with the convention $\infty - c = \infty$ on the null set Z), and $f - \eta$ is a nonnegative measurable function with $(f - \eta) + \eta = f$ pointwise on E . Its measurability is immediate and does not require f to be finite: writing the canonical representation $\eta = \sum_i c_i \chi_{F_i}$ with $\{F_i\}$ a finite disjoint measurable partition of E , for each real t

$$\{x \in E \mid f(x) - \eta(x) > t\} = \bigcup_i (F_i \cap \{x \in E \mid f(x) > t + c_i\}),$$

a finite union of measurable sets. By the linearity of integration for nonnegative measurable functions, Theorem 10,

$$\int_E f = \int_E (f - \eta) + \int_E \eta.$$

Both $\int_E f$ and $\int_E \eta$ are finite (the latter because $\eta \leq f$ and monotonicity, (12) of Theorem 10), so we may subtract and conclude

$$\int_E |f - \eta| = \int_E (f - \eta) = \int_E f - \int_E \eta < \epsilon.$$

This is the required simple function.

Part 2: approximation by a step function when $E = [a, b]$.

Let $E = [a, b]$ be a closed, bounded interval. Note that every function on E has finite support, since $m(E) = b - a < \infty$; so the substance of the claim is the integral estimate. Note also that h is *not* required to satisfy $0 \leq h \leq f$.

By Part 1 there is a simple function η on E with finite support, $0 \leq \eta \leq f$ on E , and

$$\int_E |f - \eta| < \frac{\epsilon}{2}.$$

It therefore suffices to produce a step function h on E with $\int_E |\eta - h| < \epsilon/2$, for then the triangle inequality finishes the proof, as follows. Let $Z = \{x \in E \mid f(x) = \infty\}$, a set of measure zero by Proposition 13. On $E \sim Z$ all three functions f, η, h are finite, so the pointwise inequality $|f - h| \leq |f - \eta| + |\eta - h|$ holds there; by the excision formula (15) of Theorem 11 and then the monotonicity and linearity of integration for nonnegative measurable functions, Theorem 10,

$$\int_E |f - h| = \int_{E \sim Z} |f - h| \leq \int_{E \sim Z} |f - \eta| + \int_{E \sim Z} |\eta - h| = \int_E |f - \eta| + \int_E |\eta - h| < \epsilon.$$

Construction of the step function. Let

$$\eta = \sum_{k=1}^n a_k \cdot \chi_{E_k}$$

be the canonical representation of η on E , where $a_1, \dots, a_n$ are the distinct *nonzero* values taken by η and $E_k = \{x \in E \mid \eta(x) = a_k\}$ (we discard the value 0, which contributes nothing). The E_k are disjoint measurable subsets of $[a, b]$, so each has finite measure. Put

$$\delta = \frac{\epsilon}{2(1 + \sum_{k=1}^n |a_k|)} > 0.$$

Each E_k is measurable of finite outer measure, so Theorem 12 of Chapter 2 applies: there is a finite disjoint collection of open intervals $\{I_{k,j}\}_{j=1}^{m_k}$ such that, setting $O_k = \bigcup_{j=1}^{m_k} I_{k,j}$,

$$m^*(E_k \Delta O_k) < \delta,$$

where $E_k \Delta O_k = [E_k \sim O_k] \cup [O_k \sim E_k]$ denotes the symmetric difference. Since E_k and O_k are both measurable, so is $E_k \Delta O_k$, and the displayed inequality reads $m(E_k \Delta O_k) < \delta$. Define

$$h = \sum_{k=1}^n a_k \cdot \chi_{O_k \cap [a,b]} \quad \text{on } [a, b].$$

Each set $O_k \cap [a, b]$ is a finite disjoint union of intervals, so each $\chi_{O_k \cap [a,b]}$ is a step function on $[a, b]$; a finite linear combination of step functions is a step function, so h is a step function on $[a, b]$, and it has finite support because $m([a, b]) < \infty$.

The estimate. For every $x \in [a, b]$,

$$|\eta(x) - h(x)| = \left| \sum_{k=1}^n a_k [\chi_{E_k}(x) - \chi_{O_k \cap [a,b]}(x)] \right| \leq \sum_{k=1}^n |a_k| \cdot \chi_{E_k \Delta (O_k \cap [a,b])}(x),$$

since $|\chi_A - \chi_B| = \chi_{A \Delta B}$ for any sets A, B . Because $E_k \subseteq [a, b]$, we have $E_k \sim (O_k \cap [a, b]) = E_k \sim O_k$ and $(O_k \cap [a, b]) \sim E_k \subseteq O_k \sim E_k$, so

$$E_k \Delta (O_k \cap [a, b]) \subseteq E_k \Delta O_k.$$

All the functions here are bounded and measurable on the set $[a, b]$ of finite measure, so the monotonicity and linearity of integration, Theorem 5, apply. Since for each k

$$\int_{[a,b]} \chi_{E_k \Delta (O_k \cap [a,b])} = m(E_k \Delta (O_k \cap [a, b])) \leq m(E_k \Delta O_k) < \delta,$$

we obtain

$$\int_{[a,b]} |\eta - h| \leq \sum_{k=1}^n |a_k| \cdot m(E_k \Delta O_k) \leq \delta \sum_{k=1}^n |a_k| = \frac{\epsilon}{2} \cdot \frac{\sum_{k=1}^n |a_k|}{1 + \sum_{k=1}^n |a_k|} < \frac{\epsilon}{2}.$$

(If $n = 0$, that is if $\eta \equiv 0$ on E , take $h \equiv 0$; the estimate is then trivial.)

Combining with the triangle inequality established above, $\int_E |f - h| < \epsilon$, as required.

Remark. The step function h produced in Part 2 need not satisfy $0 \leq h \leq f$, and in general no step function can: f may be unbounded, and more to the point the sets O_k may spill outside the E_k . What the two parts together express is the density, in the L^1 sense, of the simple functions of finite support in the nonnegative integrable functions on an arbitrary measurable set, and of the step functions in the nonnegative integrable functions on a closed, bounded interval.

4.4 Problems 4.22–4.28

Problem 4.22. Let $\{f_n\}$ be a sequence of nonnegative measurable functions on $\mathbb{R}$ that converges pointwise on $\mathbb{R}$ to f and f be integrable over $\mathbb{R}$. Show that if

$$\int_{\mathbb{R}} f = \lim_{n \rightarrow \infty} \int_{\mathbb{R}} f_n,$$

then

$$\int_E f = \lim_{n \rightarrow \infty} \int_E f_n \quad \text{for any measurable set } E.$$

Solution. Let E be a measurable subset of $\mathbb{R}$ and write $E^c = \mathbb{R} \setminus E$, so that E and E^c are disjoint measurable subsets of $\mathbb{R}$ whose union is $\mathbb{R}$.

Each f_n is nonnegative and measurable, and f , being the pointwise limit of measurable functions, is nonnegative and measurable as well. Put

$$L = \int_{\mathbb{R}} f = \lim_{n \rightarrow \infty} \int_{\mathbb{R}} f_n.$$

Since f is integrable over $\mathbb{R}$ we have $L < \infty$. By Theorem 11 of Chapter 4 (Additivity Over Domains of Integration), applied to the nonnegative measurable function f and the disjoint sets E , E^c ,

$$\int_E f + \int_{E^c} f = \int_{\mathbb{R}} f = L < \infty,$$

so both $\int_E f$ and $\int_{E^c} f$ are finite. Likewise, for every index n ,

$$\int_E f_n + \int_{E^c} f_n = \int_{\mathbb{R}} f_n. \quad (*)$$

Since $\int_{\mathbb{R}} f_n \rightarrow L < \infty$, there is an index N for which $\int_{\mathbb{R}} f_n \leq L + 1 < \infty$ whenever $n \geq N$; by $(*)$ and the nonnegativity of the integrands, both $\int_E f_n$ and $\int_{E^c} f_n$ are then finite for $n \geq N$. Thus for $n \geq N$ we may rewrite $(*)$ as

$$\int_E f_n = \int_{\mathbb{R}} f_n - \int_{E^c} f_n,$$

an honest difference of real numbers.

The restriction of $\{f_n\}$ to E is a sequence of nonnegative measurable functions converging pointwise on E to f , so Fatou's Lemma gives

$$\int_E f \leq \liminf_{n \rightarrow \infty} \int_E f_n. \quad (1)$$

The same reasoning on E^c gives

$$\int_{E^c} f \leq \liminf_{n \rightarrow \infty} \int_{E^c} f_n. \quad (2)$$

Now we bound the upper limit on E . Since the sequence of real numbers $\{\int_{\mathbb{R}} f_n\}$ converges to the finite number L , for any sequence $\{b_n\}$ of real numbers we have $\limsup_n (\int_{\mathbb{R}} f_n - b_n) = L - \liminf_n b_n$. Taking $b_n = \int_{E^c} f_n$ (which is a real number for $n \geq N$) and using (2),

$$\limsup_{n \rightarrow \infty} \int_E f_n = L - \liminf_{n \rightarrow \infty} \int_{E^c} f_n \leq L - \int_{E^c} f = \int_{\mathbb{R}} f - \int_{E^c} f = \int_E f,$$

where the inequality follows from (2) upon multiplying by -1 , and the last equality is the additivity relation for f recorded above, a legitimate subtraction because $\int_{E^c} f$ is finite. Combining this with (1),

$$\int_E f \leq \liminf_{n \rightarrow \infty} \int_E f_n \leq \limsup_{n \rightarrow \infty} \int_E f_n \leq \int_E f.$$

Hence all three quantities agree, the limit $\lim_{n \rightarrow \infty} \int_E f_n$ exists, and

$$\lim_{n \rightarrow \infty} \int_E f_n = \int_E f.$$

Since E was an arbitrary measurable set, the proof is complete.

Problem 4.23. Let $\{a_n\}$ be a sequence of nonnegative real numbers. Define the function f on $E = [1, \infty)$ by setting $f(x) = a_n$ if $n \leq x < n + 1$. Show that $\int_E f = \sum_{n=1}^{\infty} a_n$.

Solution. For each natural number n put $I_n = [n, n + 1)$ and

$$u_n = a_n \cdot \chi_{I_n}.$$

The intervals $I_1, I_2, \dots$ are pairwise disjoint and their union is $E = [1, \infty)$. Consequently, for each $x \in E$ there is exactly one index n with $x \in I_n$, and for that index $f(x) = a_n = u_n(x)$, while $u_k(x) = 0$ for every $k \neq n$. Therefore

$$f = \sum_{n=1}^{\infty} u_n \quad \text{pointwise on } E,$$

the series having at most one nonzero term at each point.

Each u_n is a nonnegative measurable function on E : indeed I_n is measurable, so χ_{I_n} is measurable, and a constant multiple of a measurable function is measurable. In particular f , being a pointwise sum of measurable functions (equivalently: f is constant on each of the countably many measurable pieces I_n , so $\{x \in E \mid f(x) > c\}$ is a countable union of intervals for every c), is a nonnegative measurable function on E .

Each u_n is a nonnegative simple function of finite support: it takes only the two values a_n and 0, and $\{x \in E \mid u_n(x) \neq 0\} \subseteq I_n$ has measure at most 1. Hence, by the definition of the integral of a simple function,

$$\int_E u_n = a_n \cdot m(I_n) = a_n \cdot 1 = a_n.$$

(If $a_n = 0$ this reads $0 = 0$.)

Now apply Corollary 12 of Chapter 4, which asserts that if $f = \sum_{n=1}^{\infty} u_n$ pointwise a.e. on E with each u_n nonnegative and measurable, then $\int_E f = \sum_{n=1}^{\infty} \int_E u_n$. We conclude

$$\int_E f = \sum_{n=1}^{\infty} \int_E u_n = \sum_{n=1}^{\infty} a_n,$$

the equality holding in the extended sense: both sides are simultaneously finite with the same value, or both equal ∞ .

For completeness, here is the argument behind Corollary 12 in this concrete case. Let $s_N = \sum_{n=1}^N u_n$. Since the u_n are nonnegative, $\{s_N\}$ is an increasing sequence of nonnegative measurable functions on E , and $s_N \rightarrow f$ pointwise on E (for $x \in I_n$ we have $s_N(x) = f(x)$ as soon as $N \geq n$). The Monotone Convergence Theorem and the linearity of integration for nonnegative measurable functions give

$$\int_E f = \lim_{N \rightarrow \infty} \int_E s_N = \lim_{N \rightarrow \infty} \sum_{n=1}^N \int_E u_n = \lim_{N \rightarrow \infty} \sum_{n=1}^N a_n = \sum_{n=1}^{\infty} a_n.$$

Problem 4.24. Let f be a nonnegative measurable function on E .

- (i) Show there is an increasing sequence $\{\varphi_n\}$ of nonnegative simple functions on E , each of finite support, which converges pointwise on E to f .
- (ii) Show that $\int_E f = \sup \left\{ \int_E \varphi \mid \varphi \text{ simple, of finite support and } 0 \leq \varphi \leq f \text{ on } E \right\}$.

Solution. Throughout, a function is said to be of finite support when the set on which it fails to vanish has finite measure, and f is permitted to take the value ∞ .

Part (i). For each natural number n define g_n on E by

$$g_n(x) = \min \left\{ n, \frac{\lfloor 2^n f(x) \rfloor}{2^n} \right\},$$

with the convention $g_n(x) = n$ where $f(x) = \infty$, and set

$$E_n = E \cap [-n, n], \quad \varphi_n = g_n \cdot \chi_{E_n}.$$

Each φ_n is a nonnegative simple function of finite support. Indeed, g_n takes values only in the finite set $\{k/2^n \mid k = 0, 1, \dots, n2^n\}$, and for each such value c the set $\{x \in E \mid g_n(x) = c\}$ is measurable because it is described by inequalities on f , which is measurable; hence g_n is simple. Multiplying by χ_{E_n} keeps the range inside that same finite set, and E_n is measurable, so φ_n is simple. Moreover $\{x \in E \mid \varphi_n(x) \neq 0\} \subseteq E_n \subseteq [-n, n]$, a set of measure at most $2n < \infty$; thus φ_n has finite support. Nonnegativity is clear, and since $\lfloor 2^n t \rfloor / 2^n \leq t$ for $t \geq 0$ we also have $0 \leq \varphi_n \leq g_n \leq f$ on E .

The sequence is increasing. First, $\{g_n\}$ is increasing: for a real number $t \geq 0$ we have $2^{n+1}t \geq 2\lfloor 2^n t \rfloor$, and $2\lfloor 2^n t \rfloor$ is an integer, so by the defining property of the floor function $\lfloor 2^{n+1}t \rfloor \geq 2\lfloor 2^n t \rfloor$; dividing by 2^{n+1} gives

$$\frac{\lfloor 2^{n+1}t \rfloor}{2^{n+1}} \geq \frac{\lfloor 2^n t \rfloor}{2^n},$$

and since also $n+1 \geq n$, the minimum of the two increasing quantities increases: $g_{n+1} \geq g_n$ (this also holds trivially where $f = \infty$, where $g_n = n$). Second, $E_n \subseteq E_{n+1}$, so $\chi_{E_n} \leq \chi_{E_{n+1}}$. As all quantities are nonnegative,

$$\varphi_n = g_n \chi_{E_n} \leq g_{n+1} \chi_{E_{n+1}} = \varphi_{n+1} \quad \text{on } E.$$

The sequence converges pointwise to f . Fix $x \in E$. Since x is a real number, $x \in E_n$ for all $n \geq |x|$, and for such n , $\varphi_n(x) = g_n(x)$. If $f(x) < \infty$, then for every $n > f(x)$ we have $\lfloor 2^n f(x) \rfloor / 2^n \leq f(x) < n$, so $g_n(x) = \lfloor 2^n f(x) \rfloor / 2^n$ and

$$0 \leq f(x) - g_n(x) < \frac{1}{2^n},$$

whence $\varphi_n(x) \rightarrow f(x)$. If $f(x) = \infty$, then $\varphi_n(x) = n \rightarrow \infty = f(x)$. In both cases $\varphi_n(x) \rightarrow f(x)$, which proves (i).

Part (ii). Write

$$S = \sup \left\{ \int_E \varphi \mid \varphi \text{ simple, of finite support, } 0 \leq \varphi \leq f \text{ on } E \right\}.$$

First, $S \leq \int_E f$. A simple function φ of finite support with $0 \leq \varphi \leq f$ takes finitely many real values, so it is a bounded measurable function of finite support with $0 \leq \varphi \leq f$ on E . By the very definition of the integral of the nonnegative measurable function f over E ,

$$\int_E f = \sup \left\{ \int_E h \mid h \text{ bounded, measurable, of finite support, } 0 \leq h \leq f \text{ on } E \right\},$$

each such $\int_E \varphi$ is one of the numbers over which this supremum is taken. Hence $S \leq \int_E f$.

Second, $\int_E f \leq S$. Let $\{\varphi_n\}$ be the sequence produced in part (i). Each φ_n is simple, of finite support, and satisfies $0 \leq \varphi_n \leq f$ on E , so $\int_E \varphi_n \leq S$ for every n . Since $\{\varphi_n\}$ is an increasing sequence of nonnegative measurable functions on E converging pointwise on E to f , the Monotone Convergence Theorem gives

$$\int_E f = \lim_{n \rightarrow \infty} \int_E \varphi_n \leq S.$$

The two inequalities together give $\int_E f = S$, which is (ii).

Problem 4.25. Let $\{f_n\}$ be a sequence of nonnegative measurable functions on E that converges pointwise on E to f . Suppose $f_n \leq f$ on E for each n . Show that

$$\lim_{n \rightarrow \infty} \int_E f_n = \int_E f.$$

Solution. The limit function f is nonnegative and measurable on E , being the pointwise limit on E of the sequence $\{f_n\}$ of nonnegative measurable functions. Thus $\int_E f$ is defined as an element of $[0, \infty]$, as is each $\int_E f_n$.

Upper bound. Fix an index n . By hypothesis $0 \leq f_n \leq f$ on E , so the monotonicity of integration for nonnegative measurable functions gives

$$\int_E f_n \leq \int_E f.$$

Since this holds for every n , the upper limit obeys

$$\limsup_{n \rightarrow \infty} \int_E f_n \leq \int_E f. \quad (1)$$

Lower bound. The sequence $\{f_n\}$ consists of nonnegative measurable functions on E and converges pointwise on E to f , so Fatou's Lemma applies and gives

$$\int_E f \leq \liminf_{n \rightarrow \infty} \int_E f_n. \quad (2)$$

Conclusion. Combining (2) and (1),

$$\int_E f \leq \liminf_{n \rightarrow \infty} \int_E f_n \leq \limsup_{n \rightarrow \infty} \int_E f_n \leq \int_E f.$$

Hence the lower and upper limits of the sequence of extended real numbers $\{\int_E f_n\}$ coincide and equal $\int_E f$. Therefore the limit exists in $[0, \infty]$ and

$$\lim_{n \rightarrow \infty} \int_E f_n = \int_E f.$$

Observe that no integrability hypothesis was needed: if $\int_E f = \infty$ the chain of inequalities forces $\int_E f_n \rightarrow \infty$ as well. The hypothesis $f_n \leq f$ is what rules out the loss of mass exhibited by the examples following Fatou's Lemma (for instance $f_n = n \cdot \chi_{(0,1/n)}$ on $E = (0, 1]$, where no such dominating limit function is available since $f \equiv 0$ there).

Problem 4.26. Show that the Monotone Convergence Theorem may not hold for decreasing sequences of functions.

Solution. The Monotone Convergence Theorem asserts that if $\{f_n\}$ is an increasing sequence of nonnegative measurable functions on E converging pointwise a.e. on E to f , then $\int_E f_n \rightarrow \int_E f$. We exhibit a decreasing sequence of nonnegative measurable functions converging pointwise everywhere for which the conclusion fails.

An example on a set of infinite measure. Let $E = \mathbb{R}$ and for each natural number n define

$$f_n = \chi_{[n, \infty)}.$$

Each f_n is nonnegative and measurable, being the characteristic function of a measurable set. Since $[n+1, \infty) \subseteq [n, \infty)$, we have $f_{n+1} \leq f_n$ on $\mathbb{R}$, so $\{f_n\}$ is decreasing. It converges pointwise on all of $\mathbb{R}$ to $f \equiv 0$: given $x \in \mathbb{R}$, choose a natural number $n_0 > x$; then $x \notin [n, \infty)$ and so $f_n(x) = 0$ for all $n \geq n_0$.

Now compute the integrals. For each n and each natural number k , the bounded measurable function

$\chi_{[n,n+k]}$ has finite support and satisfies $0 \leq \chi_{[n,n+k]} \leq f_n$ on $\mathbb{R}$, and $\int_{\mathbb{R}} \chi_{[n,n+k]} = m([n, n+k]) = k$. Since $\int_{\mathbb{R}} f_n$ is the supremum of the integrals of such functions, $\int_{\mathbb{R}} f_n \geq k$ for every k , that is,

$$\int_{\mathbb{R}} f_n = \infty \quad \text{for every } n.$$

On the other hand $\int_{\mathbb{R}} f = \int_{\mathbb{R}} 0 = 0$. Therefore

$$\lim_{n \rightarrow \infty} \int_{\mathbb{R}} f_n = \infty \neq 0 = \int_{\mathbb{R}} f,$$

so the conclusion of the Monotone Convergence Theorem fails for this decreasing sequence.

An example on a set of finite measure. Infinite measure is not the essential feature. Let $E = (0, 1)$ and define

$$f_n(x) = \frac{1}{x} \cdot \chi_{(0, 1/n)}(x) \quad \text{for } x \in (0, 1).$$

Each f_n is nonnegative and measurable, and since $(0, 1/(n+1)) \subseteq (0, 1/n)$ the sequence is decreasing. It converges pointwise on $(0, 1)$ to $f \equiv 0$: for fixed $x \in (0, 1)$ we have $f_n(x) = 0$ once $1/n \leq x$. Yet $\int_{(0,1)} f_n = \infty$ for every n . To see this, fix n and choose a natural number N with $2^{-N} < 1/n$. For $j \geq N$ set $A_j = (2^{-(j+1)}, 2^{-j})$; these are pairwise disjoint subsets of $(0, 1/n)$, on each of which $1/x > 2^j$, and $m(A_j) = 2^{-(j+1)}$. For a natural number $M \geq N$ the function

$$h_M = \sum_{j=N}^M 2^j \chi_{A_j}$$

is bounded, measurable, of finite support, and satisfies $0 \leq h_M \leq f_n$ on $(0, 1)$, while

$$\int_{(0,1)} h_M = \sum_{j=N}^M 2^j \cdot 2^{-(j+1)} = \frac{M - N + 1}{2}.$$

Since $\int_{(0,1)} f_n$ is the supremum of the integrals of such functions and M is arbitrary, $\int_{(0,1)} f_n = \infty$. Meanwhile $\int_{(0,1)} f = 0$, so again $\lim_n \int_E f_n \neq \int_E f$.

Remark. The failure in both examples is caused by non-integrability of the first term, and this is no accident. Suppose $\{f_n\}$ is a decreasing sequence of nonnegative measurable functions on E converging pointwise on E to f , and suppose f_1 is integrable over E . By Proposition 13 of Chapter 4, f_1 is finite a.e. on E , so after excising a set of measure zero (permissible by (15)) we may assume f_1 is finite on E . Then $\{f_1 - f_n\}$ is an increasing sequence of nonnegative measurable functions converging pointwise on E to $f_1 - f$, so the Monotone Convergence Theorem gives $\int_E (f_1 - f_n) \rightarrow \int_E (f_1 - f)$. Now $f_1 - f_n$ and f_n are nonnegative measurable functions on E whose sum is f_1 , so the linearity of integration for nonnegative measurable functions, Theorem 10 of Chapter 4, gives $\int_E (f_1 - f_n) + \int_E f_n = \int_E f_1$; since $0 \leq f_n \leq f_1$ and $\int_E f_1 < \infty$, monotonicity makes both summands finite and we may write $\int_E (f_1 - f_n) = \int_E f_1 - \int_E f_n$. The same argument applied to $f_1 - f$ and f gives $\int_E (f_1 - f) = \int_E f_1 - \int_E f$. Cancelling the finite number $\int_E f_1$ yields $\int_E f_n \rightarrow \int_E f$. Hence any counterexample must have $\int_E f_n = \infty$ for every n , as above.

Problem 4.27. Prove the following generalization of Fatou's Lemma: If $\{f_n\}$ is a sequence of nonnegative measurable functions on E , then

$$\int_E \liminf_{n \rightarrow \infty} f_n \leq \liminf_{n \rightarrow \infty} \int_E f_n.$$

Solution. No convergence of $\{f_n\}$ is assumed; the point is that the pointwise lower limit always exists as an extended real-valued function and obeys the Fatou inequality.

For each natural number n define the function g_n on E by

$$g_n(x) = \inf_{k \geq n} f_k(x), \quad x \in E,$$

and set $g = \liminf_{n \rightarrow \infty} f_n$, that is, $g(x) = \lim_{n \rightarrow \infty} g_n(x)$ for $x \in E$.

Step 1: each g_n is a nonnegative measurable function on E . Nonnegativity is immediate, since each $f_k \geq 0$. For measurability, note that it suffices to show that $\{x \in E \mid g_n(x) \geq c\}$ is measurable for every real number c , since the complements of these sets are the sets $\{g_n < c\}$ and measurability of a function is equivalent to measurability of all the sets $\{g_n < c\}$. Now for every real c ,

$$\{x \in E \mid g_n(x) \geq c\} = \bigcap_{k \geq n} \{x \in E \mid f_k(x) \geq c\},$$

because $\inf_{k \geq n} f_k(x) \geq c$ precisely when $f_k(x) \geq c$ for every $k \geq n$. Each set on the right is measurable since f_k is measurable, and the countable intersection of measurable sets is measurable. As the sets $\{g_n \geq c\}$ are measurable for every real c , the function g_n is measurable. (This is the standard fact that the pointwise infimum of a countable family of measurable functions is measurable.)

Step 2: $\{g_n\}$ is increasing and converges pointwise on E to g . Fix $x \in E$. The family $\{f_k(x) \mid k \geq n+1\}$ is a subfamily of $\{f_k(x) \mid k \geq n\}$, so its infimum is at least as large:

$$g_n(x) \leq g_{n+1}(x).$$

Thus $\{g_n(x)\}$ is an increasing sequence in $[0, \infty]$, hence convergent in $[0, \infty]$, and its limit is by definition $\liminf_n f_n(x) = g(x)$. In particular g is a nonnegative measurable function on E , being a pointwise limit of nonnegative measurable functions, so $\int_E g$ is defined.

Step 3: comparison of integrals. Fix n and let $k \geq n$. By construction $0 \leq g_n \leq f_k$ on E , so the monotonicity of integration for nonnegative measurable functions gives

$$\int_E g_n \leq \int_E f_k \quad \text{for every } k \geq n.$$

Taking the infimum over $k \geq n$ on the right,

$$\int_E g_n \leq \inf_{k \geq n} \int_E f_k. \quad (*)$$

Step 4: pass to the limit. The sequence $\{g_n\}$ is an increasing sequence of nonnegative measurable functions on E converging pointwise on E to g , so the Monotone Convergence Theorem yields

$$\int_E g = \lim_{n \rightarrow \infty} \int_E g_n.$$

The right-hand sides of $(*)$ form an increasing sequence in $[0, \infty]$ whose limit is, by definition, $\liminf_{n \rightarrow \infty} \int_E f_n$. Letting $n \rightarrow \infty$ in $(*)$ therefore gives

$$\int_E \liminf_{n \rightarrow \infty} f_n = \int_E g = \lim_{n \rightarrow \infty} \int_E g_n \leq \lim_{n \rightarrow \infty} \left(\inf_{k \geq n} \int_E f_k \right) = \liminf_{n \rightarrow \infty} \int_E f_n,$$

which is the asserted inequality.

This contains Fatou's Lemma as stated in the text: if $\{f_n\} \rightarrow f$ pointwise a.e. on E , then $\liminf_n f_n = f$ a.e. on E , and integrals over E are unchanged by altering the integrand on a set of measure zero, by (15).

Problem 4.28. Let f be integrable over E and C a measurable subset of E . Show that $\int_C f = \int_E f \cdot \chi_C$.

Solution. Here χ_C denotes the characteristic function of C , regarded as a function on E ; since C is measurable, χ_C is measurable on E , and therefore so is the product $f \cdot \chi_C$.

Step 1: the identity for nonnegative measurable functions. Let h be a nonnegative measurable function on E and let $C \subseteq E$ be measurable. We claim

$$\int_C h = \int_E h \cdot \chi_C. \quad (*)$$

Indeed, $h \cdot \chi_C$ is a nonnegative measurable function on E , and C and $E \setminus C$ are disjoint measurable subsets of E with union E . By Theorem 11 of Chapter 4 (Additivity Over Domains of Integration),

$$\int_E h \cdot \chi_C = \int_C h \cdot \chi_C + \int_{E \setminus C} h \cdot \chi_C.$$

On C we have $\chi_C \equiv 1$, so $h \cdot \chi_C = h$ there and the first integral equals $\int_C h$; the integral over a set depends only on the restriction of the integrand to that set. On $E \setminus C$ we have $\chi_C \equiv 0$, so $h \cdot \chi_C$ is the zero function there and the second integral is 0 (the only bounded measurable function ψ of finite support with $0 \leq \psi \leq 0$ is $\psi \equiv 0$, whose integral is 0; hence the defining supremum is 0). This proves (*).

Step 2: integrability of the two sides. Since f is integrable over E , $|f|$ is integrable over E . Because $|f \cdot \chi_C| \leq |f|$ on E , Proposition 16 of Chapter 4 (the Integral Comparison Test) shows that $f \cdot \chi_C$ is integrable over E , so the right-hand side of the desired identity is a well-defined real number. Moreover, applying (*) with $h = |f|$,

$$\int_C |f| = \int_E |f| \cdot \chi_C \leq \int_E |f| < \infty,$$

where the inequality is the monotonicity of integration for nonnegative measurable functions applied to $|f| \cdot \chi_C \leq |f|$. Hence $|f|$ is integrable over C , i.e. f is integrable over C , and the left-hand side is a well-defined real number too.

Step 3: reduction to positive and negative parts. Write $f = f^+ - f^-$, where $f^+ = \max\{f, 0\}$ and $f^- = \max\{-f, 0\}$ are nonnegative measurable functions on E , each integrable over E by Proposition 14 of Chapter 4. At each point of E , at most one of f^+, f^- is nonzero, and multiplying by the factor χ_C , which takes only the values 0 and 1, preserves the description of the positive and negative parts: for $x \in E$,

$$(f \cdot \chi_C)^+(x) = \max\{f(x)\chi_C(x), 0\} = \chi_C(x) \max\{f(x), 0\} = f^+(x)\chi_C(x),$$

using $\chi_C(x) \in \{0, 1\}$, and likewise $(f \cdot \chi_C)^- = f^- \cdot \chi_C$ on E .

Therefore, by the definition of the general Lebesgue integral applied on C and then on E , together with (*) applied to the nonnegative measurable functions f^+ and f^- ,

$$\begin{aligned} \int_C f &= \int_C f^+ - \int_C f^- \\ &= \int_E f^+ \cdot \chi_C - \int_E f^- \cdot \chi_C \\ &= \int_E (f \cdot \chi_C)^+ - \int_E (f \cdot \chi_C)^- \\ &= \int_E f \cdot \chi_C. \end{aligned}$$

All four integrals of nonnegative functions appearing here are finite, by Step 2 and monotonicity, so the subtractions are legitimate. This is the asserted identity.

Note that the argument uses only Theorem 11, which concerns nonnegative measurable functions; it does not use Corollary 18 (Additivity Over Domains of Integration for integrable functions), whose proof in the text invokes the present result.

4.5 Problems 4.29–4.35

Problem 4.29. For a measurable function f on $[1, \infty)$ which is bounded on bounded sets, define $a_n = \int_n^{n+1} f$ for each natural number n . Is it true that f is integrable over $[1, \infty)$ if and only if the series $\sum_{n=1}^{\infty} a_n$ converges? Is it true that f is integrable over $[1, \infty)$ if and only if the series $\sum_{n=1}^{\infty} a_n$ converges absolutely?

Solution. The answer to both questions is no: in each case one implication is true and the other fails. First observe that each a_n is a well-defined real number. Indeed, f is measurable and bounded on the bounded set $[n, n+1]$, which has finite measure, so $|f| \leq M_n$ there for some $M_n \geq 0$ and hence, by the monotonicity of integration for nonnegative functions, $\int_{[n, n+1]} |f| \leq M_n \cdot 1 < \infty$. Thus f is integrable over $[n, n+1]$ and $a_n = \int_n^{n+1} f$ is finite.

The implication that is true. Suppose f is integrable over $[1, \infty)$. For $n \geq 1$ put $u_n = |f| \cdot \chi_{[n, n+1)}$, a nonnegative measurable function on $[1, \infty)$. Since the intervals $[n, n+1)$ are disjoint with union $[1, \infty)$, we have $|f| = \sum_{n=1}^{\infty} u_n$ pointwise on $[1, \infty)$, and therefore, by Corollary 12 of Chapter 4,

$$\int_{[1, \infty)} |f| = \sum_{n=1}^{\infty} \int_{[1, \infty)} u_n = \sum_{n=1}^{\infty} \int_{[n, n+1)} |f|,$$

where the last equality is the additivity over domains of integration for nonnegative functions (Theorem 11 of Chapter 4), which gives $\int_{[1, \infty)} u_n = \int_{[n, n+1)} u_n + \int_{[1, \infty) \setminus [n, n+1)} u_n = \int_{[n, n+1)} |f| + 0$. By the Integral Comparison Test (Proposition 16 of Chapter 4),

$$|a_n| = \left| \int_{[n, n+1)} f \right| \leq \int_{[n, n+1)} |f|,$$

where we have used that the value of the integral of an integrable function is unchanged by excising the single point $n+1$, a set of measure zero, so that $a_n = \int_{[n, n+1]} f = \int_{[n, n+1)} f$; this is (18) of Proposition 15 of Chapter 4. Hence

$$\sum_{n=1}^{\infty} |a_n| \leq \sum_{n=1}^{\infty} \int_{[n, n+1)} |f| = \int_{[1, \infty)} |f| < \infty.$$

So integrability of f implies that $\sum_{n=1}^{\infty} a_n$ converges absolutely, and in particular that it converges. This is the true half of both assertions.

The first converse fails. Define f on $[1, \infty)$ by

$$f(x) = \frac{(-1)^n}{n} \quad \text{for } n \leq x < n+1, \quad n = 1, 2, \dots$$

Then f is measurable (it is constant on each interval of a countable disjoint measurable decomposition of $[1, \infty)$) and $|f| \leq 1$, so f is certainly bounded on bounded sets. Here $a_n = (-1)^n/n$, and $\sum_{n=1}^{\infty} (-1)^n/n$ converges by the alternating series test. But by the computation above,

$$\int_{[1, \infty)} |f| = \sum_{n=1}^{\infty} \int_{[n, n+1)} |f| = \sum_{n=1}^{\infty} \frac{1}{n} = \infty,$$

so $|f|$ is not integrable, that is, f is not integrable over $[1, \infty)$. Thus convergence of $\sum_{n=1}^{\infty} a_n$ does not imply integrability, and the answer to the first question is no.

The second converse fails. Define f on $[1, \infty)$ by setting, for each natural number n , $f(x) = 1$ for $n \leq x < n+1/2$ and $f(x) = -1$ for $n+1/2 \leq x < n+1$. Again f is measurable and $|f| \equiv 1$, so f is bounded on bounded sets. Fix n . Excising the single point $n+1$, which changes no integral by (18), and then applying additivity over domains for integrable functions (Corollary 18 of Chapter 4) to the disjoint decomposition $[n, n+1) = [n, n+1/2) \cup [n+1/2, n+1)$,

$$a_n = \int_{[n, n+1)} f = \int_{[n, n+1/2)} 1 + \int_{[n+1/2, n+1)} (-1) = \frac{1}{2} - \frac{1}{2} = 0.$$

Hence $\sum_{n=1}^{\infty} |a_n| = 0 < \infty$, so the series converges absolutely. Yet $\int_{[1,\infty)} |f| = \sum_{n=1}^{\infty} \int_{[n,n+1)} 1 = \sum_{n=1}^{\infty} 1 = \infty$, so f is not integrable over $[1, \infty)$. Thus the answer to the second question is also no.

Remark. What is true in general is that f is integrable over $[1, \infty)$ if and only if $\sum_{n=1}^{\infty} b_n < \infty$, where $b_n = \int_n^{n+1} |f|$; this is exactly the identity $\int_{[1,\infty)} |f| = \sum_{n=1}^{\infty} b_n$ established above. In particular, if f is nonnegative, then $a_n = b_n$ and both assertions of the problem do hold: f is integrable over $[1, \infty)$ if and only if $\sum_{n=1}^{\infty} a_n$ converges, and for a series of nonnegative terms convergence and absolute convergence coincide.

Problem 4.30. Let g be a nonnegative integrable function over E and suppose $\{f_n\}$ is a sequence of measurable functions on E such that for each n , $|f_n| \leq g$ a.e. on E . Show that

$$\int_E \liminf f_n \leq \liminf \int_E f_n \leq \limsup \int_E f_n \leq \int_E \limsup f_n.$$

Solution. We first record the generalized form of Fatou's Lemma that is the content of Problem 27: if $\{h_n\}$ is a sequence of nonnegative measurable functions on E , then

$$\int_E \liminf h_n \leq \liminf \int_E h_n.$$

Call this the generalized Fatou inequality. Indeed, put $u_k = \inf_{n \geq k} h_n$. Each u_k is nonnegative and measurable, $\{u_k\}$ is increasing, and $u_k \rightarrow \liminf h_n$ pointwise on E . By the Monotone Convergence Theorem, $\lim_{k \rightarrow \infty} \int_E u_k = \int_E \liminf h_n$. On the other hand $u_k \leq h_n$ on E for every $n \geq k$, so by the monotonicity of integration for nonnegative functions $\int_E u_k \leq \inf_{n \geq k} \int_E h_n$. Letting $k \rightarrow \infty$ gives the generalized Fatou inequality.

Now we set up the excision. For each n let E_n be the set of measure zero outside of which $|f_n| \leq g$, and let E_0 be the set of measure zero outside of which g is finite; such a set exists because g is a nonnegative integrable function, by Proposition 13 of Chapter 4. The set $Z = E_0 \cup \bigcup_{n=1}^{\infty} E_n$ has measure zero by the countable subadditivity of Lebesgue measure. By the excision property (15) for nonnegative measurable functions, and by (18) of Proposition 15 of Chapter 4 for the integrable ones, the integral over E of any of the functions appearing in the asserted inequalities equals its integral over $E \sim Z$, and the functions $\liminf f_n$, $\limsup f_n$ are unchanged off Z . Hence, replacing E by $E \sim Z$, we may and do assume that

$$|f_n| \leq g \text{ on } E \text{ for every } n, \quad \text{and } g \text{ is finite on } E.$$

Three preliminary integrability remarks. First, each f_n is measurable and dominated in absolute value by the integrable function g , so by the Integral Comparison Test (Proposition 16 of Chapter 4) each f_n is integrable over E and $\int_E f_n$ is a real number; thus the two middle quantities in the assertion are the lower and upper limits of a bounded sequence of real numbers, and the middle inequality $\liminf \int_E f_n \leq \limsup \int_E f_n$ is immediate. Second, since $|f_n| \leq g$ for all n we also have $|\liminf f_n| \leq g$ and $|\limsup f_n| \leq g$ on E , so both $\liminf f_n$ and $\limsup f_n$ are integrable over E by the same Integral Comparison Test; in particular all four quantities in the assertion are finite. Third, $g + f_n$ and $g - f_n$ are properly defined (because g is finite), measurable, integrable over E by the Integral Comparison Test since $|g \pm f_n| \leq 2g$, and nonnegative on E because $|f_n| \leq g$.

The left-hand inequality. Apply the generalized Fatou inequality to the nonnegative measurable sequence $\{g + f_n\}$. Since g is finite, $\liminf(g + f_n) = g + \liminf f_n$ pointwise on E , so

$$\int_E g + \int_E \liminf f_n = \int_E (g + \liminf f_n) \leq \liminf \int_E (g + f_n) = \int_E g + \liminf \int_E f_n,$$

where the first and last equalities use the linearity of integration (Theorem 17 of Chapter 4), legitimate because g , $\liminf f_n$ and each f_n are integrable over E , and the last equality also uses that $\int_E g$ is a fixed real number, so that $\liminf(\int_E g + \int_E f_n) = \int_E g + \liminf \int_E f_n$. Since $\int_E g$ is finite, it may be cancelled from both ends, giving

$$\int_E \liminf f_n \leq \liminf \int_E f_n.$$

The right-hand inequality. Apply the generalized Fatou inequality to the nonnegative measurable sequence $\{g - f_n\}$. Since g is finite, $\liminf(g - f_n) = g - \limsup f_n$ pointwise on E , so, again by Theorem 17,

$$\int_E g - \int_E \limsup f_n \leq \liminf \int_E (g - f_n) = \int_E g + \liminf \left(- \int_E f_n \right) = \int_E g - \limsup \int_E f_n.$$

Cancelling the finite number $\int_E g$ and multiplying by -1 reverses the inequality and yields

$$\limsup \int_E f_n \leq \int_E \limsup f_n.$$

Combining the three inequalities gives the asserted chain.

Problem 4.31. Let f be a measurable function on E which can be expressed as $f = g + h$ on E , where g is finite and integrable over E and h is nonnegative on E . Define $\int_E f = \int_E g + \int_E h$. Show that this is properly defined in the sense that it is independent of the particular choice of finite integrable function g and nonnegative function h whose sum is f .

Solution. First note that the proposed definition makes sense for any single such decomposition. If $f = g + h$ with g finite, measurable and integrable over E and $h \geq 0$ on E , then $h = f - g$ is a properly defined extended real-valued function (no expression $\infty - \infty$ arises, since g is finite) and it is measurable, being the difference of the measurable functions f and g . Therefore $\int_E h$ is defined as an element of $[0, \infty]$, while $\int_E g$ is a real number, and the sum $\int_E g + \int_E h$ is an unambiguous element of $(-\infty, \infty]$.

Now suppose we have two such decompositions,

$$f = g_1 + h_1 = g_2 + h_2 \quad \text{on } E,$$

where g_1, g_2 are finite and integrable over E and h_1, h_2 are nonnegative measurable functions on E . We must show

$$\int_E g_1 + \int_E h_1 = \int_E g_2 + \int_E h_2.$$

The difficulty is that h_1 and h_2 may take the value ∞ , so we may not simply subtract. We therefore rearrange the identity $g_1 + h_1 = g_2 + h_2$ into an identity between nonnegative functions. Write $g_i = g_i^+ - g_i^-$, where g_i^+ and g_i^- are the nonnegative and finite positive and negative parts of g_i ; each of $g_1^+, g_1^-, g_2^+, g_2^-$ is a nonnegative measurable function on E which is integrable over E , by Proposition 14 of Chapter 4. Adding the finite nonnegative function $g_1^- + g_2^-$ to both sides of $g_1 + h_1 = g_2 + h_2$ gives

$$h_1 + g_1^+ + g_2^- = h_2 + g_2^+ + g_1^- \quad \text{on } E.$$

Let us verify this identity carefully, since extended values occur. At a point x where $h_1(x)$ and $h_2(x)$ are both finite, every term is a real number and the identity is the elementary rearrangement

$$h_1 + (g_1 + g_1^-) + g_2^- = (g_1 + h_1) + g_1^- + g_2^- = (g_2 + h_2) + g_2^- + g_1^- = h_2 + (g_2 + g_2^-) + g_1^-,$$

using $g_i + g_i^- = g_i^+$. At a point x where $h_1(x) = \infty$, we get $f(x) = g_1(x) + \infty = \infty$ because $g_1(x)$ is finite; since $g_2(x)$ is finite as well and $f(x) = g_2(x) + h_2(x)$, necessarily $h_2(x) = \infty$. Thus $h_1(x) = \infty$ if and only if $h_2(x) = \infty$, and at such a point both sides of the displayed identity equal ∞ (each is the sum of ∞ with finite nonnegative numbers). So the identity holds at every point of E , and every function appearing in it is nonnegative and measurable.

Integrate. By the linearity of integration for nonnegative measurable functions,

$$\int_E h_1 + \int_E g_1^+ + \int_E g_2^- = \int_E h_2 + \int_E g_2^+ + \int_E g_1^-,$$

an equality of elements of $[0, \infty]$. The four numbers $\int_E g_1^+, \int_E g_1^-, \int_E g_2^+, \int_E g_2^-$ are finite because g_1 and g_2 are integrable over E . Hence we may subtract the finite number $\int_E g_1^- + \int_E g_2^-$ from both sides, which is a legitimate operation in $(-\infty, \infty]$, to obtain

$$\int_E h_1 + \left(\int_E g_1^+ - \int_E g_1^- \right) = \int_E h_2 + \left(\int_E g_2^+ - \int_E g_2^- \right),$$

that is, by the definition of the integral of an integrable function,

$$\int_E h_1 + \int_E g_1 = \int_E h_2 + \int_E g_2.$$

This is precisely the required independence: the value $\int_E g + \int_E h$ does not depend on the decomposition chosen. (In particular both sides are simultaneously $+\infty$, or simultaneously the same real number.)

Finally, the new definition is consistent with the old one. If f is itself integrable over E , then f is finite a.e. on E by Proposition 15 of Chapter 4; excising a set of measure zero, which changes no integral by (18) of that same proposition, we may take f finite on E and use the decomposition $g = f$, $h \equiv 0$, for which $\int_E g + \int_E h = \int_E f$, the integral of f in the sense of Section 4.4. By the independence just proved, every admissible decomposition gives this same value.

Problem 4.32. Prove the General Lebesgue Dominated Convergence Theorem by following the proof of the Lebesgue Dominated Convergence Theorem, but replacing the sequences $\{g - f_n\}$ and $\{g + f_n\}$, respectively, by $\{g_n - f_n\}$ and $\{g_n + f_n\}$.

Solution. We must prove Theorem 19 of Chapter 4: let $\{f_n\}$ be a sequence of measurable functions on E that converges pointwise a.e. on E to f , and suppose there is a sequence $\{g_n\}$ of nonnegative measurable functions on E that converges pointwise a.e. on E to g and dominates $\{f_n\}$ in the sense that $|f_n| \leq g_n$ on E for all n ; if $\lim_{n \rightarrow \infty} \int_E g_n = \int_E g < \infty$, then $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$.

Preliminaries. Since $\lim_{n \rightarrow \infty} \int_E g_n = \int_E g < \infty$, there is an index N such that $\int_E g_n < \infty$ for all $n \geq N$; that is, g_n is integrable over E for all $n \geq N$. As the conclusion concerns only the behavior of $\int_E f_n$ for large n , we may discard the first $N - 1$ terms and assume that every g_n is integrable over E . Then, for each n , f_n is measurable and $|f_n| \leq g_n$ with g_n nonnegative and integrable, so by the Integral Comparison Test (Proposition 16 of Chapter 4) each f_n is integrable over E and $\int_E f_n$ is a real number.

Next, g is nonnegative and measurable, being an a.e. pointwise limit of such functions, and $\int_E g < \infty$, so g is integrable over E and hence finite a.e. on E by Proposition 13 of Chapter 4. Also each g_n is finite a.e. on E , for the same reason. Passing to the limit in $|f_n| \leq g_n$ at each point where both $f_n \rightarrow f$ and $g_n \rightarrow g$, we get $|f| \leq g$ a.e. on E ; since f is measurable as an a.e. pointwise limit of measurable functions, the Integral Comparison Test shows f is integrable over E .

Let Z be the union of the following sets of measure zero: the set where $\{f_n\}$ fails to converge to f , the set where $\{g_n\}$ fails to converge to g , the set where g is infinite, the set where $|f| > g$, and, for each n , the set where g_n is infinite. By the countable subadditivity of Lebesgue measure, $m(Z) = 0$; by the excision property (15) applied to positive and negative parts, no integral occurring below is changed if E is replaced by $E \sim Z$. So we may and do assume that on E we have: $f_n \rightarrow f$ pointwise, $g_n \rightarrow g$ pointwise, every g_n and g are finite, $|f_n| \leq g_n$ for all n , and $|f| \leq g$.

The two Fatou arguments. For each n the functions $g_n - f_n$ and $g_n + f_n$ are properly defined (all the functions involved are finite on E), measurable, and nonnegative on E , since $|f_n| \leq g_n$. Moreover $g_n - f_n \rightarrow g - f$ and $g_n + f_n \rightarrow g + f$ pointwise on E , and $g - f$, $g + f$ are nonnegative because $|f| \leq g$. Apply Fatou's Lemma to $\{g_n - f_n\}$:

$$\int_E (g - f) \leq \liminf \int_E (g_n - f_n).$$

Both g_n and f_n are integrable over E , so by the linearity of integration (Theorem 17 of Chapter 4), $\int_E (g_n - f_n) = \int_E g_n - \int_E f_n$; likewise $\int_E (g - f) = \int_E g - \int_E f$, since g and f are integrable over E .

Because $\lim_{n \rightarrow \infty} \int_E g_n$ exists and is the finite number $\int_E g$, we may split the lower limit:

$$\liminf \left(\int_E g_n - \int_E f_n \right) = \int_E g + \liminf \left(- \int_E f_n \right) = \int_E g - \limsup \int_E f_n.$$

Hence

$$\int_E g - \int_E f \leq \int_E g - \limsup \int_E f_n,$$

and cancelling the finite number $\int_E g$ gives

$$\limsup \int_E f_n \leq \int_E f.$$

Now apply Fatou's Lemma to $\{g_n + f_n\}$:

$$\int_E (g + f) \leq \liminf \int_E (g_n + f_n).$$

Exactly as before, by Theorem 17 and the finiteness of $\lim_{n \rightarrow \infty} \int_E g_n = \int_E g$,

$$\int_E g + \int_E f \leq \int_E g + \liminf \int_E f_n,$$

so that

$$\int_E f \leq \liminf \int_E f_n.$$

Conclusion. Combining the two displayed inequalities,

$$\int_E f \leq \liminf \int_E f_n \leq \limsup \int_E f_n \leq \int_E f,$$

so all four quantities are equal and $\lim_{n \rightarrow \infty} \int_E f_n$ exists and equals $\int_E f$. This is the assertion of Theorem 19.

Note that the hypothesis $\lim_{n \rightarrow \infty} \int_E g_n = \int_E g < \infty$ was used exactly where the ordinary Dominated Convergence Theorem uses the constancy of the dominating function: it is what permits the terms $\int_E g_n$ to be pulled out of the lower limit as the finite number $\int_E g$ and then cancelled.

Problem 4.33. Let $\{f_n\}$ be a sequence of integrable functions on E for which $f_n \rightarrow f$ a.e. on E and f is integrable over E . Show that $\int_E |f - f_n| \rightarrow 0$ if and only if $\lim_{n \rightarrow \infty} \int_E |f_n| = \int_E |f|$. (Hint: Use the General Lebesgue Dominated Convergence Theorem.)

Solution. Throughout, f and each f_n are integrable over E , so $|f|$ and each $|f_n|$ are nonnegative integrable functions on E and all the integrals below are finite real numbers. Also, $f - f_n$ is measurable and $|f - f_n| \leq |f| + |f_n|$, which is integrable, so by the Integral Comparison Test (Proposition 16 of Chapter 4) $f - f_n$ is integrable over E and $\int_E |f - f_n| < \infty$.

Necessity. Suppose $\int_E |f - f_n| \rightarrow 0$. For each n , the reverse triangle inequality for real numbers gives

$$||f_n(x)| - |f(x)|| \leq |f(x) - f_n(x)| \quad \text{for a.e. } x \in E$$

(at every point where f and f_n are finite, hence a.e. on E by Proposition 15 of Chapter 4). By the linearity of integration (Theorem 17 of Chapter 4), the Integral Comparison Test, and the monotonicity of integration,

$$\left| \int_E |f_n| - \int_E |f| \right| = \left| \int_E (|f_n| - |f|) \right| \leq \int_E ||f_n| - |f|| \leq \int_E |f - f_n|.$$

Since the right-hand side tends to 0, we conclude $\lim_{n \rightarrow \infty} \int_E |f_n| = \int_E |f|$. Observe that this half did not use the pointwise convergence of $\{f_n\}$.

Sufficiency. Suppose $\lim_{n \rightarrow \infty} \int_E |f_n| = \int_E |f|$. Define, for each n ,

$$h_n = |f - f_n| \quad \text{and} \quad g_n = |f| + |f_n| \quad \text{on } E.$$

We check the hypotheses of the General Lebesgue Dominated Convergence Theorem (Theorem 19 of Chapter 4) for the sequence $\{h_n\}$ dominated by $\{g_n\}$.

Each h_n is measurable, and $h_n \rightarrow 0$ a.e. on E : indeed at a.e. point x we have $f_n(x) \rightarrow f(x)$ with $f(x)$ finite (Proposition 15), so $|f(x) - f_n(x)| \rightarrow 0$. Each g_n is nonnegative and measurable, and $g_n \rightarrow 2|f|$ a.e. on E , since $|f_n| \rightarrow |f|$ a.e. by the continuity of the absolute value. The domination $|h_n| = |f - f_n| \leq |f| + |f_n| = g_n$ holds a.e. on E (at every point where both f and f_n are finite); excising a set of measure zero, which by (15) changes none of the integrals involved, we may assume it holds on all of E .

Finally, the crucial hypothesis on the integrals of the dominating sequence holds: by the linearity of integration for nonnegative functions and the assumed convergence,

$$\lim_{n \rightarrow \infty} \int_E g_n = \lim_{n \rightarrow \infty} \left(\int_E |f| + \int_E |f_n| \right) = \int_E |f| + \int_E |f| = \int_E 2|f| < \infty,$$

the finiteness because f is integrable over E , and $\int_E 2|f|$ is precisely the integral of the a.e. pointwise limit of $\{g_n\}$.

Therefore Theorem 19 applies to $\{h_n\}$ with dominating sequence $\{g_n\}$ and limit function 0, and yields

$$\lim_{n \rightarrow \infty} \int_E |f - f_n| = \lim_{n \rightarrow \infty} \int_E h_n = \int_E 0 = 0.$$

This completes the proof of both implications.

Remark. The ordinary Lebesgue Dominated Convergence Theorem is not enough here: there is in general no single integrable function dominating all the $|f - f_n|$, and this is exactly the situation the generalized theorem was designed for.

Problem 4.34. Let f be a nonnegative measurable function on $\mathbb{R}$. Show that

$$\lim_{n \rightarrow \infty} \int_{-n}^n f = \int_{\mathbb{R}} f.$$

Solution. Here $\int_{-n}^n f$ denotes $\int_{[-n,n]} f$, and since f is nonnegative and measurable all the integrals occurring are defined as elements of $[0, \infty]$; the assertion is an equality in $[0, \infty]$.

For each natural number n define

$$f_n = f \cdot \chi_{[-n,n]} \quad \text{on } \mathbb{R}.$$

Each f_n is nonnegative and measurable, being the product of the nonnegative measurable function f with the characteristic function of a measurable set.

The sequence $\{f_n\}$ is increasing on $\mathbb{R}$. Indeed, $[-n, n] \subseteq [-(n+1), n+1]$, so $\chi_{[-n,n]} \leq \chi_{[-(n+1), n+1]}$ and, f being nonnegative, $f_n \leq f_{n+1}$ on $\mathbb{R}$.

The sequence $\{f_n\}$ converges pointwise on $\mathbb{R}$ to f . Let $x \in \mathbb{R}$ and choose a natural number $N > |x|$, which is possible by the Archimedean property. Then $x \in [-n, n]$ for all $n \geq N$, so $f_n(x) = f(x)$ for all $n \geq N$; in particular $f_n(x) \rightarrow f(x)$.

The Monotone Convergence Theorem therefore applies and gives

$$\lim_{n \rightarrow \infty} \int_{\mathbb{R}} f_n = \int_{\mathbb{R}} f,$$

this limit existing in $[0, \infty]$ since $\{\int_{\mathbb{R}} f_n\}$ is increasing by the monotonicity of integration for nonnegative functions.

It remains to identify $\int_{\mathbb{R}} f_n$ with $\int_{-n}^n f$. The sets $[-n, n]$ and $\mathbb{R} \setminus [-n, n]$ are disjoint measurable sets whose union is $\mathbb{R}$, so by the additivity over domains of integration for nonnegative measurable functions

(Theorem 11 of Chapter 4),

$$\int_{\mathbb{R}} f_n = \int_{[-n,n]} f_n + \int_{\mathbb{R} \sim [-n,n]} f_n.$$

On $[-n, n]$ we have $f_n = f$, so $\int_{[-n,n]} f_n = \int_{[-n,n]} f = \int_{-n}^n f$. On $\mathbb{R} \sim [-n, n]$ we have $f_n \equiv 0$, so $\int_{\mathbb{R} \sim [-n,n]} f_n = 0$ by the monotonicity of integration for nonnegative functions (the integral of the zero function over any measurable set is 0, being the supremum of the integrals of bounded measurable functions of finite support lying below it, all of which are 0). Hence

$$\int_{\mathbb{R}} f_n = \int_{-n}^n f \quad \text{for every } n.$$

Substituting this into the conclusion of the Monotone Convergence Theorem gives

$$\lim_{n \rightarrow \infty} \int_{-n}^n f = \int_{\mathbb{R}} f,$$

as required. Note that no integrability assumption was needed: if $\int_{\mathbb{R}} f = \infty$, the assertion says that the increasing sequence $\{\int_{-n}^n f\}$ diverges to ∞ , which is exactly what the Monotone Convergence Theorem delivers in the extended sense.

Problem 4.35. Let f be a real-valued function of two variables (x, y) that is defined on the square $Q = \{(x, y) \mid 0 \leq x \leq 1, 0 \leq y \leq 1\}$ and is a measurable function of x for each fixed value of y . Suppose for each fixed value of x , $\lim_{y \rightarrow 0} f(x, y) = f(x)$ and that for all y , we have $|f(x, y)| \leq g(x)$, where g is integrable over $[0, 1]$. Show that

$$\lim_{y \rightarrow 0} \int_0^1 f(x, y) dx = \int_0^1 f(x) dx.$$

Also show that if the function $f(x, y)$ is continuous in y for each x , then

$$h(y) = \int_0^1 f(x, y) dx$$

is a continuous function of y .

Solution. Throughout, $E = [0, 1]$ and, for $y \in [0, 1]$, we write f_y for the function $x \mapsto f(x, y)$ on E . By hypothesis each f_y is measurable on E and $|f_y| \leq g$ on E , and g is integrable over E ; note that g is automatically nonnegative, since $g(x) \geq |f(x, 0)| \geq 0$ for every $x \in E$. Hence, by the Integral Comparison Test (Proposition 16 of Chapter 4), each f_y is integrable over E , so

$$H(y) = \int_0^1 f(x, y) dx$$

is a well-defined real number for every $y \in [0, 1]$.

The limit function f is measurable and integrable. Fix any sequence $\{y_n\}$ in $(0, 1]$ with $y_n \rightarrow 0$. Then for each $x \in E$ we have $f_{y_n}(x) = f(x, y_n) \rightarrow f(x)$ by the hypothesis $\lim_{y \rightarrow 0} f(x, y) = f(x)$. Thus f is the pointwise limit on E of the sequence of measurable functions $\{f_{y_n}\}$ and is therefore measurable on E . Moreover $|f(x)| = \lim_n |f(x, y_n)| \leq g(x)$ for all $x \in E$, so f is integrable over E by the Integral Comparison Test, and $\int_0^1 f(x) dx$ is a real number.

The first assertion. Let $\{y_n\}$ be an arbitrary sequence in $(0, 1]$ with $y_n \rightarrow 0$. The sequence of measurable functions $\{f_{y_n}\}$ converges pointwise on E to f , and it is dominated on E by the single integrable function g , since $|f_{y_n}| \leq g$ for every n . By the Lebesgue Dominated Convergence Theorem,

$$\lim_{n \rightarrow \infty} H(y_n) = \lim_{n \rightarrow \infty} \int_0^1 f(x, y_n) dx = \int_0^1 f(x) dx.$$

We now pass from sequences to the limit as $y \rightarrow 0$. Let $L = \int_0^1 f(x) dx$ and suppose, by way of contradiction, that $H(y)$ does not converge to L as $y \rightarrow 0$. Then there is an $\epsilon_0 > 0$ such that for every $\delta > 0$ there is a $y \in (0, 1]$ with $y < \delta$ and $|H(y) - L| \geq \epsilon_0$. Taking $\delta = 1/n$ for each natural number n produces a sequence $\{y_n\}$ in $(0, 1]$ with $y_n < 1/n$, hence $y_n \rightarrow 0$, and $|H(y_n) - L| \geq \epsilon_0$ for all n . This contradicts the convergence $H(y_n) \rightarrow L$ established above for every such sequence. Therefore

$$\lim_{y \rightarrow 0} \int_0^1 f(x, y) dx = \int_0^1 f(x) dx,$$

which is the first assertion.

The second assertion. Assume now in addition that for each fixed $x \in [0, 1]$ the function $y \mapsto f(x, y)$ is continuous on $[0, 1]$, and let $h(y) = \int_0^1 f(x, y) dx$, which is the function H above and is real-valued by the first paragraph. Fix $y_0 \in [0, 1]$; we show h is continuous at y_0 .

Let $\{y_n\}$ be any sequence in $[0, 1]$ with $y_n \rightarrow y_0$. For each fixed $x \in [0, 1]$, continuity of $f(x, \cdot)$ at y_0 gives $f(x, y_n) \rightarrow f(x, y_0)$. Thus $\{f_{y_n}\}$ is a sequence of measurable functions on E converging pointwise on E to the measurable function f_{y_0} , and $|f_{y_n}| \leq g$ on E for every n , with g integrable over E . By the Lebesgue Dominated Convergence Theorem,

$$\lim_{n \rightarrow \infty} h(y_n) = \lim_{n \rightarrow \infty} \int_0^1 f(x, y_n) dx = \int_0^1 f(x, y_0) dx = h(y_0).$$

Since $\{y_n\}$ was an arbitrary sequence in $[0, 1]$ converging to y_0 , the sequential criterion for continuity gives that h is continuous at y_0 . Explicitly, were h discontinuous at y_0 , there would be an $\epsilon_0 > 0$ and, for each natural number n , a point $y_n \in [0, 1]$ with $|y_n - y_0| < 1/n$ and $|h(y_n) - h(y_0)| \geq \epsilon_0$; this sequence converges to y_0 yet $h(y_n) \not\rightarrow h(y_0)$, contradicting what was just proved. As $y_0 \in [0, 1]$ was arbitrary, h is a continuous function of y on $[0, 1]$.

4.6 Problems 4.36–4.42

Problem 4.36. Let f be a real-valued function of two variables (x, y) that is defined on the square $Q = \{(x, y) \mid 0 \leq x \leq 1, 0 \leq y \leq 1\}$ and is a measurable function of x for each fixed value of y . For each $(x, y) \in Q$ let the partial derivative $\partial f / \partial y$ exist. Suppose there is a function g that is integrable over $[0, 1]$ and such that

$$\left| \frac{\partial f}{\partial y}(x, y) \right| \leq g(x) \quad \text{for all } (x, y) \in Q.$$

Prove that

$$\frac{d}{dy} \left[\int_0^1 f(x, y) dx \right] = \int_0^1 \frac{\partial f}{\partial y}(x, y) dx \quad \text{for all } y \in [0, 1].$$

Solution. For the assertion to have content the inner integral must be defined, so we assume, as the statement implicitly does, that $x \mapsto f(x, y_0)$ is integrable over $[0, 1]$ for at least one $y_0 \in [0, 1]$. This much cannot be dispensed with: the function $f(x, y) = 1/x$ for $0 < x \leq 1$, $f(0, y) = 0$, is real-valued on Q , is measurable in x for each y , and has $\partial f / \partial y \equiv 0$, so it meets every stated hypothesis with $g \equiv 0$, yet $\int_0^1 f(x, y) dx = \infty$ for every y . We first check that integrability at a single y_0 forces integrability for every y .

Step 1: $f(\cdot, y)$ is integrable over $[0, 1]$ for each $y \in [0, 1]$.

Fix $x \in [0, 1]$. By hypothesis the function $t \mapsto f(x, t)$ is differentiable at every point of $[0, 1]$, hence continuous there. Therefore, given $y \in [0, 1]$ with $y \neq y_0$, the Mean Value Theorem applied to $t \mapsto f(x, t)$ on the closed interval with endpoints y_0 and y provides a point ξ strictly between them with

$$f(x, y) - f(x, y_0) = \frac{\partial f}{\partial y}(x, \xi) (y - y_0).$$

Since $|y - y_0| \leq 1$ and $|\partial f / \partial y| \leq g$ on Q , we conclude

$$|f(x, y)| \leq |f(x, y_0)| + g(x) \quad \text{for all } x \in [0, 1].$$

The right-hand side is integrable over $[0, 1]$, and $f(\cdot, y)$ is measurable by hypothesis; by the Integral Comparison Test (Proposition 16 of Chapter 4), $f(\cdot, y)$ is integrable over $[0, 1]$. Thus

$$F(y) := \int_0^1 f(x, y) dx$$

is a well-defined real number for every $y \in [0, 1]$.

Step 2: the difference quotients are dominated by g .

Fix $y \in [0, 1]$ and let $\{y_n\}$ be any sequence in $[0, 1]$ with $y_n \neq y$ for all n and $y_n \rightarrow y$. Define, for $x \in [0, 1]$,

$$h_n(x) = \frac{f(x, y_n) - f(x, y)}{y_n - y}.$$

Each h_n is measurable on $[0, 1]$, being a linear combination of the measurable functions $f(\cdot, y_n)$ and $f(\cdot, y)$. Exactly as in Step 1, the Mean Value Theorem applied to $t \mapsto f(x, t)$ on the interval with endpoints y and y_n yields a point $\xi_{n,x}$ between y and y_n (so $\xi_{n,x} \in [0, 1]$) with

$$h_n(x) = \frac{\partial f}{\partial y}(x, \xi_{n,x}), \quad \text{hence} \quad |h_n(x)| \leq g(x) \quad \text{for all } x \in [0, 1] \text{ and all } n.$$

Step 3: pointwise convergence and passage to the limit.

For each fixed $x \in [0, 1]$, the very definition of the partial derivative $\partial f / \partial y(x, y)$, which exists by hypothesis, gives

$$\lim_{n \rightarrow \infty} h_n(x) = \frac{\partial f}{\partial y}(x, y).$$

(At $y = 0$ and $y = 1$ this derivative is the appropriate one-sided derivative, and the sequences $\{y_n\}$ necessarily approach y from one side.) Hence $\partial f / \partial y(\cdot, y)$ is measurable on $[0, 1]$, being a pointwise limit of measurable functions, and it satisfies $|\partial f / \partial y(\cdot, y)| \leq g$; by the Integral Comparison Test it is integrable over $[0, 1]$.

The sequence $\{h_n\}$ consists of measurable functions on $[0, 1]$, converges pointwise to $\partial f / \partial y(\cdot, y)$, and is dominated on $[0, 1]$ by the integrable function g . By the Lebesgue Dominated Convergence Theorem,

$$\lim_{n \rightarrow \infty} \int_0^1 h_n(x) dx = \int_0^1 \frac{\partial f}{\partial y}(x, y) dx.$$

On the other hand, by the linearity of integration (Theorem 17 of Chapter 4; all three functions involved are integrable by Step 1),

$$\int_0^1 h_n(x) dx = \frac{1}{y_n - y} \left[\int_0^1 f(x, y_n) dx - \int_0^1 f(x, y) dx \right] = \frac{F(y_n) - F(y)}{y_n - y}.$$

Therefore

$$\lim_{n \rightarrow \infty} \frac{F(y_n) - F(y)}{y_n - y} = \int_0^1 \frac{\partial f}{\partial y}(x, y) dx.$$

Step 4: conclusion.

The sequence $\{y_n\}$ in $[0, 1] \setminus \{y\}$ converging to y was arbitrary, and the limit obtained does not depend on it. By the sequential characterization of limits of a function of a real variable, the limit

$$\lim_{t \rightarrow y, t \in [0, 1], t \neq y} \frac{F(t) - F(y)}{t - y}$$

exists and equals $\int_0^1 (\partial f / \partial y)(x, y) dx$. That is, F is differentiable at y (one-sidedly at the endpoints $y = 0$ and $y = 1$) and

$$\frac{d}{dy} \left[\int_0^1 f(x, y) dx \right] = \int_0^1 \frac{\partial f}{\partial y}(x, y) dx \quad \text{for all } y \in [0, 1],$$

which is what we were to prove.

Problem 4.37. Let f be an integrable function on E . Show that for each $\epsilon > 0$, there is a natural number N for which if $n \geq N$, then $\left| \int_{E_n} f \right| < \epsilon$ where $E_n = \{x \in E \mid |x| \geq n\}$.

Solution. Here E is a measurable set of real numbers and f is integrable over E .

First, each $E_n = E \cap \{x \in \mathbb{R} : |x| \geq n\} = E \cap ((-\infty, -n] \cup [n, \infty))$ is measurable, being the intersection of the measurable set E with a closed set. Moreover f is integrable over E_n , since E_n is a measurable subset of E and hence, by the monotonicity of integration for nonnegative functions,

$$\int_{E_n} |f| \leq \int_E |f| < \infty.$$

Thus $\int_{E_n} f$ is a well-defined real number for every n .

Observe that $\{E_n\}_{n=1}^\infty$ is a descending collection of measurable sets, since $|x| \geq n+1$ implies $|x| \geq n$, and that

$$\bigcap_{n=1}^\infty E_n = \emptyset,$$

because each $x \in E$ is a real number and therefore fails to satisfy $|x| \geq n$ as soon as $n > |x|$ (by the Archimedean property of $\mathbb{R}$).

We give a direct argument. Define $g_n = |f| \cdot \chi_{E_n}$ on E . Each g_n is measurable, and for every $x \in E$ we have $g_n(x) \rightarrow 0$: indeed, once $n > |x|$ we have $x \notin E_n$ and so $g_n(x) = 0$. Furthermore $0 \leq g_n \leq |f|$ on E , and $|f|$ is integrable over E . By the Lebesgue Dominated Convergence Theorem,

$$\lim_{n \rightarrow \infty} \int_{E_n} |f| = \lim_{n \rightarrow \infty} \int_E g_n = \int_E 0 = 0.$$

By the Integral Comparison Test (Proposition 16 of Chapter 4), which supplies the triangle inequality for integrals,

$$\left| \int_{E_n} f \right| \leq \int_{E_n} |f| \quad \text{for every } n.$$

Hence, given $\epsilon > 0$, choose N so that $\int_{E_n} |f| < \epsilon$ for all $n \geq N$; then for all $n \geq N$,

$$\left| \int_{E_n} f \right| \leq \int_{E_n} |f| < \epsilon.$$

Alternatively, the conclusion is immediate from the Continuity of Integration (Theorem 21 of Chapter 4): since f is integrable over E and $\{E_n\}$ is a descending countable collection of measurable subsets of E with $\bigcap_{n=1}^\infty E_n = \emptyset$, formula (25) gives

$$\lim_{n \rightarrow \infty} \int_{E_n} f = \int_{\bigcap_{n=1}^\infty E_n} f = \int_\emptyset f = 0,$$

and the definition of this limit supplies, for each $\epsilon > 0$, a natural number N such that $\left| \int_{E_n} f \right| < \epsilon$ whenever $n \geq N$.

Problem 4.38. For each of the two functions f on $[1, \infty)$ defined below, show that $\lim_{n \rightarrow \infty} \int_1^n f$ exists while f is not integrable over $[1, \infty)$. Does this contradict the continuity of integration?

- (i) Define $f(x) = (-1)^n/n$, for $n \leq x < n+1$.
- (ii) Define $f(x) = (\sin x)/x$ for $1 \leq x < \infty$.

Solution. Throughout, recall that in Royden a measurable function f is said to be **integrable over** E provided $\int_E |f| < \infty$. So to show f is not integrable over $[1, \infty)$ we show $\int_{[1, \infty)} |f| = \infty$.

(i) The step function $f(x) = (-1)^n/n$ for $n \leq x < n+1$.

The function f is measurable on $[1, \infty)$: it is constant on each of the intervals $[n, n+1)$, $n \geq 1$, so for any c the set $\{x : f(x) > c\}$ is a countable union of such intervals, hence measurable.

Fix a natural number $N \geq 2$. The interval $[1, N)$ is the disjoint union of $[n, n+1)$ for $n = 1, \dots, N-1$, so by the additivity over domains of integration and the fact that $\int_{[n, n+1)} c = c \cdot m([n, n+1)) = c$,

$$\int_1^N f = \sum_{n=1}^{N-1} \frac{(-1)^n}{n} m([n, n+1)) = \sum_{n=1}^{N-1} \frac{(-1)^n}{n}.$$

The alternating series $\sum_{n=1}^{\infty} (-1)^n/n$ converges (its terms alternate in sign and $1/n$ decreases monotonically to 0; this is the alternating series test), with sum $-\ln 2$. Therefore

$$\lim_{N \rightarrow \infty} \int_1^N f = \sum_{n=1}^{\infty} \frac{(-1)^n}{n} = -\ln 2,$$

so the limit exists and is finite.

On the other hand, $|f| = 1/n$ on $[n, n+1)$, so on $[1, \infty)$ we have the pointwise identity

$$|f| = \sum_{n=1}^{\infty} u_n, \quad u_n := \frac{1}{n} \chi_{[n, n+1)},$$

with each u_n nonnegative and measurable. Note that Theorem 20 of Chapter 4 is not available here, since it presupposes that f is integrable over $[1, \infty)$, which is exactly what is in question; but Corollary 12 of Chapter 4, which is the countable additivity of integration for nonnegative measurable functions and assumes no integrability, applies and gives

$$\int_{[1, \infty)} |f| = \sum_{n=1}^{\infty} \int_{[1, \infty)} u_n = \sum_{n=1}^{\infty} \frac{1}{n} m([n, n+1)) = \sum_{n=1}^{\infty} \frac{1}{n} = \infty,$$

the harmonic series being divergent. Hence f is not integrable over $[1, \infty)$.

(ii) $f(x) = (\sin x)/x$ on $[1, \infty)$.

This f is continuous on $[1, \infty)$, hence measurable. On each bounded interval $[1, b]$ it is continuous and therefore Riemann integrable, and by Theorem 3 of Chapter 4 its Riemann and Lebesgue integrals over $[1, b]$ agree. Integrating by parts (a legitimate Riemann-integral manipulation, both integrands being continuous),

$$\int_1^b \frac{\sin x}{x} dx = \left[\frac{-\cos x}{x} \right]_1^b - \int_1^b \frac{\cos x}{x^2} dx = \cos 1 - \frac{\cos b}{b} - \int_1^b \frac{\cos x}{x^2} dx.$$

Now $|\cos b/b| \leq 1/b \rightarrow 0$ as $b \rightarrow \infty$. Also, the function $x \mapsto (\cos x)/x^2$ satisfies $|\cos x/x^2| \leq 1/x^2$ on $[1, \infty)$, and $1/x^2$ is integrable over $[1, \infty)$. Indeed, the functions $x^{-2} \chi_{[1, n]}$ form an increasing sequence of nonnegative measurable functions converging pointwise to x^{-2} on $[1, \infty)$, so the Monotone Convergence Theorem, together with Theorem 3 of Chapter 4 for the integrals over $[1, n]$, gives

$$\int_{[1, \infty)} \frac{dx}{x^2} = \lim_{n \rightarrow \infty} \int_1^n \frac{dx}{x^2} = \lim_{n \rightarrow \infty} \left(1 - \frac{1}{n} \right) = 1 < \infty.$$

Hence $(\cos x)/x^2$ is integrable over $[1, \infty)$, and applying the Lebesgue Dominated Convergence Theorem to $(\cos x)/x^2 \cdot \chi_{[1, n]}$, which converges pointwise to $(\cos x)/x^2$ and is dominated by $1/x^2$, we get

$$\lim_{n \rightarrow \infty} \int_1^n \frac{\cos x}{x^2} dx = \int_{[1, \infty)} \frac{\cos x}{x^2} dx.$$

Combining, the limit exists:

$$\lim_{n \rightarrow \infty} \int_1^n \frac{\sin x}{x} dx = \cos 1 - \int_{[1, \infty)} \frac{\cos x}{x^2} dx \in \mathbb{R}.$$

To see that f is not integrable over $[1, \infty)$, note that for each integer $k \geq 1$ the interval $[k\pi, (k+1)\pi)$ is contained in $[1, \infty)$, and on it $x \leq (k+1)\pi$, so

$$\int_{[k\pi, (k+1)\pi)} \frac{|\sin x|}{x} dx \geq \frac{1}{(k+1)\pi} \int_{k\pi}^{(k+1)\pi} |\sin x| dx = \frac{2}{(k+1)\pi},$$

since $\int_{k\pi}^{(k+1)\pi} |\sin x| dx = 2$ for every k . These intervals are pairwise disjoint measurable subsets of $[1, \infty)$. Writing $v_k = |f| \cdot \chi_{[k\pi, (k+1)\pi)}$, the v_k are nonnegative measurable functions with $\sum_{k=1}^{\infty} v_k \leq |f|$ pointwise on $[1, \infty)$, so Corollary 12 of Chapter 4 together with the monotonicity of integration for nonnegative functions gives

$$\int_{[1, \infty)} \frac{|\sin x|}{x} dx \geq \sum_{k=1}^{\infty} \int_{[1, \infty)} v_k \geq \sum_{k=1}^{\infty} \frac{2}{(k+1)\pi} = \frac{2}{\pi} \sum_{k=2}^{\infty} \frac{1}{k} = \infty.$$

Hence f is not integrable over $[1, \infty)$.

Does this contradict the continuity of integration?

No. Theorem 21 of Chapter 4 (the Continuity of Integration) begins with the hypothesis “Let f be integrable over E .” Here one would want to take $E = [1, \infty)$ and $E_n = [1, n]$, an ascending countable collection of measurable subsets of E with $\bigcup_{n=1}^{\infty} E_n = [1, \infty)$, and conclude from (24) that

$$\int_{[1, \infty)} f = \lim_{n \rightarrow \infty} \int_{[1, n]} f.$$

But in both examples f fails to be integrable over $E = [1, \infty)$, so the hypothesis of the theorem is not met and the left-hand side is not even defined: $\int_{[1, \infty)} f^+ = \int_{[1, \infty)} f^- = \infty$ in each case, so the difference $\int f^+ - \int f^-$ is meaningless.

These examples therefore show only that the converse of the theorem fails: the existence of $\lim_{n \rightarrow \infty} \int_{E_n} f$ for an ascending sequence $\{E_n\}$ exhausting E does not imply that f is integrable over E . The limit in question is an improper (conditionally convergent) integral, and the Lebesgue integral is by design an absolutely convergent theory.

Problem 4.39. Prove the theorem regarding the continuity of integration.

[That is, prove Theorem 21: Let f be integrable over E .

- (i) If $\{E_n\}_{n=1}^{\infty}$ is an ascending countable collection of measurable subsets of E , then

$$\int_{\bigcup_{n=1}^{\infty} E_n} f = \lim_{n \rightarrow \infty} \int_{E_n} f.$$

- (ii) If $\{E_n\}_{n=1}^{\infty}$ is a descending countable collection of measurable subsets of E , then

$$\int_{\bigcap_{n=1}^{\infty} E_n} f = \lim_{n \rightarrow \infty} \int_{E_n} f.$$

Use as a pattern the proof of the continuity of measure based on the countable additivity of measure.]

Solution. Throughout, note first that if A is any measurable subset of E , then f is integrable over A : f is measurable on A , and by the monotonicity of integration for nonnegative measurable functions,

$$\int_A |f| \leq \int_E |f| < \infty.$$

So every integral appearing below is a well-defined real number, and finite. We also use freely the Additivity Over Domains of Integration (Corollary 18 of Chapter 4): if A and B are disjoint measurable subsets of E , then $\int_{A \cup B} f = \int_A f + \int_B f$.

(i) The ascending case.

Let $\{E_n\}_{n=1}^{\infty}$ be ascending, that is $E_n \subseteq E_{n+1}$ for all n , and set $E_{\infty} = \bigcup_{n=1}^{\infty} E_n$. Define $E_0 = \emptyset$ and, for each $k \geq 1$,

$$F_k = E_k \setminus E_{k-1}.$$

Each F_k is a measurable subset of E . The collection $\{F_k\}_{k=1}^\infty$ is disjoint: if $j < k$ then $F_j \subseteq E_j \subseteq E_{k-1}$ while $F_k \cap E_{k-1} = \emptyset$. Moreover, for each $n \geq 1$,

$$\bigcup_{k=1}^n F_k = E_n,$$

which follows by induction: it is trivial for $n = 1$ since $F_1 = E_1$, and if it holds for n then $\bigcup_{k=1}^{n+1} F_k = E_n \cup (E_{n+1} \setminus E_n) = E_{n+1}$, using $E_n \subseteq E_{n+1}$. Taking the union over all n ,

$$\bigcup_{k=1}^\infty F_k = \bigcup_{n=1}^\infty E_n = E_\infty.$$

Thus $\{F_k\}_{k=1}^\infty$ is a disjoint countable collection of measurable subsets of E_∞ whose union is E_∞ , and f is integrable over E_∞ . By the Countable Additivity of Integration (Theorem 20 of Chapter 4), applied with E_∞ in the role of E ,

$$\int_{E_\infty} f = \sum_{k=1}^\infty \int_{F_k} f = \lim_{n \rightarrow \infty} \sum_{k=1}^n \int_{F_k} f,$$

the last equality being the definition of the sum of a series. But for each fixed n , E_n is the disjoint union of the finitely many measurable sets $F_1, \dots, F_n$, so a finite induction on the additivity over domains of integration gives

$$\sum_{k=1}^n \int_{F_k} f = \int_{E_n} f.$$

Combining the last two displays,

$$\int_{\bigcup_{n=1}^\infty E_n} f = \int_{E_\infty} f = \lim_{n \rightarrow \infty} \int_{E_n} f,$$

which is (24).

(ii) The descending case.

Let $\{E_n\}_{n=1}^\infty$ be descending, that is $E_{n+1} \subseteq E_n$ for all n , and set $E_\infty = \bigcap_{n=1}^\infty E_n$. Then $E_\infty \subseteq E_n \subseteq E_1$ for every n .

Define $G_n = E_1 \setminus E_n$ for $n \geq 1$. Since $\{E_n\}$ is descending, $\{G_n\}$ is an ascending collection of measurable subsets of E . Moreover, by De Morgan's identities,

$$\bigcup_{n=1}^\infty G_n = \bigcup_{n=1}^\infty (E_1 \setminus E_n) = E_1 \setminus \bigcap_{n=1}^\infty E_n = E_1 \setminus E_\infty.$$

Applying part (i) to the ascending collection $\{G_n\}$,

$$\int_{E_1 \setminus E_\infty} f = \lim_{n \rightarrow \infty} \int_{E_1 \setminus E_n} f.$$

Now E_1 is the disjoint union of E_∞ and $E_1 \setminus E_\infty$, and also, for each n , the disjoint union of E_n and $E_1 \setminus E_n$. By additivity over domains,

$$\int_{E_1} f = \int_{E_\infty} f + \int_{E_1 \setminus E_\infty} f, \quad \int_{E_1} f = \int_{E_n} f + \int_{E_1 \setminus E_n} f.$$

Every term here is a finite real number, so we may solve and subtract. From the second identity, $\int_{E_n} f = \int_{E_1} f - \int_{E_1 \setminus E_n} f$; letting $n \rightarrow \infty$ and using the limit established above,

$$\lim_{n \rightarrow \infty} \int_{E_n} f = \int_{E_1} f - \int_{E_1 \setminus E_\infty} f = \int_{E_\infty} f,$$

the last equality being the first identity. That is,

$$\int_{\bigcap_{n=1}^{\infty} E_n} f = \lim_{n \rightarrow \infty} \int_{E_n} f,$$

which is (25). This completes the proof.

Remark. The finiteness of $\int_{E_1} f$, which is where the integrability of f over E is used in part (ii), is essential; it is what licenses the cancellation. This is exactly parallel to the proof of the continuity of measure, where the descending case requires $m(E_1) < \infty$.

Problem 4.40. Let f be integrable over $\mathbb{R}$. Show that the function F defined by

$$F(x) = \int_{-\infty}^x f \quad \text{for all } x \in \mathbb{R}$$

is properly defined and continuous. Is it necessarily Lipschitz?

Solution. F is properly defined.

Fix $x \in \mathbb{R}$. The set $(-\infty, x]$ is closed, hence measurable, and f is measurable on it. Since $|f| \geq 0$ and $(-\infty, x] \subseteq \mathbb{R}$, monotonicity of integration gives

$$\int_{(-\infty, x]} |f| \leq \int_{\mathbb{R}} |f| < \infty,$$

so f is integrable over $(-\infty, x]$ and $F(x) = \int_{(-\infty, x]} f$ is a well-defined real number.

F is (uniformly) continuous.

Let $\epsilon > 0$. Since f is integrable over $\mathbb{R}$, Proposition 23 of Chapter 4 provides a $\delta > 0$ such that

$$\text{if } A \subseteq \mathbb{R} \text{ is measurable and } m(A) < \delta, \text{ then } \int_A |f| < \epsilon.$$

Let $x, y \in \mathbb{R}$ with $|x - y| < \delta$; without loss of generality $x < y$. The set $(-\infty, y]$ is the disjoint union of the measurable sets $(-\infty, x]$ and $(x, y]$, so by the Additivity Over Domains of Integration (Corollary 18 of Chapter 4),

$$F(y) = \int_{(-\infty, y]} f = \int_{(-\infty, x]} f + \int_{(x, y]} f = F(x) + \int_{(x, y]} f,$$

all terms being finite. Hence, by the Integral Comparison Test (Proposition 16 of Chapter 4),

$$|F(y) - F(x)| = \left| \int_{(x, y]} f \right| \leq \int_{(x, y]} |f| < \epsilon,$$

since $m((x, y]) = y - x = |x - y| < \delta$. As δ depends only on ϵ , F is uniformly continuous on $\mathbb{R}$, and in particular continuous.

F need not be Lipschitz.

The identity $F(y) - F(x) = \int_{(x, y]} f$ shows that if $|f| \leq M$ a.e. on $\mathbb{R}$ then $|F(y) - F(x)| \leq M|y - x|$, so boundedness of f would give the Lipschitz property. Without boundedness it can fail. Define

$$f(x) = \begin{cases} \frac{1}{\sqrt{x}}, & 0 < x \leq 1, \\ 0, & \text{otherwise.} \end{cases}$$

Then f is nonnegative and measurable on $\mathbb{R}$ (it is continuous off the two points 0 and 1). The functions $f \cdot \chi_{[1/n, 1]}$ are nonnegative, measurable, and increase pointwise to f , so by the Monotone Convergence Theorem, together with Theorem 3 of Chapter 4 (which identifies the Lebesgue and Riemann integrals of a continuous function on a closed bounded interval),

$$\int_{\mathbb{R}} f = \lim_{n \rightarrow \infty} \int_{1/n}^1 \frac{dt}{\sqrt{t}} = \lim_{n \rightarrow \infty} \left(2 - \frac{2}{\sqrt{n}} \right) = 2 < \infty.$$

Thus f is integrable over $\mathbb{R}$. The same computation applied on $(0, x]$ for $0 < x \leq 1$ gives

$$F(x) = \int_{(-\infty, x]} f = \int_{(0, x]} \frac{dt}{\sqrt{t}} = 2\sqrt{x}, \quad 0 \leq x \leq 1,$$

and $F(x) = 0$ for $x \leq 0$.

If F were Lipschitz on $\mathbb{R}$ with constant C , then for every $x \in (0, 1]$ we would have

$$2\sqrt{x} = |F(x) - F(0)| \leq C|x - 0| = Cx, \quad \text{i.e.} \quad \frac{2}{\sqrt{x}} \leq C.$$

Letting $x \rightarrow 0^+$ makes the left-hand side unbounded, a contradiction. Hence F is not Lipschitz.

So F is always uniformly continuous, but it is Lipschitz only under an extra hypothesis such as essential boundedness of f .

Problem 4.41. Show that Proposition 25 is false if $E = \mathbb{R}$.

[Proposition 25 reads: Assume E has finite measure. Let the sequence of functions $\{f_n\}$ be uniformly integrable over E . If $\{f_n\} \rightarrow f$ pointwise a.e. on E , then f is integrable over E .]

Solution. We exhibit a sequence of functions on $E = \mathbb{R}$ which is uniformly integrable over $\mathbb{R}$ and converges pointwise on all of $\mathbb{R}$ to a function that is not integrable over $\mathbb{R}$. This shows that the conclusion of Proposition 25 fails when the hypothesis of finite measure is dropped, so the hypothesis $m(E) < \infty$ cannot be removed.

Define, for every natural number n ,

$$f_n = \chi_{[-n, n]} \quad \text{on } \mathbb{R}.$$

Each f_n is measurable, being the characteristic function of a closed set, and each f_n is in fact integrable over $\mathbb{R}$, with $\int_{\mathbb{R}} |f_n| = m([-n, n]) = 2n < \infty$; so no objection can be raised that the members of the family are themselves badly behaved.

$\{f_n\} \rightarrow f$ pointwise on all of $\mathbb{R}$, where $f \equiv 1$. Indeed, fix $x \in \mathbb{R}$ and use the Archimedean property to choose $N > |x|$; then $x \in [-n, n]$ for all $n \geq N$, so $f_n(x) = 1$ for all $n \geq N$. Hence $f_n(x) \rightarrow 1$. In particular the convergence holds pointwise a.e. on $\mathbb{R}$.

The family $\{f_n\}_{n=1}^{\infty}$ is uniformly integrable over $\mathbb{R}$.

Let $\epsilon > 0$ and take $\delta = \epsilon$. If $A \subseteq \mathbb{R}$ is measurable with $m(A) < \delta$, then for every n , since $0 \leq f_n \leq 1$, monotonicity of integration for nonnegative functions gives

$$\int_A |f_n| = \int_A \chi_{[-n, n]} \leq \int_A 1 = m(A) < \delta = \epsilon.$$

Thus this single δ responds to the ϵ challenge simultaneously for every member of the family, which is precisely criterion (27) for uniform integrability.

The limit function is not integrable over $\mathbb{R}$.

The limit is $f \equiv 1$, and

$$\int_{\mathbb{R}} |f| = \int_{\mathbb{R}} 1 = m(\mathbb{R}) = \infty.$$

Indeed, for every natural number n the function $\chi_{[-n, n]}$ is a nonnegative measurable function with $\chi_{[-n, n]} \leq 1$ on $\mathbb{R}$, so by monotonicity of integration $\int_{\mathbb{R}} 1 \geq \int_{\mathbb{R}} \chi_{[-n, n]} = 2n$ for every n , and hence $\int_{\mathbb{R}} 1 = \infty$. Therefore f is not integrable over $\mathbb{R}$.

So all the hypotheses of Proposition 25 except the finiteness of $m(E)$ are satisfied, yet the conclusion fails. Hence Proposition 25 is false if $E = \mathbb{R}$.

Remark. An even simpler family works, if one is willing to admit members that are not themselves integrable: the constant sequence $f_n \equiv 1$ is uniformly integrable over $\mathbb{R}$ by the identical $\delta = \epsilon$ computation, and converges pointwise to the non-integrable $f \equiv 1$. Royden's definition of uniform integrability imposes no integrability on the members of the family, so this is a legitimate counterexample too; the family $\{\chi_{[-n, n]}\}$ was chosen above only to forestall the objection.

What goes wrong on a set of infinite measure is that uniform integrability controls only the mass carried on sets of small measure. On a set of finite measure this is enough: Lemma 22 lets one split E into finitely many, say N , pieces each of measure less than the δ responding to $\epsilon = 1$, whence $\int_E |f_n| < N$ for every n , and Fatou's Lemma then bounds $\int_E |f|$ by N . When $m(E) = \infty$ that finite splitting is unavailable: $\mathbb{R}$ is not the union of finitely many sets of measure less than δ , and indeed in the example above $\int_{\mathbb{R}} |f_n| = 2n$ is unbounded in n .

Problem 4.42. Show that Theorem 26 is false without the assumption that the h_n 's are nonnegative. [Theorem 26 reads: Let E be of finite measure. Suppose $\{h_n\}$ is a sequence of nonnegative integrable functions that converges pointwise a.e. on E to $h \equiv 0$. Then

$$\lim_{n \rightarrow \infty} \int_E h_n = 0 \text{ if and only if } \{h_n\} \text{ is uniformly integrable over } E.$$

]

Solution. Only one of the two implications in Theorem 26 uses the nonnegativity of the h_n . The implication

$$\{h_n\} \text{ uniformly integrable} \implies \lim_{n \rightarrow \infty} \int_E h_n = 0$$

is just the Vitali Convergence Theorem applied to the pointwise limit $h \equiv 0$, and the Vitali Convergence Theorem makes no sign assumption; so that implication survives. It is the converse,

$$\lim_{n \rightarrow \infty} \int_E h_n = 0 \implies \{h_n\} \text{ uniformly integrable,}$$

that fails when the h_n are allowed to change sign. We construct a counterexample.

Take $E = [0, 1]$, which has finite measure $m(E) = 1$. For each natural number n define

$$h_n = n \cdot \chi_{(0, \frac{1}{2n})} - n \cdot \chi_{[\frac{1}{2n}, \frac{1}{n})}.$$

Explicitly,

$$h_n(x) = \begin{cases} n, & 0 < x < \frac{1}{2n}, \\ -n, & \frac{1}{2n} \leq x < \frac{1}{n}, \\ 0, & \text{otherwise on } [0, 1]. \end{cases}$$

Each h_n is integrable over E . It is a simple function taking finitely many values on measurable sets of finite measure, and

$$\int_E |h_n| = n \cdot \frac{1}{2n} + n \cdot \frac{1}{2n} = 1 < \infty.$$

$\{h_n\} \rightarrow 0$ pointwise on E . We have $h_n(0) = 0$ for every n . If $0 < x \leq 1$, choose N with $1/N < x$ (Archimedean property); then for all $n \geq N$ we have $x \geq 1/N > 1/n$, hence $h_n(x) = 0$. So $h_n(x) \rightarrow 0$ for every $x \in [0, 1]$; in particular the convergence holds a.e. on E , and $h \equiv 0$.

$\lim_{n \rightarrow \infty} \int_E h_n = 0$. By the linearity of integration, for every n ,

$$\int_E h_n = n \cdot m((0, \frac{1}{2n})) - n \cdot m([\frac{1}{2n}, \frac{1}{n})) = n \cdot \frac{1}{2n} - n \cdot \frac{1}{2n} = 0.$$

Hence $\int_E h_n = 0$ for every n and the limit is 0. The positive and negative parts cancel exactly; this is what the sign restriction in Theorem 26 was preventing.

$\{h_n\}$ is not uniformly integrable over E . Take the ϵ challenge $\epsilon = 1/2$ and let $\delta > 0$ be arbitrary. Choose n so large that $1/(2n) < \delta$, and set

$$A_n = \left(0, \frac{1}{2n}\right) \subseteq E, \quad m(A_n) = \frac{1}{2n} < \delta.$$

Then

$$\int_{A_n} |h_n| = n \cdot \frac{1}{2n} = \frac{1}{2} \not\leq \epsilon.$$

So no $\delta > 0$ responds to the challenge $\epsilon = 1/2$ in criterion (27), and $\{h_n\}$ fails to be uniformly integrable over E .

Thus E has finite measure, each h_n is integrable over E , $\{h_n\} \rightarrow 0$ pointwise on E , and $\lim_{n \rightarrow \infty} \int_E h_n = 0$, yet $\{h_n\}$ is not uniformly integrable. Theorem 26 is therefore false without the assumption that the h_n are nonnegative.

Remark on where the proof breaks. In Royden's proof of the converse direction, from $\lim_{n \rightarrow \infty} \int_E h_n = 0$ one chooses N with $\int_E h_n < \epsilon$ for $n \geq N$ and then asserts inequality (30): since $h_n \geq 0$ on E , for any measurable $A \subseteq E$ one has $\int_A h_n \leq \int_E h_n < \epsilon$. It is exactly this monotonicity step that requires $h_n \geq 0$; for the h_n above, $\int_E h_n = 0$ while $\int_{A_n} |h_n| = 1/2$.

4.7 Problems 4.43–4.49

Problem 4.43. Let the sequences of functions $\{f_n\}$ and $\{g_n\}$ be uniformly integrable over E . Show that for any α and β , the sequence of linear combinations $\{\alpha f_n + \beta g_n\}$ also is uniformly integrable over E .

Solution. Recall the definition: a family $\mathcal{F}$ of measurable functions on E is uniformly integrable over E provided for each $\epsilon > 0$ there is a $\delta > 0$ such that for each $f \in \mathcal{F}$,

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta, \text{ then } \int_A |f| < \epsilon.$$

The definition is stated for families of measurable, possibly extended real-valued, functions, so before anything else we must know that the pointwise sum $\alpha f_n + \beta g_n$ is defined a.e. on E . We claim that every member h of a uniformly integrable family on E is finite a.e. on E . Suppose not, so that $S = \{x \in E \mid |h(x)| = \infty\}$ has $m(S) > 0$. Let $\delta > 0$ respond to the $\epsilon = 1$ challenge for the family. The sets $S \cap [-n, n]$ ascend to S , so by the continuity of measure (Theorem 15 of Chapter 2) there is an n with $m(S \cap [-n, n]) > 0$. The function $t \mapsto m(S \cap [-n, t])$ is nondecreasing on $[-n, n]$ and increases by at most $t' - t$ over $[t, t']$, hence is continuous; it equals 0 at $t = -n$ and $m(S \cap [-n, n]) > 0$ at $t = n$. By the Intermediate Value Theorem there is a t for which $A = S \cap [-n, t]$ satisfies $0 < m(A) < \delta$. But $|h| \equiv \infty$ on A and $m(A) > 0$, so $\int_A |h| = \infty$, contradicting $\int_A |h| < 1$. Hence $m(S) = 0$.

Consequently, for each n there is a measurable $A_n \subseteq E$ with $m(E \setminus A_n) = 0$ on which both f_n and g_n are finite and on which $\alpha f_n + \beta g_n$ is therefore defined. As in the convention adopted in Section 4.4, the integral of $\alpha f_n + \beta g_n$ over a measurable $A \subseteq E$ means its integral over $A \cap A_n$; this is unambiguous, since the integral of a nonnegative measurable function over a set of measure zero is 0 (immediately from the definition of that integral as a supremum) and so, by the additivity of integration over domains (Theorem 11), excising the null set $E \setminus A_n$ changes nothing. Wherever it is defined we have the pointwise triangle inequality

$$|\alpha f_n + \beta g_n| \leq |\alpha| |f_n| + |\beta| |g_n|.$$

Now set

$$M = |\alpha| + |\beta| + 1 > 0.$$

Let $\epsilon > 0$. Since $\{f_n\}$ is uniformly integrable over E , there is a $\delta_1 > 0$ such that

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta_1, \text{ then } \int_A |f_n| < \frac{\epsilon}{2M} \quad \text{for all } n.$$

Since $\{g_n\}$ is uniformly integrable over E , there is a $\delta_2 > 0$ such that

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta_2, \text{ then } \int_A |g_n| < \frac{\epsilon}{2M} \quad \text{for all } n.$$

Define $\delta = \min\{\delta_1, \delta_2\} > 0$.

Let $A \subseteq E$ be measurable with $m(A) < \delta$ and let n be a natural number. Since $m(A) < \delta_1$ and $m(A) < \delta_2$, the monotonicity and linearity of integration for nonnegative measurable functions (Theorem 10) together with the pointwise inequality above give

$$\int_A |\alpha f_n + \beta g_n| \leq \int_A (|\alpha| |f_n| + |\beta| |g_n|) = |\alpha| \int_A |f_n| + |\beta| \int_A |g_n| \leq M \int_A |f_n| + M \int_A |g_n| < M \cdot \frac{\epsilon}{2M} + M \cdot \frac{\epsilon}{2M} = \epsilon.$$

Here we used $|\alpha| \leq M$ and $|\beta| \leq M$, and the final inequality is strict because $M > 0$ and both of the last two integrals are strictly less than $\epsilon/(2M)$.

Since δ was chosen independently of n and of A , this δ responds to the ϵ challenge for the sequence $\{\alpha f_n + \beta g_n\}$. Therefore $\{\alpha f_n + \beta g_n\}$ is uniformly integrable over E .

Problem 4.44. Let f be integrable over $\mathbb{R}$ and $\epsilon > 0$. Establish the following three approximation properties.

- (i) There is a simple function η on $\mathbb{R}$ which has finite support and $\int_{\mathbb{R}} |f - \eta| < \epsilon$. (Hint: First verify this if f is nonnegative.)
- (ii) There is a step function s on $\mathbb{R}$ which vanishes outside a closed, bounded interval and $\int_{\mathbb{R}} |f - s| < \epsilon$. (Hint: Apply part (i) and Problem 18 of Chapter 3.)
- (iii) There is a continuous function g on $\mathbb{R}$ which vanishes outside a bounded set and $\int_{\mathbb{R}} |f - g| < \epsilon$.

Solution. Throughout, “finite support” means vanishing outside a set of finite measure.

(i) First assume $f \geq 0$ on $\mathbb{R}$. By the definition of the integral of a nonnegative measurable function,

$$\int_{\mathbb{R}} f = \sup \left\{ \int_{\mathbb{R}} h \mid h \text{ bounded, measurable, of finite support, } 0 \leq h \leq f \text{ on } \mathbb{R} \right\},$$

and this supremum is finite since f is integrable. Hence there is a bounded measurable function h of finite support with $0 \leq h \leq f$ on $\mathbb{R}$ and

$$\int_{\mathbb{R}} f - \frac{\epsilon}{2} < \int_{\mathbb{R}} h \leq \int_{\mathbb{R}} f.$$

The function $f - h$ is nonnegative and measurable, and by the linearity of integration for nonnegative measurable functions (Theorem 10), $\int_{\mathbb{R}} h + \int_{\mathbb{R}} (f - h) = \int_{\mathbb{R}} f$. Since $\int_{\mathbb{R}} h$ is finite,

$$\int_{\mathbb{R}} |f - h| = \int_{\mathbb{R}} (f - h) = \int_{\mathbb{R}} f - \int_{\mathbb{R}} h < \frac{\epsilon}{2}.$$

Let E_0 be a measurable set of finite measure outside of which h vanishes, and choose $M > 0$ with $0 \leq h \leq M$ on $\mathbb{R}$. If $m(E_0) = 0$ then $h = 0$ a.e. and we may take $\eta = 0$; so assume $m(E_0) > 0$. Apply the Simple Approximation Lemma to the bounded measurable function h restricted to E_0 , with the challenge $\epsilon' = \epsilon/(2m(E_0) + 1)$: there are simple functions $\varphi \leq h \leq \psi$ on E_0 with $0 \leq \psi - \varphi < \epsilon'$ on E_0 ; in particular $|h - \varphi| < \epsilon'$ on E_0 . Replacing φ by $\max\{\varphi, 0\}$ (still simple, and still within ϵ' of h since $h \geq 0$), we may assume $\varphi \geq 0$. Define η on $\mathbb{R}$ by $\eta = \varphi$ on E_0 and $\eta = 0$ on $\mathbb{R} \setminus E_0$. Then η is a simple function on $\mathbb{R}$ vanishing outside the set E_0 of finite measure, so η has finite support, and by the monotonicity of integration together with additivity over domains,

$$\int_{\mathbb{R}} |h - \eta| = \int_{E_0} |h - \varphi| \leq \epsilon' \cdot m(E_0) < \frac{\epsilon}{2}.$$

Therefore, by the triangle inequality $|f - \eta| \leq |f - h| + |h - \eta|$ and the monotonicity and linearity of integration,

$$\int_{\mathbb{R}} |f - \eta| \leq \int_{\mathbb{R}} |f - h| + \int_{\mathbb{R}} |h - \eta| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Now the general case. Write $f = f^+ - f^-$. By Proposition 14 both f^+ and f^- are nonnegative and integrable over $\mathbb{R}$. By the case just settled, there are simple functions η_1, η_2 on $\mathbb{R}$ of finite support with

$$\int_{\mathbb{R}} |f^+ - \eta_1| < \frac{\epsilon}{2}, \quad \int_{\mathbb{R}} |f^- - \eta_2| < \frac{\epsilon}{2}.$$

Set $\eta = \eta_1 - \eta_2$. A difference of simple functions is simple (Problem 19 of Chapter 3), and η vanishes outside the union of two sets of finite measure, so η has finite support. By Proposition 15, f is finite a.e. on $\mathbb{R}$; at every point where f is finite,

$$|f - \eta| = |(f^+ - \eta_1) - (f^- - \eta_2)| \leq |f^+ - \eta_1| + |f^- - \eta_2|.$$

Since a set of measure zero does not affect an integral (Proposition 15), monotonicity and linearity give

$$\int_{\mathbb{R}} |f - \eta| \leq \int_{\mathbb{R}} |f^+ - \eta_1| + \int_{\mathbb{R}} |f^- - \eta_2| < \epsilon.$$

(ii) By part (i) choose a simple function η on $\mathbb{R}$ of finite support with $\int_{\mathbb{R}} |f - \eta| < \epsilon/2$. Write $\eta = \sum_{k=1}^p a_k \chi_{E_k}$ with the E_k disjoint measurable sets and $a_k \neq 0$; since η has finite support, $m(E_k) < \infty$ for each k . For each k , the sets $E_k \sim [-N, N]$ descend to $\bigcap_N (E_k \sim [-N, N]) = \emptyset$ as $N \rightarrow \infty$ and $m(E_k) < \infty$, so by the continuity of measure $m(E_k \sim [-N, N]) \rightarrow 0$. Choose a natural number N so large that

$$\sum_{k=1}^p |a_k| \cdot m(E_k \sim [-N, N]) < \frac{\epsilon}{4}.$$

Put $I = [-N, N]$ and $\eta' = \eta \cdot \chi_I$. Then η' is simple, vanishes outside I , and

$$\int_{\mathbb{R}} |\eta - \eta'| = \int_{\mathbb{R} \sim I} |\eta| \leq \sum_{k=1}^p |a_k| \cdot m(E_k \sim I) < \frac{\epsilon}{4}.$$

Let $M = \max_k |a_k|$, so $|\eta'| \leq M$ on $\mathbb{R}$. Let $\epsilon' > 0$ be a number to be fixed presently. The restriction of η' to the closed, bounded interval I is a bounded measurable function, so by Problem 18 of Chapter 3 there is a step function h on I and a measurable subset $F \subseteq I$ for which

$$|h - \eta'| < \epsilon' \text{ on } F \quad \text{and} \quad m(I \sim F) < \epsilon'.$$

Replace h by its truncation $\tilde{h} = \min\{\max\{h, -M\}, M\}$. Truncating a step function at the levels $\pm M$ again yields a step function on I , and since $|\eta'| \leq M$, truncation does not increase the distance to η' : $|\tilde{h} - \eta'| \leq |h - \eta'|$ pointwise on I . Thus $|\tilde{h} - \eta'| < \epsilon'$ on F and $|\tilde{h} - \eta'| \leq 2M$ on all of I . Consequently, by additivity over domains and monotonicity,

$$\int_I |\eta' - \tilde{h}| = \int_F |\eta' - \tilde{h}| + \int_{I \sim F} |\eta' - \tilde{h}| \leq \epsilon' \cdot m(I) + 2M \cdot \epsilon' = \epsilon' (2N + 2M).$$

Choose $\epsilon' > 0$ small enough that $\epsilon' (2N + 2M) < \epsilon/4$.

Define s on $\mathbb{R}$ by $s = \tilde{h}$ on I and $s = 0$ on $\mathbb{R} \sim I$. Then s is a step function on $\mathbb{R}$ (adjoin the two unbounded complementary intervals to the partition) which vanishes outside the closed, bounded interval I , and since η' also vanishes outside I ,

$$\int_{\mathbb{R}} |\eta' - s| = \int_I |\eta' - \tilde{h}| < \frac{\epsilon}{4}.$$

Adding the three estimates,

$$\int_{\mathbb{R}} |f - s| \leq \int_{\mathbb{R}} |f - \eta| + \int_{\mathbb{R}} |\eta - \eta'| + \int_{\mathbb{R}} |\eta' - s| < \frac{\epsilon}{2} + \frac{\epsilon}{4} + \frac{\epsilon}{4} = \epsilon.$$

(iii) By part (ii) choose a step function s vanishing outside a closed, bounded interval $[a, b]$ with $\int_{\mathbb{R}} |f - s| < \epsilon/2$. Let

$$a = x_0 < x_1 < \cdots < x_n = b$$

be a partition of $[a, b]$ such that s is constant, say $s \equiv c_i$, on the open interval (x_{i-1}, x_i) for $1 \leq i \leq n$. Let $M = \max_i |c_i|$ (if $M = 0$ then $s = 0$ a.e. and $g \equiv 0$ works, so assume $M > 0$).

Let $\sigma > 0$ satisfy

$$\sigma < \min_{1 \leq i \leq n} (x_i - x_{i-1}) \quad \text{and} \quad 2M(n+1)\sigma < \frac{\epsilon}{2}.$$

Define $g : \mathbb{R} \rightarrow \mathbb{R}$ as follows. Let $J_i = (x_i - \sigma/2, x_i + \sigma/2)$ for $0 \leq i \leq n$; by the choice of σ these $n+1$ intervals are pairwise disjoint. Outside $\bigcup_{i=0}^n J_i$ set g equal to the value c_i on each $(x_{i-1}, x_i) \sim (J_{i-1} \cup J_i)$ and equal to 0 outside $[a, b]$. On each J_i define g to be the affine function joining the value of g at the left endpoint $x_i - \sigma/2$ to its value at the right endpoint $x_i + \sigma/2$ (these two one-sided values are the constants just prescribed; for $i = 0$ the left value is 0 and for $i = n$ the right value is 0). Then g is continuous on $\mathbb{R}$: it is locally constant off the closed intervals $\overline{J_i}$, affine on each J_i , and the definitions agree at the endpoints of each J_i . Moreover g vanishes outside the bounded set $[a - \sigma, b + \sigma]$, and $|g| \leq M$ everywhere, since on each J_i it is a convex combination of two values of modulus at most M . By construction $g = s$ except possibly on $\bigcup_{i=0}^n \overline{J_i}$, a set of measure $(n+1)\sigma$, and $|g - s| \leq 2M$ everywhere. Hence

$$\int_{\mathbb{R}} |s - g| \leq 2M \cdot (n+1)\sigma < \frac{\epsilon}{2}.$$

Therefore

$$\int_{\mathbb{R}} |f - g| \leq \int_{\mathbb{R}} |f - s| + \int_{\mathbb{R}} |s - g| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon,$$

and g is continuous on $\mathbb{R}$ and vanishes outside a bounded set.

Problem 4.45. Let f be integrable over E . Define $\hat{f}$ to be the extension of f to all of $\mathbb{R}$ obtained by setting $\hat{f} = 0$ outside of E . Show that $\hat{f}$ is integrable over $\mathbb{R}$ and $\int_E f = \int_{\mathbb{R}} \hat{f}$. Use this and part (i) and (iii) of the preceding problem to show that for $\epsilon > 0$, there is a simple function η on E and a continuous function g on E for which $\int_E |f - \eta| < \epsilon$ and $\int_E |f - g| < \epsilon$.

Solution. Measurability of $\hat{f}$. For $c \geq 0$,

$$\{x \in \mathbb{R} \mid \hat{f}(x) > c\} = \{x \in E \mid f(x) > c\},$$

while for $c < 0$,

$$\{x \in \mathbb{R} \mid \hat{f}(x) > c\} = \{x \in E \mid f(x) > c\} \cup (\mathbb{R} \sim E).$$

In both cases the set is measurable, since f is measurable on the measurable set E and $\mathbb{R} \sim E$ is measurable. Hence $\hat{f}$ is measurable on $\mathbb{R}$.

Next suppose first that $f \geq 0$ on E , so that $\hat{f} \geq 0$ on $\mathbb{R}$. We claim

$$\int_{\mathbb{R}} \hat{f} = \int_E f.$$

Let h be bounded, measurable, of finite support on $\mathbb{R}$ with $0 \leq h \leq \hat{f}$ on $\mathbb{R}$. Since $\hat{f} = 0$ on $\mathbb{R} \sim E$ and $h \geq 0$, we get $h = 0$ on $\mathbb{R} \sim E$. Since h is nonnegative and measurable, the additivity of integration over domains (Theorem 11) applies and gives

$$\int_{\mathbb{R}} h = \int_E h + \int_{\mathbb{R} \sim E} h = \int_E h.$$

The restriction of h to E is bounded, measurable, of finite support, and satisfies $0 \leq h \leq f$ on E ; therefore, by the definition of $\int_E f$ as a supremum, $\int_{\mathbb{R}} h = \int_E h \leq \int_E f$. Taking the supremum over all such h gives $\int_{\mathbb{R}} \hat{f} \leq \int_E f$.

Conversely, let h be bounded, measurable, of finite support on E with $0 \leq h \leq f$ on E , and let $\hat{h}$ be its extension by 0 to $\mathbb{R}$. Then $\hat{h}$ is bounded, measurable (by the same argument as for $\hat{f}$), of finite support, and $0 \leq \hat{h} \leq \hat{f}$ on $\mathbb{R}$. Again by additivity over domains, $\int_E h = \int_{\mathbb{R}} \hat{h} \leq \int_{\mathbb{R}} \hat{f}$. Taking the supremum over all such h gives $\int_E f \leq \int_{\mathbb{R}} \hat{f}$. The two inequalities give the claimed equality for nonnegative f .

For general integrable f over E , observe that

$$(\hat{f})^+ = \widehat{f^+}, \quad (\hat{f})^- = \widehat{f^-}, \quad |\hat{f}| = \widehat{|f|}.$$

Applying the nonnegative case to $|f|$ gives $\int_{\mathbb{R}} |\hat{f}| = \int_E |f| < \infty$, so $\hat{f}$ is integrable over $\mathbb{R}$. Applying it to f^+ and to f^- and using the definition of the general integral,

$$\int_{\mathbb{R}} \hat{f} = \int_{\mathbb{R}} (\hat{f})^+ - \int_{\mathbb{R}} (\hat{f})^- = \int_E f^+ - \int_E f^- = \int_E f.$$

Now let $\epsilon > 0$. Since $\hat{f}$ is integrable over $\mathbb{R}$, part (i) of the preceding problem provides a simple function $\tilde{\eta}$ on $\mathbb{R}$ of finite support with

$$\int_{\mathbb{R}} |\hat{f} - \tilde{\eta}| < \epsilon.$$

Let η be the restriction of $\tilde{\eta}$ to E . The restriction of a simple function to a measurable subset is a simple function on that subset, so η is simple on E . Since $|\hat{f} - \tilde{\eta}|$ is nonnegative and $\hat{f} = f$ on E , the monotonicity together with the additivity over domains of integration for nonnegative functions gives

$$\int_E |f - \eta| = \int_E |\hat{f} - \tilde{\eta}| \leq \int_E |\hat{f} - \tilde{\eta}| + \int_{\mathbb{R} \sim E} |\hat{f} - \tilde{\eta}| = \int_{\mathbb{R}} |\hat{f} - \tilde{\eta}| < \epsilon.$$

Similarly, part (iii) of the preceding problem provides a function $\tilde{g}$ that is continuous on $\mathbb{R}$ and vanishes outside a bounded set, with $\int_{\mathbb{R}} |\hat{f} - \tilde{g}| < \epsilon$. Let g be the restriction of $\tilde{g}$ to E ; a restriction of a continuous function is continuous on its domain, so g is continuous on E , and exactly as above

$$\int_E |f - g| = \int_E |\hat{f} - \tilde{g}| \leq \int_{\mathbb{R}} |\hat{f} - \tilde{g}| < \epsilon.$$

This is what was to be shown.

Problem 4.46. (Riemann-Lebesgue) Let f be integrable over $(-\infty, \infty)$. Show that

$$\lim_{n \rightarrow \infty} \int_{-\infty}^{\infty} f(x) \cos nx \, dx = 0.$$

(Hint: First show this for f a step function that vanishes outside a closed, bounded interval and then use the approximation property (ii) of Problem 44.)

Solution. First note that for each natural number n the function $x \mapsto f(x) \cos nx$ is measurable on $\mathbb{R}$. Indeed, f is integrable, hence finite a.e. on $\mathbb{R}$ by Proposition 15, while $x \mapsto \cos nx$ is continuous and therefore measurable (Proposition 3 of Chapter 3); by Theorem 6 of Chapter 3 the product of two measurable functions that are finite a.e. is measurable off the null set where f fails to be finite, and hence, by Proposition 5 of Chapter 3 together with the completeness of Lebesgue measure, it is measurable on all of $\mathbb{R}$ however it is defined on that null set. Moreover

$$|f(x) \cos nx| \leq |f(x)| \quad \text{for all } x.$$

Since $|f|$ is integrable over $\mathbb{R}$, the Integral Comparison Test (Proposition 16) shows that $f(x) \cos nx$ is integrable over $\mathbb{R}$ and that all the integrals below are finite.

Step 1: the case of a step function. Let s be a step function on $\mathbb{R}$ that vanishes outside a closed, bounded interval $[a, b]$, and let

$$a = x_0 < x_1 < \cdots < x_p = b$$

be a partition of $[a, b]$ with $s \equiv c_i$ on (x_{i-1}, x_i) for $1 \leq i \leq p$. The finite set of partition points has measure zero, so it does not affect any integral (Proposition 15); hence for each n , by the additivity over domains and the linearity of integration,

$$\int_{-\infty}^{\infty} s(x) \cos nx \, dx = \sum_{i=1}^p c_i \int_{x_{i-1}}^{x_i} \cos nx \, dx.$$

On each bounded interval the integrand is continuous, so the Lebesgue integral agrees with the Riemann integral (Theorem 3 of this chapter), and for $n \geq 1$,

$$\int_{x_{i-1}}^{x_i} \cos nx \, dx = \frac{\sin nx_i - \sin nx_{i-1}}{n}, \quad \left| \int_{x_{i-1}}^{x_i} \cos nx \, dx \right| \leq \frac{2}{n}.$$

Therefore

$$\left| \int_{-\infty}^{\infty} s(x) \cos nx \, dx \right| \leq \frac{2}{n} \sum_{i=1}^p |c_i| \longrightarrow 0 \quad \text{as } n \rightarrow \infty.$$

Thus the assertion holds for such step functions.

Step 2: the general case. Let $\epsilon > 0$. Since f is integrable over $\mathbb{R}$, by the approximation property (ii) of Problem 44 there is a step function s on $\mathbb{R}$ which vanishes outside a closed, bounded interval and satisfies

$$\int_{\mathbb{R}} |f - s| < \frac{\epsilon}{2}.$$

(The function s is bounded and vanishes outside a set of finite measure, hence is integrable over $\mathbb{R}$; so $f - s$ is integrable and the following manipulations are legitimate by Theorem 17.) For each n , by the linearity of integration and the Integral Comparison Test,

$$\left| \int_{\mathbb{R}} f(x) \cos nx \, dx - \int_{\mathbb{R}} s(x) \cos nx \, dx \right| = \left| \int_{\mathbb{R}} (f(x) - s(x)) \cos nx \, dx \right| \leq \int_{\mathbb{R}} |f - s| \cdot |\cos nx| \leq \int_{\mathbb{R}} |f - s| < \frac{\epsilon}{2},$$

where we used $|\cos nx| \leq 1$ and the monotonicity of integration for nonnegative functions.

By Step 1 there is a natural number N such that

$$\left| \int_{\mathbb{R}} s(x) \cos nx \, dx \right| < \frac{\epsilon}{2} \quad \text{for all } n \geq N.$$

Hence for $n \geq N$,

$$\left| \int_{-\infty}^{\infty} f(x) \cos nx \, dx \right| \leq \left| \int_{\mathbb{R}} (f - s)(x) \cos nx \, dx \right| + \left| \int_{\mathbb{R}} s(x) \cos nx \, dx \right| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Since $\epsilon > 0$ was arbitrary,

$$\lim_{n \rightarrow \infty} \int_{-\infty}^{\infty} f(x) \cos nx \, dx = 0.$$

Problem 4.47. Let f be integrable over $(-\infty, \infty)$.

- (i) Show that for each t ,

$$\int_{-\infty}^{\infty} f(x) \, dx = \int_{-\infty}^{\infty} f(x + t) \, dx.$$

- (ii) Let g be a bounded measurable function on $\mathbb{R}$. Show that

$$\lim_{t \rightarrow 0} \int_{-\infty}^{\infty} g(x) \cdot [f(x) - f(x + t)] \, dx = 0.$$

(Hint: First show this, using uniform continuity of f on $\mathbb{R}$, if f is continuous and vanishes outside a bounded set. Then use the approximation property (iii) of Problem 44.)

Solution. For a function h on $\mathbb{R}$ and a number t , write $h_t(x) = h(x + t)$.

- (i) First, f_t is measurable: for each c ,

$$\{x \mid f_t(x) > c\} = \{x \mid f(x + t) > c\} = \{y \mid f(y) > c\} - t,$$

which is measurable by Proposition 10 of Chapter 2 (the translate of a measurable set is measurable).

Now suppose first that $f \geq 0$ on $\mathbb{R}$. We claim

$$\int_{\mathbb{R}} f = \int_{\mathbb{R}} f_t.$$

Consider the map $h \mapsto h_t$. If h is bounded, measurable, of finite support, and $0 \leq h \leq f$ on $\mathbb{R}$, then h_t is bounded, measurable (same argument as above), and vanishes outside $E_0 - t$ where h vanishes outside the finite-measure set E_0 ; since Lebesgue measure is translation invariant (Theorem 14 of Chapter 2), $m(E_0 - t) = m(E_0) < \infty$, so h_t has finite support. Also $0 \leq h_t \leq f_t$ on $\mathbb{R}$. Moreover $\int_{\mathbb{R}} h = \int_{\mathbb{R}} h_t$. Indeed, for a simple function $\varphi = \sum_{k=1}^p a_k \chi_{E_k}$ with the E_k of finite measure we have $\varphi_t = \sum_{k=1}^p a_k \chi_{E_k - t}$, so by the translation invariance of measure $\int_{\mathbb{R}} \varphi = \sum_k a_k m(E_k) = \sum_k a_k m(E_k - t) = \int_{\mathbb{R}} \varphi_t$; and the integral of a bounded measurable function of finite support over a set of finite measure is, by definition, the common value of the infimum of integrals of simple functions above it and the supremum of integrals of simple functions below it, and $\varphi \leq h$ on $\mathbb{R}$ if and only if $\varphi_t \leq h_t$ on $\mathbb{R}$. Hence $\int_{\mathbb{R}} h = \int_{\mathbb{R}} h_t$.

The map $h \mapsto h_t$ is a bijection of the family of bounded measurable functions of finite support lying between 0 and f onto the corresponding family for f_t (its inverse is $k \mapsto k_{-t}$). Since it preserves integrals, the two suprema in the definition of $\int_{\mathbb{R}} f$ and $\int_{\mathbb{R}} f_t$ coincide:

$$\int_{\mathbb{R}} f = \int_{\mathbb{R}} f_t \quad (f \geq 0).$$

For general integrable f , note $(f_t)^+ = (f^+)_t$ and $(f_t)^- = (f^-)_t$, and likewise $|f_t| = |f|_t$. Applying the nonnegative case to $|f|$ shows f_t is integrable over $\mathbb{R}$, and applying it to f^+ and f^- gives

$$\int_{-\infty}^{\infty} f(x+t) dx = \int_{\mathbb{R}} (f^+)_t - \int_{\mathbb{R}} (f^-)_t = \int_{\mathbb{R}} f^+ - \int_{\mathbb{R}} f^- = \int_{-\infty}^{\infty} f(x) dx.$$

(ii) Let $M > 0$ be such that $|g| \leq M$ on $\mathbb{R}$. By part (i), f_t is integrable over $\mathbb{R}$ for every t , hence $f - f_t$ is integrable (Theorem 17), and since g is bounded and measurable, $g \cdot (f - f_t)$ is integrable over $\mathbb{R}$ by Problem 48. Moreover, by the Integral Comparison Test,

$$\left| \int_{\mathbb{R}} g \cdot [f - f_t] \right| \leq M \int_{\mathbb{R}} |f - f_t|.$$

Call this estimate (*); the same reasoning bounds $\left| \int_{\mathbb{R}} g \cdot u \right|$ by $M \int_{\mathbb{R}} |u|$ for any function u integrable over $\mathbb{R}$.

Case 1: f continuous on $\mathbb{R}$ and vanishing outside a bounded set. Say $f = 0$ outside $[-N, N]$. Then f is continuous on the compact interval $[-N-1, N+1]$ and vanishes on a neighbourhood of each of its endpoints, from which it follows that f is uniformly continuous on all of $\mathbb{R}$. (Explicitly: f is uniformly continuous on the compact set $[-N-1, N+1]$; f is identically 0 off $[-N, N]$; combining the two, given $\epsilon' > 0$ pick $\delta' \in (0, 1)$ that works for uniform continuity on $[-N-1, N+1]$, and note that if $|x-y| < \delta'$ and not both x, y lie in $[-N-1, N+1]$, then both lie outside $[-N, N]$, so $f(x) = f(y) = 0$.)

Let $\epsilon > 0$. Choose $\delta \in (0, 1)$ such that

$$|f(x) - f(y)| < \frac{\epsilon}{M(2N+2)+1} \quad \text{whenever } |x-y| < \delta.$$

Let $|t| < \delta$. If $|x| > N+1$ then $|x+t| > N$ as well, so $f(x) - f(x+t) = 0$. Hence $f - f_t$ vanishes outside $[-N-1, N+1]$, a set of measure $2N+2$, and $|f - f_t| < \epsilon/(M(2N+2)+1)$ everywhere. By monotonicity of integration and (*),

$$\left| \int_{\mathbb{R}} g \cdot [f - f_t] \right| \leq M \int_{[-N-1, N+1]} |f - f_t| \leq M \cdot (2N+2) \cdot \frac{\epsilon}{M(2N+2)+1} < \epsilon.$$

Thus the limit is 0 in this case.

Case 2: general integrable f . Let $\epsilon > 0$. By the approximation property (iii) of Problem 44 there is a function h , continuous on $\mathbb{R}$ and vanishing outside a bounded set, with

$$\int_{\mathbb{R}} |f - h| < \frac{\epsilon}{3(M+1)}.$$

For any t , decompose (all four functions being integrable, by part (i), Theorem 17 and Problem 48)

$$\int_{\mathbb{R}} g \cdot [f - f_t] = \int_{\mathbb{R}} g \cdot [f - h] + \int_{\mathbb{R}} g \cdot [h - h_t] + \int_{\mathbb{R}} g \cdot [h_t - f_t].$$

The first term is bounded, by $(*)$ -type estimation, by $M \int_{\mathbb{R}} |f - h| < \epsilon/3$. For the third term, note $|h_t - f_t| = |h - f|_t$, so by part (i) applied to the integrable nonnegative function $|h - f|$,

$$\left| \int_{\mathbb{R}} g \cdot [h_t - f_t] \right| \leq M \int_{\mathbb{R}} |h - f|_t = M \int_{\mathbb{R}} |h - f| < \frac{\epsilon}{3}.$$

By Case 1 applied to h , there is a $\delta > 0$ such that

$$\left| \int_{\mathbb{R}} g \cdot [h - h_t] \right| < \frac{\epsilon}{3} \quad \text{whenever } |t| < \delta.$$

Therefore, for $0 < |t| < \delta$,

$$\left| \int_{-\infty}^{\infty} g(x) \cdot [f(x) - f(x+t)] dx \right| < \frac{\epsilon}{3} + \frac{\epsilon}{3} + \frac{\epsilon}{3} = \epsilon.$$

Since $\epsilon > 0$ was arbitrary, the limit is 0.

Problem 4.48. Let f be integrable over E and g be a bounded measurable function on E . Show that $f \cdot g$ is integrable over E .

Solution. Choose $M \geq 0$ with $|g| \leq M$ on E .

First we check that $f \cdot g$ is measurable on E . Since f is integrable over E , Proposition 15 tells us that f is finite a.e. on E ; let

$$E_0 = \{x \in E \mid |f(x)| = \infty\},$$

so $m(E_0) = 0$. On $E \sim E_0$ both f and g are real-valued measurable functions, so their product $f \cdot g$ is measurable on $E \sim E_0$ by Theorem 6 of Chapter 3. Since Lebesgue measure is complete, a function on E that agrees with a measurable function outside a set of measure zero is measurable on E (Proposition 5 of Chapter 3); as $f \cdot g$ restricted to $E \sim E_0$ is measurable and $m(E_0) = 0$, $f \cdot g$ is measurable on E whatever convention is used for the product at points of E_0 .

Next, at every point of E ,

$$|f \cdot g| = |f| \cdot |g| \leq M \cdot |f|.$$

The function $M|f|$ is nonnegative and, by the linearity of integration (Theorem 17, or Theorem 10 for nonnegative functions), integrable over E with $\int_E M|f| = M \int_E |f| < \infty$. Thus $M|f|$ is a nonnegative integrable function on E that dominates $f \cdot g$ in the sense of the Integral Comparison Test.

By the Integral Comparison Test (Proposition 16), $f \cdot g$ is integrable over E and

$$\left| \int_E f \cdot g \right| \leq \int_E |f \cdot g| \leq M \int_E |f|.$$

Problem 4.49. Let f be integrable over $\mathbb{R}$. Show that the following four assertions are equivalent:

- (i) $f = 0$ a.e. on $\mathbb{R}$.
- (ii) $\int_{\mathbb{R}} fg = 0$ for every bounded measurable function g on $\mathbb{R}$.
- (iii) $\int_A f = 0$ for every measurable set A .
- (iv) $\int_{\mathcal{O}} f = 0$ for every open set $\mathcal{O}$.

Solution. We prove (i) $\Rightarrow$ (ii) $\Rightarrow$ (iii) $\Rightarrow$ (iv) $\Rightarrow$ (i).

We use repeatedly the following consequence of Proposition 15: if h is integrable over a measurable set B and $h = 0$ a.e. on B , then $\int_B h = 0$. Indeed, letting $B_0 = \{x \in B \mid h(x) \neq 0\}$, we have $m(B_0) = 0$, so

by Proposition 15, $\int_B h = \int_{B \sim B_0} h = 0$, the last integral vanishing because its integrand is identically 0.

(i) $\Rightarrow$ (ii). Let g be a bounded measurable function on $\mathbb{R}$. By Problem 48, fg is integrable over $\mathbb{R}$. Since $f = 0$ a.e. on $\mathbb{R}$, also $fg = 0$ a.e. on $\mathbb{R}$, and therefore $\int_{\mathbb{R}} fg = 0$ by the remark above.

(ii) $\Rightarrow$ (iii). Let A be a measurable set. The characteristic function χ_A is measurable and bounded (by 1) on $\mathbb{R}$, so by hypothesis $\int_{\mathbb{R}} f\chi_A = 0$. On the other hand $f\chi_A$ is integrable over $\mathbb{R}$ (Problem 48), $f\chi_A = f$ on A and $f\chi_A = 0$ on $\mathbb{R} \sim A$; hence, by the additivity of integration over domains (Corollary 18),

$$\int_{\mathbb{R}} f\chi_A = \int_A f\chi_A + \int_{\mathbb{R} \sim A} f\chi_A = \int_A f + 0 = \int_A f.$$

Therefore $\int_A f = 0$.

(iii) $\Rightarrow$ (iv). Every open subset $\mathcal{O}$ of $\mathbb{R}$ is measurable, so this is immediate.

(iv) $\Rightarrow$ (i). Assume $\int_{\mathcal{O}} f = 0$ for every open set $\mathcal{O}$.

Step 1: $\int_A f = 0$ for every measurable set A of finite measure. Let A be such a set and let $\epsilon > 0$. Since f is integrable over $\mathbb{R}$, Proposition 23 provides a $\delta > 0$ such that

$$\text{if } B \subseteq \mathbb{R} \text{ is measurable and } m(B) < \delta, \text{ then } \int_B |f| < \epsilon.$$

By assertion (i) of Theorem 11 of Chapter 2 (outer approximation by open sets), there is an open set $\mathcal{O}$ containing A with $m(\mathcal{O} \sim A) < \delta$. Note that f is integrable over every measurable subset B of $\mathbb{R}$: by the additivity of integration over domains for nonnegative measurable functions (Theorem 11), $\int_{\mathbb{R}} |f| = \int_B |f| + \int_{\mathbb{R} \sim B} |f| \geq \int_B |f|$, so $\int_B |f| < \infty$ and the Integral Comparison Test applies. Hence, applying the additivity of integration over domains (Corollary 18) to the disjoint decomposition $\mathcal{O} = A \cup (\mathcal{O} \sim A)$,

$$\int_A f = \int_{\mathcal{O}} f - \int_{\mathcal{O} \sim A} f = 0 - \int_{\mathcal{O} \sim A} f.$$

By the Integral Comparison Test and the choice of δ ,

$$\left| \int_A f \right| = \left| \int_{\mathcal{O} \sim A} f \right| \leq \int_{\mathcal{O} \sim A} |f| < \epsilon.$$

As $\epsilon > 0$ was arbitrary, $\int_A f = 0$.

Step 2: $f = 0$ a.e. Let

$$A^+ = \{x \in \mathbb{R} \mid f(x) > 0\}, \quad A^- = \{x \in \mathbb{R} \mid f(x) < 0\}.$$

For natural numbers n put

$$A_n^+ = \left\{ x \in (-n, n) \mid f(x) > \frac{1}{n} \right\}.$$

Each A_n^+ is measurable and $m(A_n^+) \leq 2n < \infty$, so by Step 1, $\int_{A_n^+} f = 0$. But $f > 1/n$ on A_n^+ , so by the monotonicity of integration for nonnegative functions,

$$0 = \int_{A_n^+} f \geq \int_{A_n^+} \frac{1}{n} = \frac{1}{n} m(A_n^+) \geq 0.$$

Hence $m(A_n^+) = 0$ for every n . Since

$$A^+ = \bigcup_{n=1}^{\infty} A_n^+$$

(if $f(x) > 0$, choose n with $|x| < n$ and $f(x) > 1/n$, which is possible whether $f(x)$ is finite and positive or $f(x) = \infty$), the countable subadditivity of measure gives $m(A^+) = 0$.

Applying the same argument to $-f$, which also satisfies the hypothesis of (iv) since $\int_{\mathcal{O}} (-f) = -\int_{\mathcal{O}} f = 0$ for every open $\mathcal{O}$, we obtain $m(A^-) = 0$.

Therefore $m(\{x \in \mathbb{R} \mid f(x) \neq 0\}) = m(A^+) + m(A^-) = 0$, that is, $f = 0$ a.e. on $\mathbb{R}$.

This closes the cycle, so the four assertions are equivalent.

4.8 Problems 4.50–4.52

Problem 4.50. Let $\mathcal{F}$ be a family of functions, each of which is integrable over E . Show that $\mathcal{F}$ is uniformly integrable over E if and only if for each $\epsilon > 0$, there is a $\delta > 0$ such that for each $f \in \mathcal{F}$,

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta, \text{ then } \left| \int_A f \right| < \epsilon.$$

Solution. Recall the definition in force: $\mathcal{F}$ is **uniformly integrable over E** provided for each $\epsilon > 0$ there is a $\delta > 0$ such that for each $f \in \mathcal{F}$, if $A \subseteq E$ is measurable and $m(A) < \delta$, then $\int_A |f| < \epsilon$. So the content of the problem is that the absolute value may be moved outside the integral sign in this criterion.

Observe first that each $f \in \mathcal{F}$ is integrable over E , hence integrable over every measurable subset A of E : indeed $|f| \cdot \chi_A \leq |f|$ on E , so $|f|$ is integrable over A by the monotonicity of integration for nonnegative functions, and therefore f is integrable over A by the definition of the general Lebesgue integral. In particular all the integrals written below are finite.

The criterion is necessary. Assume $\mathcal{F}$ is uniformly integrable over E . Let $\epsilon > 0$ and let $\delta > 0$ respond to the ϵ challenge in the definition of uniform integrability. Let $f \in \mathcal{F}$ and let $A \subseteq E$ be measurable with $m(A) < \delta$. Since $-|f| \leq f \leq |f|$ on A , the monotonicity of integration (Theorem 17 of Chapter 4) gives

$$-\int_A |f| \leq \int_A f \leq \int_A |f|,$$

that is, $|\int_A f| \leq \int_A |f| < \epsilon$. Thus the same δ responds to the ϵ challenge in the stated criterion.

The criterion is sufficient. Assume that for each $\epsilon > 0$ there is a $\delta > 0$ such that for every $f \in \mathcal{F}$ and every measurable $A \subseteq E$ with $m(A) < \delta$ we have $|\int_A f| < \epsilon$. Let $\epsilon > 0$ be given and let $\delta > 0$ respond to the challenge $\epsilon/2$ in this criterion. We claim this same δ responds to the ϵ challenge in the definition of uniform integrability.

Indeed, let $f \in \mathcal{F}$ and let $A \subseteq E$ be measurable with $m(A) < \delta$. Since f is measurable, the sets

$$A^+ = \{x \in A \mid f(x) \geq 0\}, \quad A^- = \{x \in A \mid f(x) < 0\}$$

are measurable. They are disjoint, their union is A , and each is a measurable subset of E with

$$m(A^+) \leq m(A) < \delta, \quad m(A^-) \leq m(A) < \delta$$

by the monotonicity of Lebesgue measure. Hence, by the choice of δ ,

$$\left| \int_{A^+} f \right| < \frac{\epsilon}{2}, \quad \left| \int_{A^-} f \right| < \frac{\epsilon}{2}.$$

Now $|f| = f$ on A^+ and $|f| = -f$ on A^- . Since $|f|$ is integrable over E and $A = A^+ \cup A^-$ is a disjoint union of measurable subsets of E , the additivity over domains of integration (Corollary 18 of Chapter 4), applied to $|f|$ and then to f over each piece, yields

$$\int_A |f| = \int_{A^+} |f| + \int_{A^-} |f| = \int_{A^+} f - \int_{A^-} f.$$

But $f \geq 0$ on A^+ forces $\int_{A^+} f \geq 0$, so $\int_{A^+} f = |\int_{A^+} f|$; and $f \leq 0$ on A^- forces $\int_{A^-} f \leq 0$, so $-\int_{A^-} f = |\int_{A^-} f|$. Therefore

$$\int_A |f| = \left| \int_{A^+} f \right| + \left| \int_{A^-} f \right| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Since $f \in \mathcal{F}$ and the measurable set $A \subseteq E$ with $m(A) < \delta$ were arbitrary, $\mathcal{F}$ is uniformly integrable over E .

Problem 4.51. Let $\mathcal{F}$ be a family of functions, each of which is integrable over E . Show that $\mathcal{F}$ is uniformly integrable over E if and only if for each $\epsilon > 0$, there is a $\delta > 0$ such that for all $f \in \mathcal{F}$,

$$\text{if } \mathcal{U} \text{ is open and } m(E \cap \mathcal{U}) < \delta, \text{ then } \int_{E \cap \mathcal{U}} |f| < \epsilon.$$

Solution. Throughout, $\mathcal{F}$ is uniformly integrable over E means: for each $\epsilon > 0$ there is a $\delta > 0$ such that for each $f \in \mathcal{F}$, if $A \subseteq E$ is measurable and $m(A) < \delta$, then $\int_A |f| < \epsilon$. As in the preceding problem, each $f \in \mathcal{F}$ is integrable over every measurable subset of E , so all integrals below are finite. We also use repeatedly the following consequence of the additivity over domains of integration (Corollary 18 of Chapter 4) for the nonnegative integrable function $|f|$: if $A \subseteq B$ are measurable subsets of E , then, writing $B = A \cup (B \sim A)$ as a disjoint union,

$$\int_B |f| = \int_A |f| + \int_{B \sim A} |f| \geq \int_A |f|,$$

since $\int_{B \sim A} |f| \geq 0$ by the monotonicity of integration for nonnegative functions.

The criterion is necessary. Assume $\mathcal{F}$ is uniformly integrable over E , let $\epsilon > 0$, and let $\delta > 0$ respond to the ϵ challenge in the definition. If $\mathcal{U}$ is open and $m(E \cap \mathcal{U}) < \delta$, then $A = E \cap \mathcal{U}$ is a **measurable** subset of E (open sets are measurable, and the intersection of two measurable sets is measurable) of measure less than δ . Hence $\int_{E \cap \mathcal{U}} |f| < \epsilon$ for every $f \in \mathcal{F}$. So the same δ responds to the ϵ challenge in the stated criterion.

The criterion is sufficient. Assume that for each $\epsilon > 0$ there is a $\delta > 0$ such that for all $f \in \mathcal{F}$, if $\mathcal{U}$ is open and $m(E \cap \mathcal{U}) < \delta$, then $\int_{E \cap \mathcal{U}} |f| < \epsilon$.

Let $\epsilon > 0$ be given. Choose $\delta_0 > 0$ responding to this ϵ challenge in the assumed criterion, and define

$$\delta = \frac{\delta_0}{2} > 0.$$

We claim δ responds to the ϵ challenge in the definition of uniform integrability. Let $f \in \mathcal{F}$ and let $A \subseteq E$ be measurable with $m(A) < \delta$.

Since A is measurable, by the outer approximation property of measurable sets, Theorem 11(i) of Chapter 2, there is an open set $\mathcal{U}$ containing A for which

$$m^*(\mathcal{U} \sim A) < \frac{\delta_0}{2}.$$

Now $E \cap \mathcal{U} \subseteq A \cup (\mathcal{U} \sim A)$, because a point of $E \cap \mathcal{U}$ that fails to lie in A lies in $\mathcal{U} \sim A$. Hence, by the monotonicity and finite subadditivity of outer measure,

$$m(E \cap \mathcal{U}) \leq m(A) + m^*(\mathcal{U} \sim A) < \frac{\delta_0}{2} + \frac{\delta_0}{2} = \delta_0.$$

Therefore, by the choice of δ_0 ,

$$\int_{E \cap \mathcal{U}} |f| < \epsilon.$$

Finally, $A \subseteq E \cap \mathcal{U}$, since $A \subseteq E$ and $A \subseteq \mathcal{U}$. By the monotonicity over domains noted at the outset, applied to the nonnegative function $|f|$,

$$\int_A |f| \leq \int_{E \cap \mathcal{U}} |f| < \epsilon.$$

Since $f \in \mathcal{F}$ and the measurable set $A \subseteq E$ with $m(A) < \delta$ were arbitrary, $\mathcal{F}$ is uniformly integrable over E .

Problem 4.52. (a) Let $\mathcal{F}$ be the family of functions f on $[0, 1]$, each of which is integrable over $[0, 1]$ and has $\int_0^1 |f| \leq 1$. Is $\mathcal{F}$ uniformly integrable over $[0, 1]$?
(b) Let $\mathcal{F}$ be the family of functions f on $[0, 1]$, each of which is continuous on $[0, 1]$ and has $|f| \leq 1$ on $[0, 1]$. Is $\mathcal{F}$ uniformly integrable over $[0, 1]$?
(c) Let $\mathcal{F}$ be the family of functions f on $[0, 1]$, each of which is integrable over $[0, 1]$ and has $\int_a^b |f| \leq b - a$ for all $[a, b] \subseteq [0, 1]$. Is $\mathcal{F}$ uniformly integrable over $[0, 1]$?

Solution. (a) No. A uniform bound on the integrals does not prevent the mass of $|f|$ from concentrating on sets of arbitrarily small measure.

For each natural number n define

$$f_n = n \cdot \chi_{(0, 1/n]} \quad \text{on } [0, 1].$$

Each f_n is a nonnegative simple function, hence bounded and measurable on the set $[0, 1]$ of finite measure, and so integrable over $[0, 1]$, with

$$\int_0^1 |f_n| = n \cdot m((0, 1/n]) = n \cdot \frac{1}{n} = 1 \leq 1.$$

Thus $f_n \in \mathcal{F}$ for every n .

Now take the challenge $\epsilon = 1/2$ and let $\delta > 0$ be arbitrary. By the Archimedean property of $\mathbb{R}$ choose a natural number n with $1/n < \delta$, and set $A_n = (0, 1/n]$. Then A_n is a measurable subset of $[0, 1]$ with $m(A_n) = 1/n < \delta$, yet

$$\int_{A_n} |f_n| = n \cdot m(A_n) = 1 > \frac{1}{2} = \epsilon.$$

So no $\delta > 0$ responds to the challenge $\epsilon = 1/2$, and $\mathcal{F}$ is not uniformly integrable over $[0, 1]$.

(b) Yes. Here the whole family is dominated by a single integrable function, namely the constant function 1.

Let $f \in \mathcal{F}$. Being continuous on $[0, 1]$, f is measurable (Proposition 3 of Chapter 3), and it is bounded, since $|f| \leq 1$; as $m([0, 1]) = 1 < \infty$, f is integrable over $[0, 1]$ by Theorem 4 of Chapter 4. Let $\epsilon > 0$ and put $\delta = \epsilon$. If $A \subseteq [0, 1]$ is measurable with $m(A) < \delta$, then $|f| \leq 1$ on A , so by the monotonicity of integration for nonnegative functions (Theorem 10 of Chapter 4),

$$\int_A |f| \leq \int_A 1 = m(A) < \delta = \epsilon.$$

Since δ was chosen independently of $f \in \mathcal{F}$, the family $\mathcal{F}$ is uniformly integrable over $[0, 1]$. This is in fact an instance of the Example following the definition of uniform integrability in Section 4.6, taken with $g \equiv 1$: continuity plays no role, only the uniform bound $|f| \leq 1$ matters.

(c) Yes. The hypothesis controls $\int_A |f|$ only when A is a closed, bounded interval; but by Proposition 9 of Chapter 1 every open set is assembled from intervals, and by the preceding problem it suffices to test the uniform integrability criterion on open sets.

Step 1: the estimate on open sets. We claim that for each $f \in \mathcal{F}$ and each open set $\mathcal{U} \subseteq \mathbb{R}$,

$$\int_{[0, 1] \cap \mathcal{U}} |f| \leq m([0, 1] \cap \mathcal{U}).$$

Put $\mathcal{V} = (0, 1) \cap \mathcal{U}$, an open subset of $\mathbb{R}$. The set $([0, 1] \cap \mathcal{U}) \sim \mathcal{V}$ is contained in $\{0, 1\}$ and so has measure zero; hence $m([0, 1] \cap \mathcal{U}) = m(\mathcal{V})$, and since $|f|$ is a nonnegative measurable function on $[0, 1]$, Theorem 11 of Chapter 4 (additivity over domains of integration, together with the vanishing of the integral over a subset of measure zero) gives

$$\int_{[0, 1] \cap \mathcal{U}} |f| = \int_{\mathcal{V}} |f|.$$

If $\mathcal{V} = \emptyset$, both sides of the claimed inequality are 0 and there is nothing to prove. Otherwise, by Proposition 9 of Chapter 1, $\mathcal{V}$ is the union of a countable disjoint collection $\{I_k\}$ of open intervals.

Since $\mathcal{V} \subseteq (0, 1)$, each I_k is bounded, say $I_k = (a_k, b_k)$ with $0 \leq a_k < b_k \leq 1$, so that $[a_k, b_k] \subseteq [0, 1]$. The set $[a_k, b_k] \sim (a_k, b_k) = \{a_k, b_k\}$ has measure zero, so again by Theorem 11 of Chapter 4 and the defining hypothesis on f ,

$$\int_{I_k} |f| = \int_{[a_k, b_k]} |f| = \int_{a_k}^{b_k} |f| \leq b_k - a_k = m(I_k).$$

Since f is integrable over $[0, 1]$ it is integrable over the measurable subset $\mathcal{V}$ (indeed $|f| \cdot \chi_{\mathcal{V}} \leq |f|$ on $[0, 1]$, so $\int_{\mathcal{V}} |f| \leq \int_0^1 |f| < \infty$ by the monotonicity of integration for nonnegative functions, Theorem 10 of Chapter 4), and $\mathcal{V}$ is the disjoint union of the countable collection $\{I_k\}$ of measurable sets. Therefore, by the Countable Additivity of Integration (Theorem 20 of Chapter 4) applied to the integrable function $|f|$ over $\mathcal{V}$, and then by the countable additivity of Lebesgue measure,

$$\int_{\mathcal{V}} |f| = \sum_k \int_{I_k} |f| \leq \sum_k m(I_k) = m(\mathcal{V}).$$

If the collection $\{I_k\}$ is finite, the same conclusion follows from Corollary 18 of Chapter 4 and the finite additivity of measure. Combining the three displays proves the claim.

Step 2: conclusion. Let $\epsilon > 0$ and put $\delta = \epsilon$. If $\mathcal{U}$ is open and $m([0, 1] \cap \mathcal{U}) < \delta$, then by Step 1, for every $f \in \mathcal{F}$,

$$\int_{[0, 1] \cap \mathcal{U}} |f| \leq m([0, 1] \cap \mathcal{U}) < \delta = \epsilon.$$

Thus δ responds, uniformly over all of $\mathcal{F}$, to the ϵ challenge in the criterion of the preceding problem (Problem 51). Therefore $\mathcal{F}$ is uniformly integrable over $[0, 1]$.

One can avoid invoking Problem 51 and argue directly: given a measurable $A \subseteq [0, 1]$ with $m(A) < \epsilon/2$, use Theorem 11(i) of Chapter 2 to choose an open set $\mathcal{U}$ containing A with $m^*(\mathcal{U} \sim A) < \epsilon/2$; then $m([0, 1] \cap \mathcal{U}) \leq m(A) + m^*(\mathcal{U} \sim A) < \epsilon$, and by Step 1 together with the monotonicity over domains of the integral of the nonnegative function $|f|$,

$$\int_A |f| \leq \int_{[0, 1] \cap \mathcal{U}} |f| \leq m([0, 1] \cap \mathcal{U}) < \epsilon.$$

5.1 Problems 5.1–5.7

Problem 5.1. Prove Corollary 2.

[Corollary 2: Let $\{h_n\}$ be a sequence of nonnegative integrable functions on E . Suppose $\{h_n(x)\} \rightarrow 0$ for almost all x in E . Then

$$\lim_{n \rightarrow \infty} \int_E h_n = 0 \quad \text{if and only if} \quad \{h_n\} \text{ is uniformly integrable and tight over } E.$$

]

Solution. We prove the two implications separately.

Assume first that $\{h_n\}$ is uniformly integrable and tight over E . Since $\{h_n\} \rightarrow 0$ pointwise almost everywhere on E , the Vitali Convergence Theorem of this section (the version for sets of possibly infinite measure) applies with $f \equiv 0$ and yields

$$\lim_{n \rightarrow \infty} \int_E h_n = \int_E 0 = 0.$$

Conversely, assume $\lim_{n \rightarrow \infty} \int_E h_n = 0$. Let $\epsilon > 0$. Choose a natural number N for which

$$\int_E h_n < \epsilon \quad \text{for all } n \geq N.$$

Since each h_n is nonnegative, monotonicity of integration together with additivity over domains gives, for every measurable subset A of E and every $n \geq N$,

$$\int_A |h_n| = \int_A h_n \leq \int_E h_n < \epsilon. \quad (1)$$

Thus the tail of the sequence satisfies the uniform integrability and the tightness criteria for this ϵ with no restriction at all on A , and with the empty set serving as the set of finite measure.

It remains to handle the finitely many initial indices. If $N = 1$ there are none, and we may take $\delta = 1$ and $E_0 = \emptyset$. Otherwise consider the finite collection $\{h_n\}_{n=1}^{N-1}$, each member of which is integrable over E . By Proposition 23 of Chapter 4, for each n with $1 \leq n \leq N-1$ there is a $\delta_n > 0$ such that

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta_n, \text{ then } \int_A |h_n| < \epsilon.$$

Define $\delta = \min\{\delta_1, \dots, \delta_{N-1}\} > 0$. (This is exactly Proposition 24 of Chapter 4: a finite collection of integrable functions is uniformly integrable.) By (1), the same δ responds to the ϵ challenge for every index n , so $\{h_n\}_{n=1}^{\infty}$ is uniformly integrable over E .

For tightness, apply Proposition 1 of this section to each of the integrable functions $h_1, \dots, h_{N-1}$: there are sets $E_1, \dots, E_{N-1}$ of finite measure for which

$$\int_{E \sim E_n} h_n < \epsilon \quad \text{for } 1 \leq n \leq N-1.$$

Put $E_0 = \bigcup_{n=1}^{N-1} E_n$. Being a finite union of sets of finite measure, E_0 has finite measure. For $1 \leq n \leq N-1$ we have $E \sim E_0 \subseteq E \sim E_n$, so by monotonicity

$$\int_{E \sim E_0} h_n \leq \int_{E \sim E_n} h_n < \epsilon,$$

while for $n \geq N$ inequality (1), applied with $A = E \sim E_0$, gives $\int_{E \sim E_0} h_n < \epsilon$. Hence E_0 responds to the ϵ challenge for the whole sequence, and $\{h_n\}$ is tight over E .

Since $\epsilon > 0$ was arbitrary, $\{h_n\}$ is uniformly integrable and tight over E . The proof is complete.

Problem 5.2. Let $\{f_k\}_{k=1}^n$ be a finite family of functions, each of which is integrable over E . Show that $\{f_k\}_{k=1}^n$ is uniformly integrable and tight over E .

Solution. Let $\epsilon > 0$.

Uniform integrability. For each index k with $1 \leq k \leq n$, the function f_k is integrable over E , so by Proposition 23 of Chapter 4 there is a $\delta_k > 0$ for which

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta_k, \text{ then } \int_A |f_k| < \epsilon.$$

Define $\delta = \min\{\delta_1, \dots, \delta_n\}$. Since this is a minimum of finitely many positive numbers, $\delta > 0$. If $A \subseteq E$ is measurable with $m(A) < \delta$, then $m(A) < \delta_k$ for every k , and hence $\int_A |f_k| < \epsilon$ for every k . Thus δ responds to the ϵ challenge regarding the criterion for the family $\{f_k\}_{k=1}^n$ to be uniformly integrable over E . This is Proposition 24 of Chapter 4.

Tightness. For each index k with $1 \leq k \leq n$, the function f_k is integrable over E , so by Proposition 1 of this section there is a set $E_k \subseteq E$ of finite measure for which

$$\int_{E \sim E_k} |f_k| < \epsilon.$$

Define

$$E_0 = \bigcup_{k=1}^n E_k.$$

Then E_0 is a measurable subset of E , and by the finite subadditivity of measure $m(E_0) \leq \sum_{k=1}^n m(E_k) < \infty$, so E_0 has finite measure. Moreover, for each k we have $E_0 \supseteq E_k$ and therefore $E \sim E_0 \subseteq E \sim E_k$. By the monotonicity of integration over domains (the integrand $|f_k|$ being nonnegative),

$$\int_{E \sim E_0} |f_k| \leq \int_{E \sim E_k} |f_k| < \epsilon \quad \text{for } 1 \leq k \leq n.$$

Hence E_0 responds to the ϵ challenge regarding the criterion for tightness.

Since $\epsilon > 0$ was arbitrary, the finite family $\{f_k\}_{k=1}^n$ is both uniformly integrable and tight over E .

Problem 5.3. Let the sequences of functions $\{f_n\}$ and $\{g_n\}$ be uniformly integrable and tight over E . Show that for any α and β , $\{\alpha f_n + \beta g_n\}$ also is uniformly integrable and tight over E .

Solution. Set $M = |\alpha| + |\beta| + 1$, so that $M > 0$.

We first check that the functions $\alpha f_n + \beta g_n$ are properly defined. As the book observes just after the definition of tightness, a family that is uniformly integrable and tight over E consists of functions that are integrable over E ; hence each f_n and each g_n is integrable over E and therefore, by Proposition 15 of Chapter 4, finite a.e. on E . Let Z be the union over all n of the sets where f_n or g_n fails to be finite. Being a countable union of sets of measure zero, Z has measure zero by the countable subadditivity of measure. Off Z every combination $\alpha f_n + \beta g_n$ is defined and finite, and it is measurable there as a linear combination of measurable functions; since altering a function on a set of measure zero changes neither its measurability nor any of its integrals, we may and do work on $E \sim Z$, and all integrals below are unaffected.

Pointwise on $E \sim Z$ we have

$$|\alpha f_n + \beta g_n| \leq |\alpha| |f_n| + |\beta| |g_n|.$$

Consequently, by the monotonicity and linearity of integration for nonnegative measurable functions, for every measurable subset A of E ,

$$\int_A |\alpha f_n + \beta g_n| \leq |\alpha| \int_A |f_n| + |\beta| \int_A |g_n|. \quad (2)$$

Uniform integrability. Let $\epsilon > 0$. Since $\{f_n\}$ is uniformly integrable over E , there is a $\delta_1 > 0$ such that

for every index n ,

$$\text{if } A \subseteq E \text{ is measurable and } m(A) < \delta_1, \text{ then } \int_A |f_n| < \epsilon/M.$$

Since $\{g_n\}$ is uniformly integrable over E , there is a $\delta_2 > 0$ that does the same for the g_n 's with the same bound ϵ/M . Define $\delta = \min\{\delta_1, \delta_2\} > 0$. If $A \subseteq E$ is measurable with $m(A) < \delta$, then by (2), for every index n ,

$$\int_A |\alpha f_n + \beta g_n| \leq |\alpha| \cdot \frac{\epsilon}{M} + |\beta| \cdot \frac{\epsilon}{M} = \frac{|\alpha| + |\beta|}{M} \epsilon < \epsilon,$$

since $|\alpha| + |\beta| < M$. Thus δ responds to the ϵ challenge, and $\{\alpha f_n + \beta g_n\}$ is uniformly integrable over E .

Tightness. Let $\epsilon > 0$. By the tightness of $\{f_n\}$ there is a set $E_1 \subseteq E$ of finite measure for which $\int_{E \sim E_1} |f_n| < \epsilon/M$ for all n , and by the tightness of $\{g_n\}$ there is a set $E_2 \subseteq E$ of finite measure for which $\int_{E \sim E_2} |g_n| < \epsilon/M$ for all n . Define $E_0 = E_1 \cup E_2$. Then $m(E_0) \leq m(E_1) + m(E_2) < \infty$, so E_0 has finite measure, and

$$E \sim E_0 \subseteq E \sim E_1, \quad E \sim E_0 \subseteq E \sim E_2.$$

Hence, by monotonicity of integration over domains and by (2) applied with $A = E \sim E_0$, for every index n ,

$$\int_{E \sim E_0} |\alpha f_n + \beta g_n| \leq |\alpha| \int_{E \sim E_1} |f_n| + |\beta| \int_{E \sim E_2} |g_n| < \frac{|\alpha| + |\beta|}{M} \epsilon < \epsilon.$$

Thus E_0 responds to the ϵ challenge for tightness, and $\{\alpha f_n + \beta g_n\}$ is tight over E .

Problem 5.4. Let $\{f_n\}$ be a sequence of measurable functions on E . Show that $\{f_n\}$ is uniformly integrable and tight over E if and only if for each $\epsilon > 0$, there is a measurable subset E_0 of E that has finite measure and a $\delta > 0$ such that for each measurable subset A of E and index n ,

$$\text{if } m(A \cap E_0) < \delta, \text{ then } \int_A |f_n| < \epsilon.$$

Solution. Suppose first that $\{f_n\}$ is uniformly integrable and tight over E , and let $\epsilon > 0$. By tightness there is a measurable subset E_0 of E of finite measure for which

$$\int_{E \sim E_0} |f_n| < \epsilon/2 \quad \text{for all } n. \quad (3)$$

By uniform integrability there is a $\delta > 0$ such that

$$\text{if } B \subseteq E \text{ is measurable and } m(B) < \delta, \text{ then } \int_B |f_n| < \epsilon/2 \text{ for all } n. \quad (4)$$

We claim this E_0 and this δ respond to the ϵ challenge. Indeed, let A be a measurable subset of E with $m(A \cap E_0) < \delta$, and let n be any index. Decompose A as the disjoint union of the measurable sets $A \cap E_0$ and $A \sim E_0$. By the additivity over domains of integration of the nonnegative function $|f_n|$,

$$\int_A |f_n| = \int_{A \cap E_0} |f_n| + \int_{A \sim E_0} |f_n|.$$

The first term is less than $\epsilon/2$ by (4), since $m(A \cap E_0) < \delta$. For the second, $A \sim E_0 \subseteq E \sim E_0$, so by monotonicity and (3) it is at most $\int_{E \sim E_0} |f_n| < \epsilon/2$. Adding,

$$\int_A |f_n| < \epsilon/2 + \epsilon/2 = \epsilon,$$

which is what was to be shown.

Conversely, suppose that for each $\epsilon > 0$ there is a measurable subset E_0 of E of finite measure and a $\delta > 0$ with the stated property. Let $\epsilon > 0$ and let E_0 and δ be so chosen.

For uniform integrability: if $A \subseteq E$ is measurable and $m(A) < \delta$, then by monotonicity of measure $m(A \cap E_0) \leq m(A) < \delta$, and therefore $\int_A |f_n| < \epsilon$ for every index n . Thus this same δ responds to the ϵ challenge in the definition of uniform integrability.

For tightness: take $A = E \sim E_0$. Then $A \cap E_0 = \emptyset$, so $m(A \cap E_0) = 0 < \delta$, and the hypothesis gives

$$\int_{E \sim E_0} |f_n| < \epsilon \quad \text{for all } n.$$

Since E_0 has finite measure, E_0 responds to the ϵ challenge in the definition of tightness.

As $\epsilon > 0$ was arbitrary, $\{f_n\}$ is uniformly integrable and tight over E .

Problem 5.5. Let $\{f_n\}$ be a sequence of integrable functions on $\mathbb{R}$. Show that $\{f_n\}$ is uniformly integrable and tight over $\mathbb{R}$ if and only if for each $\epsilon > 0$, there are positive numbers r and δ such that for each open subset $\mathcal{O}$ of $\mathbb{R}$ and index n ,

$$\text{if } m(\mathcal{O} \cap (-r, r)) < \delta, \text{ then } \int_{\mathcal{O}} |f_n| < \epsilon.$$

Solution. Suppose first that $\{f_n\}$ is uniformly integrable and tight over $\mathbb{R}$, and let $\epsilon > 0$.

By uniform integrability there is a $\delta > 0$ such that

$$\text{if } A \subseteq \mathbb{R} \text{ is measurable and } m(A) < \delta, \text{ then } \int_A |f_n| < \epsilon/3 \text{ for all } n. \quad (5)$$

By tightness there is a measurable set $E_0 \subseteq \mathbb{R}$ of finite measure for which

$$\int_{\mathbb{R} \sim E_0} |f_n| < \epsilon/3 \quad \text{for all } n. \quad (6)$$

Since $m(E_0) < \infty$, and since the sets $E_0 \sim (-k, k)$, for k a natural number, form a descending sequence of measurable sets of finite measure whose intersection is empty, Theorem 15 of Chapter 2 (the Continuity of Measure) tells us that $\lim_{k \rightarrow \infty} m(E_0 \sim (-k, k)) = 0$. Choose $r > 0$ (a natural number will do) for which

$$m(E_0 \sim (-r, r)) < \delta.$$

Now

$$\mathbb{R} \sim (-r, r) \subseteq (\mathbb{R} \sim E_0) \cup (E_0 \sim (-r, r)),$$

so by the monotonicity and the (finite) subadditivity of integration of the nonnegative function $|f_n|$ over domains, together with (5) and (6),

$$\int_{\mathbb{R} \sim (-r, r)} |f_n| \leq \int_{\mathbb{R} \sim E_0} |f_n| + \int_{E_0 \sim (-r, r)} |f_n| < \epsilon/3 + \epsilon/3 = 2\epsilon/3 \quad \text{for all } n. \quad (7)$$

We claim this r and this δ respond to the ϵ challenge. Indeed, let $\mathcal{O}$ be an open subset of $\mathbb{R}$ with $m(\mathcal{O} \cap (-r, r)) < \delta$ and let n be any index. Splitting $\mathcal{O}$ into the disjoint measurable pieces $\mathcal{O} \cap (-r, r)$ and $\mathcal{O} \sim (-r, r)$ and using additivity over domains, (5) and (7),

$$\int_{\mathcal{O}} |f_n| = \int_{\mathcal{O} \cap (-r, r)} |f_n| + \int_{\mathcal{O} \sim (-r, r)} |f_n| < \frac{\epsilon}{3} + \int_{\mathbb{R} \sim (-r, r)} |f_n| < \frac{\epsilon}{3} + \frac{2\epsilon}{3} = \epsilon.$$

(Openness of $\mathcal{O}$ was not needed here; the estimate holds for every measurable set.)

Conversely, suppose that for each $\epsilon > 0$ there are positive numbers r and δ with the stated property. Let $\epsilon > 0$, and let $r > 0$ and $\delta > 0$ respond to this ϵ .

Tightness. Take $E_0 = (-r, r)$, a set of finite measure $2r$. The set $\mathcal{O} = \mathbb{R} \sim [-r, r]$ is open and $\mathcal{O} \cap (-r, r) = \emptyset$, so $m(\mathcal{O} \cap (-r, r)) = 0 < \delta$ and therefore $\int_{\mathcal{O}} |f_n| < \epsilon$ for all n . Since $\mathbb{R} \sim (-r, r)$

differs from $\mathcal{O}$ only by the two-point set $\{-r, r\}$, which has measure zero, the integrals over these two domains agree, and hence

$$\int_{\mathbb{R} \sim E_0} |f_n| = \int_{\mathcal{O}} |f_n| < \epsilon \quad \text{for all } n.$$

Thus E_0 responds to the ϵ challenge for tightness.

Uniform integrability. We claim $\delta/2$ responds to the ϵ challenge. Let $A \subseteq \mathbb{R}$ be measurable with $m(A) < \delta/2$. Since A is measurable, assertion (i) of Theorem 11 of Chapter 2 provides an open set $\mathcal{O}$ containing A for which $m(\mathcal{O} \sim A) < \delta/2$. By the additivity of measure,

$$m(\mathcal{O}) = m(A) + m(\mathcal{O} \sim A) < \delta/2 + \delta/2 = \delta,$$

and hence $m(\mathcal{O} \cap (-r, r)) \leq m(\mathcal{O}) < \delta$. By hypothesis $\int_{\mathcal{O}} |f_n| < \epsilon$ for every index n , and since $A \subseteq \mathcal{O}$, monotonicity of integration over domains gives

$$\int_A |f_n| \leq \int_{\mathcal{O}} |f_n| < \epsilon \quad \text{for all } n.$$

Since $\epsilon > 0$ was arbitrary, $\{f_n\}$ is uniformly integrable and tight over $\mathbb{R}$.

Problem 5.6. Let $\{f_n\} \rightarrow f$ in measure on E and g be a measurable function on E that is finite a.e. on E . Show that $\{f_n\} \rightarrow g$ in measure on E if and only if $f = g$ a.e. on E .

Solution. Recall that, by the definition of convergence in measure, the hypothesis $\{f_n\} \rightarrow f$ in measure on E carries with it the assertion that f and each f_n is measurable and finite a.e. on E ; and g is measurable and finite a.e. on E by hypothesis. Let Z be the set of points of E at which f or g fails to be finite. Being the union of two sets of measure zero, Z has measure zero.

Suppose first that $f = g$ a.e. on E , and let $Z' = \{x \in E \mid f(x) \neq g(x)\}$, a set of measure zero. Write $W = Z \cup Z'$, so $m(W) = 0$ by the countable subadditivity of measure. Fix $\eta > 0$ and an index n . If $x \in E \sim W$ then $f(x) = g(x)$ and this common value is a real number, so the two differences $f_n(x) - g(x)$ and $f_n(x) - f(x)$ are the same extended real number and

$$|f_n(x) - g(x)| > \eta \iff |f_n(x) - f(x)| > \eta \quad \text{for } x \in E \sim W.$$

Consequently

$$\{x \in E \mid |f_n - g| > \eta\} \subseteq W \cup \{x \in E \mid |f_n - f| > \eta\},$$

and so, by the monotonicity and countable subadditivity of measure together with $m(W) = 0$,

$$m\{x \in E \mid |f_n - g| > \eta\} \leq m\{x \in E \mid |f_n - f| > \eta\}.$$

Since $\{f_n\} \rightarrow f$ in measure, the right-hand side tends to 0 as $n \rightarrow \infty$, and hence so does the left-hand side. As $\eta > 0$ was arbitrary, and as g is by hypothesis measurable and finite a.e. on E , we conclude $\{f_n\} \rightarrow g$ in measure on E .

Conversely, suppose $\{f_n\} \rightarrow g$ in measure on E as well. Fix $\eta > 0$. Let $x \in E \sim Z$ be a point at which $|f(x) - g(x)| > \eta$, and let n be any index. Since $f(x)$ and $g(x)$ are finite, the triangle inequality gives

$$\eta < |f(x) - g(x)| \leq |f(x) - f_n(x)| + |f_n(x) - g(x)|,$$

and hence at least one of the two summands exceeds $\eta/2$ (this remains true, trivially, if $f_n(x)$ is infinite). Therefore, for every index n ,

$$\{x \in E \mid |f(x) - g(x)| > \eta\} \subseteq Z \cup \{x \in E \mid |f_n(x) - f(x)| > \eta/2\} \cup \{x \in E \mid |f_n(x) - g(x)| > \eta/2\}.$$

By the monotonicity and countable subadditivity of measure, together with $m(Z) = 0$,

$$m\{x \in E \mid |f(x) - g(x)| > \eta\} \leq m\{x \in E \mid |f_n - f| > \eta/2\} + m\{x \in E \mid |f_n - g| > \eta/2\}.$$

The left-hand side does not depend on n , while by hypothesis both terms on the right tend to 0 as $n \rightarrow \infty$. Letting $n \rightarrow \infty$ we conclude

$$m\{x \in E \mid |f(x) - g(x)| > \eta\} = 0 \quad \text{for every } \eta > 0.$$

Finally, on $E \sim Z$ the functions f and g are finite, so

$$\{x \in E \sim Z \mid f(x) \neq g(x)\} = \bigcup_{k=1}^{\infty} \{x \in E \sim Z \mid |f(x) - g(x)| > 1/k\},$$

a countable union of sets of measure zero, which therefore has measure zero by the countable subadditivity of measure. Adjoining the null set Z , we conclude that $\{x \in E \mid f(x) \neq g(x)\}$ has measure zero, that is, $f = g$ a.e. on E .

Problem 5.7. Let E have finite measure, $\{f_n\} \rightarrow f$ in measure on E and g be a measurable function on E that is finite a.e. on E . Prove that $\{f_n \cdot g\} \rightarrow f \cdot g$ in measure, and use this to show that $\{f_n^2\} \rightarrow f^2$ in measure. Infer from this that if $\{g_n\} \rightarrow g$ in measure, then $\{f_n \cdot g_n\} \rightarrow f \cdot g$ in measure.

Solution. Throughout, recall that convergence in measure presupposes that the limit function is measurable and finite a.e. on E . All products below are defined a.e. on E and are measurable, and the exceptional null sets may be discarded without affecting any of the measures computed.

We first record an elementary lemma.

Lemma. If $\{u_n\} \rightarrow u$ and $\{v_n\} \rightarrow v$ in measure on E , and α, β are real numbers, then $\{\alpha u_n + \beta v_n\} \rightarrow \alpha u + \beta v$ in measure on E .

Proof of the Lemma. Set $M = |\alpha| + |\beta| + 1$, so $M > 0$ and $|\alpha| + |\beta| < M$. By the definition of convergence in measure, u, v and every u_n, v_n is measurable and finite a.e. on E ; let Z be the union of the countably many sets of measure zero on which one of these functions fails to be finite. By the countable subadditivity of measure $m(Z) = 0$, and off Z every function in sight is real-valued, so all the algebraic manipulations below are legitimate there and no integral or measure is affected by discarding Z . Let $\eta > 0$. For $x \in E \sim Z$,

$$|(\alpha u_n + \beta v_n)(x) - (\alpha u + \beta v)(x)| \leq |\alpha| |u_n(x) - u(x)| + |\beta| |v_n(x) - v(x)|,$$

so if the left side exceeds η then $|u_n(x) - u(x)| > \eta/(2M)$ or $|v_n(x) - v(x)| > \eta/(2M)$ (otherwise the right side would be at most $(|\alpha| + |\beta|)\eta/(2M) < \eta$). Hence

$$\{|\alpha u_n + \beta v_n - (\alpha u + \beta v)| > \eta\} \subseteq Z \cup \{|u_n - u| > \eta/(2M)\} \cup \{|v_n - v| > \eta/(2M)\},$$

and by the monotonicity and countable subadditivity of measure, together with $m(Z) = 0$, the measure of the left-hand set is at most the sum of the measures of the last two sets, each of which tends to 0 as $n \rightarrow \infty$. Since $\eta > 0$ was arbitrary, and since $\alpha u + \beta v$ is measurable and finite a.e. on E because u and v are, the Lemma is proved.

Part 1: $\{f_n \cdot g\} \rightarrow f \cdot g$ in measure on E .

Let $\eta > 0$ and $\epsilon > 0$. For each natural number k define

$$E_k = \{x \in E \mid |g(x)| > k\}.$$

These are measurable sets that descend, and $\bigcap_{k=1}^{\infty} E_k = \{x \in E \mid |g(x)| = \infty\}$, a set of measure zero since g is finite a.e. on E . Since $m(E_1) \leq m(E) < \infty$, Theorem 15 of Chapter 2 (the Continuity of Measure) gives $\lim_{k \rightarrow \infty} m(E_k) = 0$. (This is exactly where the finiteness of $m(E)$ is used.) Choose k with $m(E_k) < \epsilon$.

Let Z be the union of the countably many sets of measure zero on which one of $f, g, f_1, f_2, \dots$ fails to be finite; by the countable subadditivity of measure $m(Z) = 0$. Suppose $x \in E$ satisfies $|f_n(x)g(x) - f(x)g(x)| > \eta$ and $x \notin Z \cup E_k$. Then $f(x), g(x), f_n(x)$ are all real numbers and $|g(x)| \leq k$, so the factorization $f_n(x)g(x) - f(x)g(x) = g(x)[f_n(x) - f(x)]$ is legitimate and

$$\eta < |g(x)| |f_n(x) - f(x)| \leq k |f_n(x) - f(x)|,$$

so $|f_n(x) - f(x)| > \eta/k$. Therefore

$$\{x \in E \mid |f_n g - f g| > \eta\} \subseteq Z \cup E_k \cup \{x \in E \mid |f_n - f| > \eta/k\},$$

and hence, by the monotonicity and countable subadditivity of measure, together with $m(Z) = 0$ and $m(E_k) < \epsilon$,

$$m\{x \in E \mid |f_n g - f g| > \eta\} \leq \epsilon + m\{x \in E \mid |f_n - f| > \eta/k\}.$$

Since $\{f_n\} \rightarrow f$ in measure, letting $n \rightarrow \infty$ yields

$$\limsup_{n \rightarrow \infty} m\{x \in E \mid |f_n g - f g| > \eta\} \leq \epsilon.$$

As $\epsilon > 0$ was arbitrary, this limit superior is 0, that is,

$$\lim_{n \rightarrow \infty} m\{x \in E \mid |f_n(x)g(x) - f(x)g(x)| > \eta\} = 0.$$

Since $\eta > 0$ was arbitrary and $f \cdot g$ is measurable and finite a.e. on E , we conclude $\{f_n \cdot g\} \rightarrow f \cdot g$ in measure on E .

Part 2: $\{f_n^2\} \rightarrow f^2$ in measure on E .

Let Z again denote the null set off which f and all the f_n are finite; every set equality below is asserted on $E \sim Z$, and adjoining or deleting Z changes no measure.

First, $\{f_n - f\} \rightarrow 0$ in measure on E by the Lemma (take $u_n = f_n$, v_n the constant sequence f , $\alpha = 1$, $\beta = -1$; the constant sequence trivially converges to f in measure). Next, for $\eta > 0$ and $x \in E \sim Z$ the numbers $f_n(x)$ and $f(x)$ are real, so $(f_n(x) - f(x))^2 > \eta$ holds precisely when $|f_n(x) - f(x)| > \sqrt{\eta}$. Hence

$$\{x \in E \mid (f_n(x) - f(x))^2 > \eta\} \subseteq Z \cup \{x \in E \mid |f_n(x) - f(x)| > \sqrt{\eta}\},$$

and the measure of the right-hand side tends to 0 as $n \rightarrow \infty$. Since $(f_n - f)^2$ is measurable and finite a.e. on E , this says $\{(f_n - f)^2\} \rightarrow 0$ in measure on E .

Second, f itself is a measurable function on E that is finite a.e. on E , so Part 1 applied with $g = f$ gives $\{f_n \cdot f\} \rightarrow f^2$ in measure on E .

Now put $h_n = (f_n - f)^2 + [2ff_n - f^2]$. The sequence $\{(f_n - f)^2\}$ converges in measure to 0, and the sequence $\{2ff_n - f^2\}$ converges in measure to $2f^2 - f^2 = f^2$ (apply the Lemma with $u_n = ff_n \rightarrow f^2$, $\alpha = 2$, and the constant sequence $v_n = f^2 \rightarrow f^2$, $\beta = -1$). Hence the Lemma, applied once more with $\alpha = \beta = 1$, gives $\{h_n\} \rightarrow 0 + f^2 = f^2$ in measure on E .

Finally, at each point of $E \sim Z$ all the quantities involved are real numbers and the algebraic identity

$$(f_n - f)^2 + 2ff_n - f^2 = f_n^2 - 2ff_n + f^2 + 2ff_n - f^2 = f_n^2$$

holds, so $h_n = f_n^2$ on $E \sim Z$. Therefore, for each $\eta > 0$,

$$\{x \in E \mid |f_n^2 - f^2| > \eta\} \subseteq Z \cup \{x \in E \mid |h_n - f^2| > \eta\},$$

and since $m(Z) = 0$ the measure of the left-hand set tends to 0 as $n \rightarrow \infty$. As f^2 is measurable and finite a.e. on E , we conclude

$$\{f_n^2\} \rightarrow f^2 \quad \text{in measure on } E.$$

Part 3: if also $\{g_n\} \rightarrow g$ in measure on E , then $\{f_n \cdot g_n\} \rightarrow f \cdot g$ in measure on E .

Here g is measurable and finite a.e. on E , as required by the definition of convergence in measure. By the Lemma, $\{f_n + g_n\} \rightarrow f + g$ in measure on E . The argument of Part 2 used nothing about the sequence $\{f_n\}$ beyond the facts that $m(E) < \infty$ and that $\{f_n\}$ converges in measure on E to a function that is measurable and finite a.e.; so it applies verbatim to each of the three sequences $\{f_n + g_n\}$, $\{f_n\}$ and $\{g_n\}$, whose limits $f + g$, f and g are all measurable and finite a.e. on E . Thus

$$\{(f_n + g_n)^2\} \rightarrow (f + g)^2, \quad \{f_n^2\} \rightarrow f^2, \quad \{g_n^2\} \rightarrow g^2 \quad \text{in measure on } E.$$

Applying the Lemma twice to the linear combination

$$k_n = \frac{1}{2}(f_n + g_n)^2 - \frac{1}{2}f_n^2 - \frac{1}{2}g_n^2$$

gives

$$\{k_n\} \rightarrow \frac{1}{2} [(f+g)^2 - f^2 - g^2] \quad \text{in measure on } E.$$

Let W be the null set off which f , g and every f_n , g_n is finite. At each point of $E \sim W$ all these values are real numbers, so the identity $(a+b)^2 - a^2 - b^2 = 2ab$ gives $k_n = f_n g_n$ there, and likewise $\frac{1}{2}[(f+g)^2 - f^2 - g^2] = f \cdot g$ there. Exactly as in Part 2, for each $\eta > 0$,

$$\{x \in E \mid |f_n g_n - f g| > \eta\} \subseteq W \cup \{x \in E \mid |k_n - \frac{1}{2}[(f+g)^2 - f^2 - g^2]| > \eta\},$$

whose measure tends to 0. Since $f \cdot g$ is measurable and finite a.e. on E , we conclude that $\{f_n \cdot g_n\} \rightarrow f \cdot g$ in measure on E . This completes the proof.

5.2 Problems 5.8–5.14

Problem 5.8. Show that Fatou's Lemma, the Monotone Convergence Theorem, the Lebesgue Dominated Convergence Theorem, and the Vitali Convergence Theorem remain valid if "pointwise convergence a.e." is replaced by "convergence in measure."

Solution. Throughout, recall the standing convention that when we write $\{f_n\} \rightarrow f$ in measure on E we are assuming f and each f_n is measurable and finite a.e. on E . We isolate two elementary observations and then treat the four theorems in turn.

Observation A (subsequences inherit convergence in measure). If $\{f_n\} \rightarrow f$ in measure on E and $\{f_{n_k}\}$ is any subsequence, then $\{f_{n_k}\} \rightarrow f$ in measure on E . Indeed, given $\eta > 0$ and $\epsilon > 0$ choose N with $m\{x \in E \mid |f_n(x) - f(x)| > \eta\} < \epsilon$ for all $n \geq N$; since $n_k \geq k$, the same inequality holds for all $k \geq N$. Observation B (the subsequence criterion for numerical sequences). Let $\{a_n\}$ be a sequence in $\mathbb{R}$ and $a \in \mathbb{R}$. If every subsequence of $\{a_n\}$ possesses a further subsequence converging to a , then $a_n \rightarrow a$. Indeed, if $a_n \not\rightarrow a$ there are $\epsilon_0 > 0$ and indices $n_1 < n_2 < \dots$ with $|a_{n_k} - a| \geq \epsilon_0$ for all k ; no subsequence of $\{a_{n_k}\}$ can converge to a , a contradiction.

The engine driving everything is the Riesz Theorem (Theorem 4 of this chapter): if $\{f_n\} \rightarrow f$ in measure on E , then some subsequence of $\{f_n\}$ converges to f pointwise a.e. on E . Combining it with Observation A: **every** subsequence of $\{f_n\}$ has in turn a further subsequence converging to f pointwise a.e. on E . Call this property (*).

1. Fatou's Lemma. Claim: if $\{f_n\}$ is a sequence of nonnegative measurable functions on E and $\{f_n\} \rightarrow f$ in measure on E , then $f \geq 0$ a.e. on E (indeed, by the Riesz Theorem some subsequence converges to f pointwise a.e., and a pointwise limit of nonnegative numbers is nonnegative), so that $\int_E f$ is defined, and

$$\int_E f \leq \liminf_{n \rightarrow \infty} \int_E f_n.$$

Set $L = \liminf_{n \rightarrow \infty} \int_E f_n \in [0, \infty]$. Choose a subsequence $\{f_{n_k}\}$ with $\lim_{k \rightarrow \infty} \int_E f_{n_k} = L$. By (*) there is a further subsequence $\{f_{n_{k_j}}\}$ converging to f pointwise a.e. on E . Fatou's Lemma in its original form (Chapter 4) applies to this further subsequence and gives

$$\int_E f \leq \liminf_{j \rightarrow \infty} \int_E f_{n_{k_j}} = \lim_{k \rightarrow \infty} \int_E f_{n_k} = L,$$

the middle equality because a subsequence of a convergent sequence of numbers has the same limit. This is the assertion.

1. The Monotone Convergence Theorem. Claim: if $\{f_n\}$ is an increasing sequence of nonnegative measurable functions on E and $\{f_n\} \rightarrow f$ in measure on E , then $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$.

Since $f_n \leq f_{n+1}$ on E , the numerical sequence $\{\int_E f_n\}$ is increasing, so it converges in $[0, \infty]$; call the limit L . Part 1 already gives $\int_E f \leq L$. For the reverse inequality, fix an index p . By the Riesz Theorem select a subsequence $\{f_{n_k}\}$ converging to f pointwise a.e. on E , say on $E \sim E_0$ where E_0 is a measurable subset of E with $m(E_0) = 0$. For $x \in E \sim E_0$ and any k with $n_k \geq p$ we have $f_p(x) \leq f_{n_k}(x)$ by monotonicity, and letting $k \rightarrow \infty$ gives $f_p(x) \leq f(x)$. Hence $f_p \leq f$ a.e. on E , and by the monotonicity of integration for nonnegative measurable functions $\int_E f_p \leq \int_E f$. Letting $p \rightarrow \infty$ yields $L \leq \int_E f$. Therefore $L = \int_E f$.

1. The Lebesgue Dominated Convergence Theorem. Claim: if $\{f_n\}$ is a sequence of measurable functions on E , g is integrable over E with $|f_n| \leq g$ on E for all n , and $\{f_n\} \rightarrow f$ in measure on E , then f is integrable over E and $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$.

First, f is integrable. By the Riesz Theorem some subsequence $\{f_{n_k}\}$ converges to f pointwise a.e. on E ; passing to the limit in $|f_{n_k}| \leq g$ gives $|f| \leq g$ a.e. on E , and since f is measurable and g is integrable, f is integrable over E by the Integral Comparison Test (Proposition 16 of Chapter 4). In particular each $\int_E f_n$ and $\int_E f$ is a real number.

Now let $\{\int_E f_{n_k}\}$ be an arbitrary subsequence of the numerical sequence $\{\int_E f_n\}$. By (*) there is a further subsequence $\{f_{n_{k_j}}\}$ converging to f pointwise a.e. on E ; it is dominated by g , so the Dominated Convergence Theorem in its original form gives $\int_E f_{n_{k_j}} \rightarrow \int_E f$. Thus every subsequence of $\{\int_E f_n\}$ has a further subsequence converging to $\int_E f$, and Observation B gives $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$.

1. The Vitali Convergence Theorem. Claim: let $\{f_n\}$ be a sequence of measurable functions on E that is uniformly integrable and tight over E (if $m(E) < \infty$, tightness is automatic, since one may take $E_0 = E$ in its definition), and suppose $\{f_n\} \rightarrow f$ in measure on E . Then f is integrable over E and $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$.

The argument is verbatim that of part 3, with domination replaced by uniform integrability and tightness. First note that each f_n is integrable over E : this is exactly what uniform integrability together with tightness gives, by the remark preceding the statement of the general Vitali Convergence Theorem in Section 5.1 (which appeals to Proposition 23 of Chapter 4). So $\{\int_E f_n\}$ is a sequence of real numbers. Let $\{\int_E f_{n_k}\}$ be any subsequence. By (*) choose a further subsequence $\{f_{n_{k_j}}\}$ converging to f pointwise a.e. on E . This further subsequence is itself uniformly integrable and tight over E , since both conditions are inherited by subsequences (the δ and the set of finite measure produced for the whole family serve for any subfamily). Hence the Vitali Convergence Theorem in its original form (the general version stated in Section 5.1 of this chapter; for $m(E) < \infty$ the version of Section 4.6 suffices) tells us that f is integrable over E and $\int_E f_{n_{k_j}} \rightarrow \int_E f$. The integrability of f is thereby established once and for all (from a single such subsequence), so $\int_E f$ is a real number; and Observation B applied to $\{\int_E f_n\}$ gives $\lim_{n \rightarrow \infty} \int_E f_n = \int_E f$.

In each of the four cases the hypothesis of a.e. pointwise convergence was used only along a subsequence, which the Riesz Theorem supplies from convergence in measure; and in each case convergence in measure is a genuinely weaker hypothesis, since by Proposition 3 pointwise a.e. convergence on a set of finite measure implies convergence in measure while the example following Proposition 3 shows the converse fails.

Problem 5.9. Show that Proposition 3 does not necessarily hold for sets E of infinite measure.

Solution. Proposition 3 asserts: if $m(E) < \infty$, $\{f_n\}$ is a sequence of measurable functions on E converging pointwise a.e. on E to f , and f is finite a.e. on E , then $\{f_n\} \rightarrow f$ in measure on E . We exhibit a set of infinite measure on which the conclusion fails.

Let $E = \mathbb{R}$, which has infinite measure, and for each natural number n define

$$f_n = \chi_{[n, n+1)}.$$

Each f_n is measurable, being the characteristic function of a measurable set, and each is real-valued. Let $f \equiv 0$ on $\mathbb{R}$; then f is measurable and finite everywhere.

The sequence converges pointwise on all of $\mathbb{R}$ to f . Indeed, fix $x \in \mathbb{R}$ and choose a natural number $N > x$. For every $n \geq N$ we have $n > x$, so $x \notin [n, n+1)$ and hence $f_n(x) = 0$. Thus $f_n(x) \rightarrow 0 = f(x)$. So the hypotheses of Proposition 3 hold except for the finiteness of $m(E)$.

The sequence does not converge to f in measure. Take $\eta = 1/2$. For each n ,

$$\{x \in \mathbb{R} \mid |f_n(x) - f(x)| > 1/2\} = \{x \in \mathbb{R} \mid \chi_{[n, n+1)}(x) > 1/2\} = [n, n+1),$$

a set of measure 1. Hence for $\epsilon = 1/2$ there is no index N for which

$$m\{x \in \mathbb{R} \mid |f_n(x) - f(x)| > 1/2\} < \epsilon \quad \text{for all } n \geq N,$$

since the left-hand side equals 1 for every n . Therefore $\{f_n\}$ fails to converge to f in measure on $\mathbb{R}$, and Proposition 3 is false for sets of infinite measure.

The mechanism is exactly the one Egoroff's Theorem, on which the proof of Proposition 3 rests, cannot control on a set of infinite measure: the "bad set" on which f_n is far from its limit does not shrink, it merely escapes to infinity. One can of course produce the same failure on a set of infinite measure that is not all of $\mathbb{R}$, for instance on $E = [0, \infty)$ with the same functions.

It is worth noting that a related but distinct phenomenon occurs even on sets of finite measure with the roles reversed: as the Example following Proposition 3 shows, on $E = [0, 1]$ there is a sequence converging in measure to $f \equiv 0$ that converges pointwise at no point of $[0, 1]$. Thus on a set of finite measure the implication of Proposition 3 is strict, while on a set of infinite measure it is not even valid.

Problem 5.10. Show that linear combinations of sequences that converge in measure on a set of finite measure also converge in measure.

Solution. Let E be measurable with $m(E) < \infty$. We are to show: if $\{f_n\} \rightarrow f$ in measure on E and $\{g_n\} \rightarrow g$ in measure on E , and α, β are real numbers, then

$$\{\alpha f_n + \beta g_n\} \rightarrow \alpha f + \beta g \quad \text{in measure on } E.$$

By induction this gives the assertion for a linear combination of any finite number of sequences.

First a word on well-definedness. By our standing convention f, g and each f_n, g_n are measurable and finite a.e. on E . Let

$$E_0 = \{x \in E \mid \text{at least one of } f(x), g(x), f_1(x), g_1(x), f_2(x), g_2(x), \dots \text{ is infinite}\}.$$

This is a countable union of sets of measure zero, so $m(E_0) = 0$. On $E \sim E_0$ every one of these functions is real-valued, so the linear combinations $\alpha f_n + \beta g_n$ and $\alpha f + \beta g$ are defined there, are measurable (linear combinations of measurable real-valued functions are measurable, Theorem 6 of Chapter 3), and are finite. Since sets of measure zero contribute nothing to the measures occurring in the definition of convergence in measure, we may and do argue on $E \sim E_0$; equivalently, we adopt the (measure-irrelevant) convention that all functions are redefined to be 0 on E_0 .

If $\alpha = \beta = 0$ the assertion is trivial, both sides being identically 0. So assume $|\alpha| + |\beta| > 0$.

Fix $\eta > 0$ and $\epsilon > 0$. The heart of the matter is the following pointwise inclusion. For $x \in E \sim E_0$,

$$|(\alpha f_n(x) + \beta g_n(x)) - (\alpha f(x) + \beta g(x))| \leq |\alpha| |f_n(x) - f(x)| + |\beta| |g_n(x) - g(x)|,$$

by the triangle inequality. Consequently, if the left-hand side exceeds η , then at least one of the two summands on the right exceeds $\eta/2$: were both at most $\eta/2$, the sum would be at most η . Therefore, writing

$$A_n = \left\{x \in E \sim E_0 \mid |\alpha| |f_n(x) - f(x)| > \eta/2\right\}, \quad B_n = \left\{x \in E \sim E_0 \mid |\beta| |g_n(x) - g(x)| > \eta/2\right\},$$

we have the inclusion

$$\{x \in E \sim E_0 \mid |(\alpha f_n + \beta g_n)(x) - (\alpha f + \beta g)(x)| > \eta\} \subseteq A_n \cup B_n.$$

We now estimate $m(A_n)$ and $m(B_n)$ separately. If $\alpha = 0$ then $A_n = \emptyset$ and $m(A_n) = 0$ for all n . If $\alpha \neq 0$, then

$$A_n = \left\{x \in E \sim E_0 \mid |f_n(x) - f(x)| > \frac{\eta}{2|\alpha|}\right\},$$

and since $\eta/(2|\alpha|) > 0$ and $\{f_n\} \rightarrow f$ in measure on E , there is an index N_1 such that $m(A_n) < \epsilon/2$ for all $n \geq N_1$. In either case there is an index N_1 with $m(A_n) < \epsilon/2$ for $n \geq N_1$. Symmetrically there is an index N_2 with $m(B_n) < \epsilon/2$ for all $n \geq N_2$.

Set $N = \max\{N_1, N_2\}$. For $n \geq N$, by the monotonicity and finite subadditivity of Lebesgue measure,

$$m\{x \in E \mid |(\alpha f_n + \beta g_n)(x) - (\alpha f + \beta g)(x)| > \eta\} \leq m(E_0) + m(A_n) + m(B_n) < 0 + \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Since $\eta > 0$ and $\epsilon > 0$ were arbitrary, $\{\alpha f_n + \beta g_n\} \rightarrow \alpha f + \beta g$ in measure on E , as claimed.

Two remarks. First, the finiteness of $m(E)$ was nowhere used: the argument above is valid on an arbitrary measurable set E , finite measure or not. Finiteness of measure is needed for Proposition 3 (pointwise a.e. convergence implies convergence in measure), not for the algebra of limits in measure. Second, the same splitting argument shows that the set of sequences converging in measure on E is a real vector space and that the map sending a sequence to its limit in measure is linear; the limit is unique up to sets of measure zero, since if $\{h_n\} \rightarrow h$ and $\{h_n\} \rightarrow \tilde{h}$ in measure then by the case just proved $\{0\} = \{h_n - h_n\} \rightarrow h - \tilde{h}$ in measure, forcing $m\{|h - \tilde{h}| > \eta\} = 0$ for every $\eta > 0$ and hence $h = \tilde{h}$ a.e. on E .

Problem 5.11. Assume E has finite measure. Let $\{f_n\}$ be a sequence of measurable functions on E and f a measurable function on E for which f and each f_n is finite a.e. on E . Prove that $\{f_n\} \rightarrow f$ in measure on E if and only if every subsequence of $\{f_n\}$ has in turn a further subsequence that converges to f pointwise a.e. on E .

Solution. Throughout, $m(E) < \infty$, and f together with every f_n is measurable and finite a.e. on E , so that all the sets appearing below are measurable and all the measures involved are finite.

Suppose first that $\{f_n\} \rightarrow f$ in measure on E , and let $\{f_{n_k}\}$ be an arbitrary subsequence. We claim $\{f_{n_k}\} \rightarrow f$ in measure on E . Indeed, let $\eta > 0$ and $\epsilon > 0$. Choose N so that $m\{x \in E \mid |f_n(x) - f(x)| > \eta\} < \epsilon$ for all $n \geq N$. Since $\{n_k\}$ is strictly increasing, $n_k \geq k$; hence for all $k \geq N$ we have $n_k \geq N$ and therefore

$$m\{x \in E \mid |f_{n_k}(x) - f(x)| > \eta\} < \epsilon.$$

So the subsequence converges to f in measure. By the Riesz Theorem (Theorem 4), a sequence converging in measure has a subsequence converging pointwise a.e. to the same limit; applied to $\{f_{n_k}\}$, it produces a further subsequence $\{f_{n_{k_j}}\}$ converging to f pointwise a.e. on E . This proves the forward implication. (Note that finiteness of $m(E)$ was not needed here.)

Conversely, suppose every subsequence of $\{f_n\}$ has in turn a further subsequence converging to f pointwise a.e. on E . We argue by contradiction: assume $\{f_n\}$ does not converge to f in measure on E .

Negating the definition of convergence in measure, there exist $\eta_0 > 0$ and $\epsilon_0 > 0$ with the property that for every index N there is some $n \geq N$ for which

$$m\{x \in E \mid |f_n(x) - f(x)| > \eta_0\} \geq \epsilon_0.$$

Use this repeatedly to construct indices: take n_1 to be an index (with $n_1 \geq 1$) for which the displayed inequality holds; having chosen $n_1 < n_2 < \dots < n_k$, apply the property with $N = n_k + 1$ to obtain $n_{k+1} > n_k$ for which the inequality holds. This yields a strictly increasing sequence of natural numbers $\{n_k\}$ with

$$m\{x \in E \mid |f_{n_k}(x) - f(x)| > \eta_0\} \geq \epsilon_0 \quad \text{for every } k. \quad (\dagger)$$

By hypothesis, the subsequence $\{f_{n_k}\}$ has in turn a further subsequence $\{f_{n_{k_j}}\}$ that converges to f pointwise a.e. on E . Now E has finite measure, the functions $f_{n_{k_j}}$ are measurable, and f is finite a.e. on E ; so Proposition 3 applies to the sequence $\{f_{n_{k_j}}\}_{j=1}^\infty$ and yields

$$\{f_{n_{k_j}}\} \rightarrow f \quad \text{in measure on } E.$$

In particular, taking $\eta = \eta_0$ and $\epsilon = \epsilon_0$ in the definition, there is an index J such that

$$m\{x \in E \mid |f_{n_{k_j}}(x) - f(x)| > \eta_0\} < \epsilon_0 \quad \text{for all } j \geq J.$$

But n_{k_j} is one of the indices n_k , so $(\dagger)$ gives $m\{x \in E \mid |f_{n_{k_j}}(x) - f(x)| > \eta_0\} \geq \epsilon_0$. This contradiction shows that our assumption was false, and hence $\{f_n\} \rightarrow f$ in measure on E .

Two comments. The finiteness of $m(E)$ is genuinely needed for the converse direction, and only there: it is the hypothesis of Proposition 3, which is the sole step converting a.e. pointwise convergence

back into convergence in measure. On a set of infinite measure the criterion fails, as the sequence $f_n = \chi_{[n, n+1)}$ on $E = \mathbb{R}$ shows: it converges to $f \equiv 0$ pointwise everywhere on $\mathbb{R}$, so certainly every subsequence has a further subsequence converging pointwise a.e. to f , yet as computed in Problem 9 it does not converge to f in measure.

Finally, observe that this criterion is precisely the mechanism used in Problem 8: it is the exact analogue, for convergence in measure, of the elementary fact that a numerical sequence converges to a provided every subsequence has a further subsequence converging to a . It expresses the fact that convergence in measure on a set of finite measure is the convergence associated with a topology, indeed with the metric ρ of Problem 14, in which a.e. pointwise convergence plays the role of a “subsequential” notion.

Problem 5.12. Show that a sequence $\{a_j\}$ of real numbers converges to a real number if $|a_{j+1} - a_j| \leq 1/2^j$ for all j by showing that the sequence $\{a_j\}$ must be Cauchy.

Solution. Let $\{a_j\}_{j=1}^\infty$ be a sequence of real numbers satisfying

$$|a_{j+1} - a_j| \leq \frac{1}{2^j} \quad \text{for all } j \geq 1.$$

The key estimate is obtained by telescoping. Let $n > m \geq 1$. Writing

$$a_n - a_m = \sum_{j=m}^{n-1} (a_{j+1} - a_j)$$

and applying the triangle inequality together with the hypothesis,

$$|a_n - a_m| \leq \sum_{j=m}^{n-1} |a_{j+1} - a_j| \leq \sum_{j=m}^{n-1} \frac{1}{2^j}.$$

The last sum is a finite geometric sum, which we evaluate exactly:

$$\sum_{j=m}^{n-1} \frac{1}{2^j} = \frac{1}{2^m} \cdot \frac{1 - (1/2)^{n-m}}{1 - 1/2} = \frac{1}{2^{m-1}} \left(1 - \frac{1}{2^{n-m}}\right) < \frac{1}{2^{m-1}}.$$

Hence

$$|a_n - a_m| < \frac{1}{2^{m-1}} \quad \text{whenever } n > m \geq 1. \quad (*)$$

Now we verify the Cauchy condition. Let $\epsilon > 0$. Since $2^k \geq k + 1 > k$ for every natural number k (an immediate induction), we have $1/2^k \rightarrow 0$, so we may choose a natural number N with

$$\frac{1}{2^{N-1}} < \epsilon.$$

Let $m, n \geq N$ be arbitrary. If $m = n$ then $|a_n - a_m| = 0 < \epsilon$. If $m \neq n$, relabel so that $n > m$; then $m \geq N$, and by $(*)$,

$$|a_n - a_m| < \frac{1}{2^{m-1}} \leq \frac{1}{2^{N-1}} < \epsilon,$$

using that $k \mapsto 1/2^{k-1}$ is decreasing. In every case $|a_n - a_m| < \epsilon$ for all $m, n \geq N$. Therefore $\{a_j\}$ is a Cauchy sequence of real numbers.

By the completeness of $\mathbb{R}$, that is, by the Cauchy Convergence Criterion (Theorem 17 of Chapter 1), every Cauchy sequence of real numbers converges to a real number. Hence $\{a_j\}$ converges to some $a \in \mathbb{R}$.

It is worth recording the quantitative form of the conclusion, which is what makes this lemma useful in the proof of Problem 13. Fixing m and letting $n \rightarrow \infty$ in $(*)$, the continuity of the absolute value gives

$$|a - a_m| \leq \frac{1}{2^{m-1}} \quad \text{for every } m \geq 1,$$

so the limit is approached at a definite geometric rate. Equivalently, the hypothesis says that the telescoping series $a_1 + \sum_{j \geq 1} (a_{j+1} - a_j)$ is absolutely convergent, since $\sum_{j=1}^{\infty} |a_{j+1} - a_j| \leq \sum_{j=1}^{\infty} 2^{-j} = 1 < \infty$, and its partial sums are exactly the a_n .

Problem 5.13. A sequence $\{f_n\}$ of measurable functions on E is said to be Cauchy in measure provided given $\eta > 0$ and $\epsilon > 0$ there is an index N such that for all $m, n \geq N$,

$$m\{x \in E \mid |f_n(x) - f_m(x)| \geq \eta\} < \epsilon.$$

Show that if $\{f_n\}$ is Cauchy in measure, then there is a measurable function f on E to which the sequence $\{f_n\}$ converges in measure. (Hint: Choose a strictly increasing sequence of natural numbers $\{n_j\}$ such that for each index j , if $E_j = \{x \in E \mid |f_{n_{j+1}}(x) - f_{n_j}(x)| > 1/2^j\}$, then $m(E_j) < 1/2^j$. Now use the Borel-Cantelli Lemma and the preceding problem.)

Solution. Assume $\{f_n\}$ is Cauchy in measure on E ; as always, each f_n is measurable and finite a.e. on E . Let Z be the union of the countably many sets $\{x \in E \mid |f_n(x)| = \infty\}$; then $m(Z) = 0$ and every f_n is real-valued on $E \sim Z$.

Step 1: extraction of a rapidly Cauchy subsequence. For each natural number j apply the Cauchy-in-measure hypothesis with $\eta = 1/2^j$ and $\epsilon = 1/2^j$ to obtain an index N_j such that

$$m\{x \in E \mid |f_n(x) - f_m(x)| \geq 1/2^j\} < 1/2^j \quad \text{for all } m, n \geq N_j.$$

Define $n_1 = N_1$ and, inductively, $n_{j+1} = \max\{N_{j+1}, n_j + 1\}$. Then $\{n_j\}$ is a strictly increasing sequence of natural numbers and $n_{j+1} > n_j \geq N_j$ for every j . Consequently, setting

$$E_j = \{x \in E \mid |f_{n_{j+1}}(x) - f_{n_j}(x)| > 1/2^j\},$$

which is a measurable set contained in $\{x \in E \mid |f_{n_{j+1}}(x) - f_{n_j}(x)| \geq 1/2^j\}$, we have

$$m(E_j) < \frac{1}{2^j} \quad \text{for every } j, \quad \text{so} \quad \sum_{j=1}^{\infty} m(E_j) < \sum_{j=1}^{\infty} \frac{1}{2^j} = 1 < \infty.$$

Step 2: the subsequence converges pointwise a.e. Each E_j is measurable, and so is $\limsup_j E_j = \bigcap_{k \geq 1} \bigcup_{j \geq k} E_j$, the set of points lying in infinitely many E_j . By the Borel-Cantelli Lemma (Chapter 2), since $\sum_j m(E_j) < \infty$, we have $m(\limsup_j E_j) = 0$. Put

$$E' = (E \sim Z) \sim \limsup_{j \rightarrow \infty} E_j,$$

a measurable subset of E with $m(E \sim E') \leq m(Z) + m(\limsup_j E_j) = 0$. Fix $x \in E'$. There is an index $J = J(x)$ with $x \notin E_j$ for all $j \geq J$, that is,

$$|f_{n_{j+1}}(x) - f_{n_j}(x)| \leq \frac{1}{2^j} \quad \text{for all } j \geq J.$$

Consider the real sequence $b_i = f_{n_{J+i-1}}(x)$, $i \geq 1$. For each i ,

$$|b_{i+1} - b_i| = |f_{n_{J+i}}(x) - f_{n_{J+i-1}}(x)| \leq \frac{1}{2^{J+i-1}} \leq \frac{1}{2^i},$$

since $J \geq 1$. By the preceding problem (Problem 12), $\{b_i\}$ is Cauchy and hence converges to a real number. Prepending the finitely many terms $f_{n_1}(x), \dots, f_{n_{J-1}}(x)$ does not affect convergence, so $\lim_{j \rightarrow \infty} f_{n_j}(x)$ exists and is real for every $x \in E'$.

Define f on E by $f(x) = \lim_{j \rightarrow \infty} f_{n_j}(x)$ for $x \in E'$ and $f(x) = 0$ for $x \in E \sim E'$. Then f is real-valued on all of E . It is also measurable, and no appeal to completeness of the measure is needed: set $g_j = f_{n_j}$ on E' and $g_j = 0$ on $E \sim E'$. Since E' is measurable, the restriction of g_j to E' is measurable (it agrees there with the measurable function f_{n_j}) and its restriction to $E \sim E'$ is constant, hence measurable; so

g_j is measurable on E by part (ii) of Proposition 5 of Chapter 3. By construction $\{g_j\} \rightarrow f$ pointwise on all of E : on E' by the previous paragraph, and on $E \sim E'$ because every g_j and f vanish there. Therefore f is measurable on E by Proposition 9 of Chapter 3.

Step 3: the subsequence converges to f in measure. For each index k put

$$F_k = \bigcup_{j \geq k} E_j, \quad \text{so} \quad m(F_k) \leq \sum_{j \geq k} m(E_j) < \sum_{j \geq k} \frac{1}{2^j} = \frac{1}{2^{k-1}}$$

by countable subadditivity. Let $x \in E' \sim F_k$. Then $|f_{n_{j+1}}(x) - f_{n_j}(x)| \leq 1/2^j$ for every $j \geq k$, so for $i > k$ the telescoping estimate of Problem 12 gives

$$|f_{n_i}(x) - f_{n_k}(x)| \leq \sum_{j=k}^{i-1} \frac{1}{2^j} < \frac{1}{2^{k-1}},$$

and letting $i \rightarrow \infty$ yields

$$|f(x) - f_{n_k}(x)| \leq \frac{1}{2^{k-1}} \quad \text{for all } x \in E' \sim F_k.$$

Hence

$$\left\{ x \in E \mid |f_{n_k}(x) - f(x)| > \frac{1}{2^{k-1}} \right\} \subseteq F_k \cup (E \sim E'),$$

a set of measure less than $1/2^{k-1}$. Now let $\eta > 0$ and $\epsilon > 0$. Choose K so large that $1/2^{K-1} < \min\{\eta, \epsilon\}$. For $k \geq K$ we have $1/2^{k-1} \leq 1/2^{K-1} < \eta$, so

$$m\{x \in E \mid |f_{n_k}(x) - f(x)| > \eta\} \leq m\left\{x \in E \mid |f_{n_k}(x) - f(x)| > \frac{1}{2^{k-1}}\right\} < \frac{1}{2^{k-1}} \leq \frac{1}{2^{K-1}} < \epsilon.$$

Thus $\{f_{n_k}\} \rightarrow f$ in measure on E .

Step 4: the full sequence converges to f in measure. Let $\eta > 0$ and $\epsilon > 0$. Since $\{f_n\}$ is Cauchy in measure, choose N with

$$m\{x \in E \mid |f_n(x) - f_p(x)| \geq \eta/2\} < \epsilon/2 \quad \text{for all } n, p \geq N.$$

By Step 3 choose an index k so large that $n_k \geq N$ and

$$m\{x \in E \mid |f_{n_k}(x) - f(x)| > \eta/2\} < \epsilon/2.$$

Fix such a k . For any $n \geq N$ and any $x \in E \sim Z$ (where all the values in question are real), the triangle inequality shows that if $|f_n(x) - f(x)| > \eta$ then at least one of $|f_n(x) - f_{n_k}(x)| \geq \eta/2$ and $|f_{n_k}(x) - f(x)| > \eta/2$ must hold: if both failed, the sum of the two moduli would be less than η , contradicting $|f_n(x) - f(x)| \leq |f_n(x) - f_{n_k}(x)| + |f_{n_k}(x) - f(x)|$. That is,

$$\{x \in E \mid |f_n(x) - f(x)| > \eta\} \subseteq \{x \in E \mid |f_n(x) - f_{n_k}(x)| \geq \eta/2\} \cup \{x \in E \mid |f_{n_k}(x) - f(x)| > \eta/2\} \cup Z,$$

the last set being of measure zero and therefore contributing nothing to the estimate below. Since $n \geq N$ and $n_k \geq N$, monotonicity and finite subadditivity give

$$m\{x \in E \mid |f_n(x) - f(x)| > \eta\} < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon \quad \text{for all } n \geq N.$$

As $\eta > 0$ and $\epsilon > 0$ were arbitrary, $\{f_n\} \rightarrow f$ in measure on E . This exhibits the required measurable limit function and shows that the measurable functions on E are complete with respect to convergence in measure.

Note also that Step 2 delivers, at no extra cost, the Riesz-type conclusion that the subsequence $\{f_{n_j}\}$ converges to f pointwise almost everywhere on E ; and no assumption whatever was made about $m(E)$.

Problem 5.14. Assume $m(E) < \infty$. For two measurable functions g and h on E , define

$$\rho(g, h) = \int_E \frac{|g - h|}{1 + |g - h|}.$$

Show that $\{f_n\} \rightarrow f$ in measure on E if and only if $\lim_{n \rightarrow \infty} \rho(f_n, f) = 0$.

Solution. Write $\varphi(t) = t/(1+t)$ for $t \in [0, \infty)$. Two elementary properties of φ carry the whole proof: (i) φ is increasing on $[0, \infty)$, since $\varphi'(t) = 1/(1+t)^2 > 0$; equivalently, for $0 \leq s \leq t$ one has $s(1+t) \leq t(1+s)$, whence $\varphi(s) \leq \varphi(t)$.

(ii) $0 \leq \varphi(t) < 1$ for all $t \geq 0$, since $t < 1+t$.

First, ρ is well defined and finite. By our standing convention f and each f_n is measurable and finite a.e. on E . Let Z be the union of the countably many sets $\{x \in E \mid |f(x)| = \infty\}$ and $\{x \in E \mid |f_n(x)| = \infty\}$; then Z is measurable and $m(Z) = 0$, and on $E \sim Z$ every one of these functions is real-valued, so $|f_n - f|$ is a nonnegative real-valued measurable function there. Hence $\varphi \circ |f_n - f|$ is measurable on $E \sim Z$, being the composition of a continuous function with a measurable real-valued function (Proposition 7 of Chapter 3); extend it by the value 1 on Z , which alters no integral since $m(Z) = 0$ and leaves the extension measurable by Proposition 5 of Chapter 3. By (ii) the integrand is bounded above by 1 on E , and since $m(E) < \infty$ the monotonicity of integration gives

$$0 \leq \rho(f_n, f) = \int_E \varphi(|f_n - f|) \leq \int_E 1 = m(E) < \infty.$$

So $\{\rho(f_n, f)\}$ is a sequence of nonnegative real numbers.

Suppose first that $\{f_n\} \rightarrow f$ in measure on E ; we show $\rho(f_n, f) \rightarrow 0$. If $m(E) = 0$ then $\rho(f_n, f) = 0$ for all n and there is nothing to prove, so assume $m(E) > 0$. Let $\epsilon > 0$. Choose

$$\eta = \frac{\epsilon}{2m(E)} > 0,$$

and set $A_n = \{x \in E \mid |f_n(x) - f(x)| > \eta\}$, a measurable set. Split the integral over A_n and $E \sim A_n$ (Theorem 11 of Chapter 4, additivity over domains of integration for nonnegative measurable functions). On A_n we use only the crude bound (ii), $\varphi \leq 1$; on $E \sim A_n$ we have $|f_n - f| \leq \eta$ off the null set Z , so by (i), $\varphi(|f_n - f|) \leq \varphi(\eta) = \eta/(1+\eta) \leq \eta$ a.e. there. Therefore

$$\rho(f_n, f) = \int_{A_n} \varphi(|f_n - f|) + \int_{E \sim A_n} \varphi(|f_n - f|) \leq m(A_n) + \eta \cdot m(E \sim A_n) \leq m(A_n) + \eta \cdot m(E) = m(A_n) + \frac{\epsilon}{2}.$$

Since $\{f_n\} \rightarrow f$ in measure and $\eta > 0$, there is an index N such that $m(A_n) < \epsilon/2$ for all $n \geq N$. Hence $\rho(f_n, f) < \epsilon$ for all $n \geq N$, and $\lim_{n \rightarrow \infty} \rho(f_n, f) = 0$.

Conversely, suppose $\lim_{n \rightarrow \infty} \rho(f_n, f) = 0$; we show $\{f_n\} \rightarrow f$ in measure on E . Let $\eta > 0$ and $\epsilon > 0$ be given, and again write $A_n = \{x \in E \mid |f_n(x) - f(x)| > \eta\}$. For a.e. $x \in A_n$ we have $|f_n(x) - f(x)| > \eta$, so by the monotonicity (i) of φ ,

$$\varphi(|f_n(x) - f(x)|) \geq \varphi(\eta) = \frac{\eta}{1+\eta}.$$

Since the integrand is nonnegative on all of E , monotonicity of integration gives the Chebychev-type estimate

$$\rho(f_n, f) = \int_E \varphi(|f_n - f|) \geq \int_{A_n} \varphi(|f_n - f|) \geq \frac{\eta}{1+\eta} \cdot m(A_n),$$

that is,

$$m(A_n) \leq \frac{1+\eta}{\eta} \rho(f_n, f).$$

Because $\rho(f_n, f) \rightarrow 0$ and $(1+\eta)/\eta$ is a fixed constant, there is an index N such that $\frac{1+\eta}{\eta} \rho(f_n, f) < \epsilon$, and hence $m(A_n) < \epsilon$, for all $n \geq N$. As $\eta > 0$ and $\epsilon > 0$ were arbitrary, $\{f_n\} \rightarrow f$ in measure on E .

This completes the proof of the equivalence. Observe that finiteness of $m(E)$ was used only in the first implication, where the uniform smallness of $\varphi(|f_n - f|)$ off A_n had to be integrated over E ; the second implication is valid on any measurable set. The first implication genuinely fails when $m(E) = \infty$: on $E = \mathbb{R}$ take $f_n = (1/n)\chi_{[0,n]}$ and $f \equiv 0$. For fixed $\eta > 0$ the set $\{x \in \mathbb{R} \mid |f_n(x)| > \eta\}$ is empty as soon as $n > 1/\eta$, so $\{f_n\} \rightarrow 0$ in measure on $\mathbb{R}$; yet the integrand $\varphi(|f_n|)$ equals the constant $(1/n)/(1+1/n)$ on $[0, n]$ and vanishes off it, so

$$\rho(f_n, 0) = n \cdot \frac{1/n}{1+1/n} = \frac{1}{1+1/n} \rightarrow 1 \neq 0.$$

Finally, ρ is in fact a pseudometric on the measurable functions on E , and a metric once functions equal a.e. are identified. Symmetry and nonnegativity are clear, and $\rho(g, h) = 0$ forces $\varphi(|g - h|) = 0$ a.e. (Proposition 9 of Chapter 4), hence $g = h$ a.e. For the triangle inequality one uses that φ is increasing and subadditive: for $s, t \geq 0$,

$$\varphi(s+t) = \frac{s+t}{1+s+t} = \frac{s}{1+s+t} + \frac{t}{1+s+t} \leq \frac{s}{1+s} + \frac{t}{1+t} = \varphi(s) + \varphi(t),$$

so from $|g - k| \leq |g - h| + |h - k|$ we get $\varphi(|g - k|) \leq \varphi(|g - h|) + \varphi(|h - k|)$ pointwise, and integrating gives $\rho(g, k) \leq \rho(g, h) + \rho(h, k)$. Thus the exercise identifies convergence in measure on a set of finite measure as convergence in a metric, which is why the subsequence criterion of Problem 11 holds for it and why Problem 13 is the assertion that this metric space is complete.

5.3 Problems 5.15–5.17

Problem 5.15. Let f and g be bounded functions that are Riemann integrable over $[a, b]$. Show that the product fg also is Riemann integrable over $[a, b]$.

Solution. Since f and g are bounded, so is fg : if $|f| \leq M_1$ and $|g| \leq M_2$ on $[a, b]$, then $|fg| \leq M_1 M_2$. Put $M = \max\{M_1, M_2\}$, so that $|f| \leq M$ and $|g| \leq M$ on $[a, b]$.

A first proof, via Theorem 8. Let D_f , D_g and D_{fg} denote the sets of points of $[a, b]$ at which f , g and fg , respectively, fail to be continuous. If $x_0 \in [a, b]$ is a point at which both f and g are continuous, then fg is continuous at x_0 : indeed, for $x \in [a, b]$,

$$|f(x)g(x) - f(x_0)g(x_0)| \leq |f(x)| |g(x) - g(x_0)| + |g(x_0)| |f(x) - f(x_0)| \leq M(|g(x) - g(x_0)| + |f(x) - f(x_0)|),$$

and the right-hand side is less than ϵ once $|x - x_0| < \delta$, where $\delta > 0$ is chosen so small that $|f(x) - f(x_0)| < \epsilon/(2M + 1)$ and $|g(x) - g(x_0)| < \epsilon/(2M + 1)$ for such x . Contrapositively,

$$D_{fg} \subseteq D_f \cup D_g.$$

Now f and g are bounded and Riemann integrable over $[a, b]$, so by Theorem 8 (Lebesgue) of this chapter, $m(D_f) = 0$ and $m(D_g) = 0$. By the countable (here, finite) subadditivity of outer measure, $m^*(D_f \cup D_g) = 0$, and hence $m^*(D_{fg}) = 0$; a set of outer measure zero is measurable with measure zero. Thus fg is a bounded function on $[a, b]$ whose set of discontinuities has measure zero, and therefore, by the converse half of Theorem 8, fg is Riemann integrable over $[a, b]$.

A second proof, directly from the Darboux sums. For a nonempty set $S \subseteq [a, b]$ and a bounded function h on $[a, b]$, write

$$\text{osc}(h, S) = \sup_{x \in S} h(x) - \inf_{x \in S} h(x) = \sup_{x, y \in S} |h(x) - h(y)|.$$

For $x, y \in S$,

$$|f(x)g(x) - f(y)g(y)| \leq |f(x)| |g(x) - g(y)| + |g(y)| |f(x) - f(y)| \leq M \text{osc}(g, S) + M \text{osc}(f, S),$$

and taking the supremum over $x, y \in S$ gives

$$\text{osc}(fg, S) \leq M[\text{osc}(f, S) + \text{osc}(g, S)].$$

Let $P = \{x_0 = a < x_1 < \cdots < x_n = b\}$ be a partition of $[a, b]$ and $I_i = [x_{i-1}, x_i]$. Since $U(h, P) - L(h, P) = \sum_{i=1}^n \text{osc}(h, I_i)(x_i - x_{i-1})$, the displayed inequality gives

$$U(fg, P) - L(fg, P) \leq M[U(f, P) - L(f, P)] + M[U(g, P) - L(g, P)].$$

Let $\epsilon > 0$ and put $\eta = \epsilon/(2M + 1)$. Because f is Riemann integrable, its upper and lower Riemann integrals have the common value $\int_a^b f$; since the upper Riemann integral is the infimum of the upper Darboux sums and the lower Riemann integral is the supremum of the lower Darboux sums, there are partitions Q and Q' of $[a, b]$ with

$$U(f, Q) < \int_a^b f + \frac{\eta}{2}, \quad L(f, Q') > \int_a^b f - \frac{\eta}{2}.$$

Let $P_1 = Q \cup Q'$, a refinement of both. Under refinement upper Darboux sums decrease and lower Darboux sums increase (Problem 2 of Chapter 4), so $U(f, P_1) \leq U(f, Q)$ and $L(f, P_1) \geq L(f, Q')$, and hence $U(f, P_1) - L(f, P_1) < \eta$. Similarly there is a partition P_2 with $U(g, P_2) - L(g, P_2) < \eta$. Let P be the common refinement $P_1 \cup P_2$. Invoking monotonicity under refinement once more,

$$U(f, P) - L(f, P) \leq U(f, P_1) - L(f, P_1) < \eta, \quad U(g, P) - L(g, P) \leq U(g, P_2) - L(g, P_2) < \eta,$$

and therefore $U(fg, P) - L(fg, P) < 2M\eta = 2M\epsilon/(2M + 1) < \epsilon$. Since

$$0 \leq \overline{\int_a^b fg} - \underline{\int_a^b fg} \leq U(fg, P) - L(fg, P) < \epsilon$$

for every $\epsilon > 0$, the upper and lower Riemann integrals of fg coincide, that is, fg is Riemann integrable over $[a, b]$.

Problem 5.16. Let f be a bounded function on $[a, b]$ whose set of discontinuities has measure zero. Show that f is measurable. Then show that the same holds without the assumption of boundedness.

Solution. Throughout, D denotes the set of points of $[a, b]$ at which f fails to be continuous, and we assume $m(D) = 0$.

The bounded case. Suppose f is bounded on $[a, b]$. By Theorem 8 (Lebesgue) of this chapter, a bounded function on $[a, b]$ is Riemann integrable over $[a, b]$ if and only if its set of discontinuities has measure zero; since $m(D) = 0$, the function f is Riemann integrable over $[a, b]$. By Theorem 3 of Chapter 4, a bounded function that is Riemann integrable over the closed, bounded interval $[a, b]$ is then Lebesgue integrable over $[a, b]$ and the two integrals are equal. Finally, by Theorem 7 of this chapter, a bounded function on a set of finite measure is Lebesgue integrable over that set if and only if it is measurable; since $[a, b]$ has finite measure and f is bounded and Lebesgue integrable over $[a, b]$, the function f is measurable.

It is worth recording a direct argument for the bounded case, since it uses no integration theory at all and will not need boundedness either. Let $E = [a, b] \setminus D$ be the set of points at which f is continuous. Since $m(D) = 0$, the set D is measurable, and hence so is E , being the relative complement of a measurable set in a measurable set. The restriction $f|_E$ is continuous as a function on the metric space E : given $x_0 \in E$ and $\epsilon > 0$, continuity of f at x_0 provides $\delta > 0$ with $|f(x) - f(x_0)| < \epsilon$ for all $x \in [a, b]$ with $|x - x_0| < \delta$, and in particular for all such x lying in E . Therefore, for each $c \in \mathbb{R}$, the set

$$\{x \in E : f(x) > c\}$$

is relatively open in E , so it has the form $E \cap U$ with $U \subseteq \mathbb{R}$ open, and hence is measurable, being the intersection of two measurable sets. On the other hand

$$\{x \in D : f(x) > c\} \subseteq D,$$

and $m(D) = 0$; since Lebesgue measure is complete, every subset of a set of measure zero is measurable

(of measure zero). Consequently

$$\{x \in [a, b] : f(x) > c\} = \{x \in E : f(x) > c\} \cup \{x \in D : f(x) > c\}$$

is measurable for every $c \in \mathbb{R}$, that is, f is measurable. Note that nowhere was boundedness used. The unbounded case, by truncation. Suppose now f is an arbitrary real-valued function on $[a, b]$ whose set D of discontinuities has measure zero. For a natural number n define the truncation

$$f_n(x) = \max\{-n, \min\{n, f(x)\}\} = \begin{cases} n & \text{if } f(x) > n, \\ f(x) & \text{if } -n \leq f(x) \leq n, \\ -n & \text{if } f(x) < -n. \end{cases}$$

Then $f_n = \varphi_n \circ f$, where $\varphi_n(t) = \max\{-n, \min\{n, t\}\}$ is continuous on $\mathbb{R}$ (it is 1-Lipschitz, since $|\varphi_n(s) - \varphi_n(t)| \leq |s - t|$). If f is continuous at x_0 , then so is $\varphi_n \circ f$, since $|f_n(x) - f_n(x_0)| = |\varphi_n(f(x)) - \varphi_n(f(x_0))| \leq |f(x) - f(x_0)|$; hence f_n is continuous at every point of $E = [a, b] \setminus D$, so the set of discontinuities of f_n is contained in D and therefore has measure zero. Moreover $|f_n| \leq n$, so f_n is bounded. By the bounded case already proved, each f_n is measurable on $[a, b]$.

Finally, $\{f_n\} \rightarrow f$ pointwise on $[a, b]$: given $x \in [a, b]$, the number $f(x)$ is real, so for all $n \geq |f(x)|$ we have $f_n(x) = f(x)$. A pointwise limit of a sequence of measurable functions is measurable (Proposition 9 of Chapter 3). Therefore f is measurable.

Alternatively, and more briefly, the direct argument given above already proves the unbounded case verbatim: it shows that for every $c \in \mathbb{R}$ the set $\{x \in [a, b] : f(x) > c\}$ splits as a relatively open subset of the continuity set E together with a subset of the null set D , both of which are measurable, and boundedness of f played no role.

Problem 5.17. Let f be a function on $[0, 1]$ that is continuous on $(0, 1]$. Show that it is possible for the sequence $\left\{\int_{[1/n, 1]} f\right\}$ to converge and yet f is not Lebesgue integrable over $[0, 1]$. Can this happen if f is nonnegative?

Solution. An example. Define f on $[0, 1]$ by

$$f(x) = \begin{cases} \frac{1}{x} \sin \frac{1}{x} & \text{if } 0 < x \leq 1, \\ 0 & \text{if } x = 0. \end{cases}$$

Then f is continuous on $(0, 1]$, being built from continuous functions by composition, product and quotient with nonvanishing denominator. It is measurable on $[0, 1]$. Indeed, fix $c \in \mathbb{R}$. Since f is continuous on $(0, 1]$, the set $\{x \in (0, 1] : f(x) > c\}$ is relatively open in $(0, 1]$, so it equals $(0, 1] \cap U$ for some open $U \subseteq \mathbb{R}$ and is therefore measurable; and

$$\{x \in [0, 1] : f(x) > c\} = (\{x \in (0, 1] : f(x) > c\}) \cup S, \quad \text{where } S = \{0\} \text{ if } f(0) > c \text{ and } S = \emptyset \text{ otherwise,}$$

a union of two measurable sets. Hence f is measurable on $[0, 1]$. The same remark shows that any function on $[0, 1]$ that is continuous on $(0, 1]$ is measurable, and we use it again below.

Fix $n \geq 2$. On the closed, bounded interval $[1/n, 1]$ the function f is continuous, hence bounded and Riemann integrable (Problem 6 of Chapter 4), so by Theorem 3 of Chapter 4 its Lebesgue integral over $[1/n, 1]$ equals its Riemann integral there. The change of variable $u = 1/x$, $x = 1/u$, $dx = -du/u^2$ is a C^1 diffeomorphism of $[1/n, 1]$ onto $[1, n]$, and it gives

$$\int_{[1/n, 1]} f = \int_{1/n}^1 \frac{1}{x} \sin \frac{1}{x} dx = \int_n^1 u \sin u \cdot \left(-\frac{1}{u^2}\right) du = \int_1^n \frac{\sin u}{u} du.$$

This sequence of real numbers converges, and we verify it by the Cauchy criterion, using nothing beyond the calculus of continuous functions on closed, bounded intervals. Let $2 \leq n < m$. Integration

by parts on $[n, m]$, where $u \mapsto \sin u/u$ and $u \mapsto \cos u/u$ are continuously differentiable, gives

$$\int_n^m \frac{\sin u}{u} du = \left[\frac{-\cos u}{u} \right]_n^m - \int_n^m \frac{\cos u}{u^2} du = \frac{\cos n}{n} - \frac{\cos m}{m} - \int_n^m \frac{\cos u}{u^2} du.$$

Since $|\cos u| \leq 1$,

$$\left| \int_n^m \frac{\sin u}{u} du \right| \leq \frac{1}{n} + \frac{1}{m} + \int_n^m \frac{du}{u^2} = \frac{1}{n} + \frac{1}{m} + \frac{1}{n} - \frac{1}{m} = \frac{2}{n}.$$

Writing $a_n = \int_{[1/n, 1]} f = \int_1^n (\sin u)/u du$, this says $|a_m - a_n| \leq 2/n$ for all $m > n \geq 2$, so $\{a_n\}$ is a Cauchy sequence of real numbers and therefore converges. Thus $\{\int_{[1/n, 1]} f\}$ converges.

Nevertheless f is not Lebesgue integrable over $[0, 1]$, because $\int_{[0, 1]} |f| = \infty$. The same change of variable applied to $|f|$ gives, for each $n \geq 2$,

$$\int_{[1/n, 1]} |f| = \int_1^n \frac{|\sin u|}{u} du.$$

For each natural number k ,

$$\int_{k\pi}^{(k+1)\pi} \frac{|\sin u|}{u} du \geq \frac{1}{(k+1)\pi} \int_{k\pi}^{(k+1)\pi} |\sin u| du = \frac{2}{(k+1)\pi}.$$

Given $n \geq 4$, let K be the largest natural number with $(K+1)\pi \leq n$; then $K \geq 1$ and $K \rightarrow \infty$ as $n \rightarrow \infty$. The intervals $[k\pi, (k+1)\pi]$ for $1 \leq k \leq K$ are pairwise nonoverlapping and all contained in $[1, n]$, since $\pi > 1$. As the integrand is nonnegative,

$$\int_1^n \frac{|\sin u|}{u} du \geq \sum_{k=1}^K \int_{k\pi}^{(k+1)\pi} \frac{|\sin u|}{u} du \geq \frac{2}{\pi} \sum_{k=1}^K \frac{1}{k+1},$$

and the harmonic series diverges, so the right-hand side tends to ∞ with K . Hence $\int_1^n |\sin u| u^{-1} du \rightarrow \infty$ as $n \rightarrow \infty$. Now $\{|f| \cdot \chi_{[1/n, 1]}\}$ is an increasing sequence of nonnegative measurable functions on $[0, 1]$ converging pointwise on $[0, 1]$ to $|f| \cdot \chi_{(0, 1]}$, which differs from $|f|$ only at the single point $x = 0$ and so equals $|f|$ almost everywhere on $[0, 1]$. Two nonnegative measurable functions that agree almost everywhere have the same integral, so by the Monotone Convergence Theorem,

$$\int_{[0, 1]} |f| = \int_{[0, 1]} |f| \cdot \chi_{(0, 1]} = \lim_{n \rightarrow \infty} \int_{[0, 1]} |f| \cdot \chi_{[1/n, 1]} = \lim_{n \rightarrow \infty} \int_{[1/n, 1]} |f| = \infty.$$

A measurable function f is Lebesgue integrable over $[0, 1]$ precisely when $\int_{[0, 1]} |f| < \infty$; hence f is not Lebesgue integrable over $[0, 1]$, although $\{\int_{[1/n, 1]} f\}$ converges. This answers the first part.

The nonnegative case. No, this cannot happen if $f \geq 0$. Suppose f is a nonnegative real-valued function on $[0, 1]$ that is continuous on $(0, 1]$ and for which the sequence $\{\int_{[1/n, 1]} f\}$ converges, say to the finite number L . By the remark recorded at the start of this solution, f is measurable on $[0, 1]$, and each $\int_{[1/n, 1]} f$ is a well-defined element of $[0, \infty]$; it is in fact finite, since f is continuous, hence bounded, on the closed, bounded interval $[1/n, 1]$.

Since $f \geq 0$, the sequence of functions $f_n = f \cdot \chi_{[1/n, 1]}$ is a nondecreasing sequence of nonnegative measurable functions on $[0, 1]$, and it converges pointwise on $[0, 1]$ to $f \cdot \chi_{(0, 1]}$, a function that agrees with f except at $x = 0$, hence agrees with f almost everywhere on $[0, 1]$. By the Monotone Convergence Theorem,

$$\int_{[0, 1]} f = \int_{[0, 1]} f \cdot \chi_{(0, 1]} = \lim_{n \rightarrow \infty} \int_{[1/n, 1]} f = L < \infty.$$

Thus f is a nonnegative measurable function on $[0, 1]$ with finite integral, and since $|f| = f$, this says exactly that f is Lebesgue integrable over $[0, 1]$. So for nonnegative f the convergence of $\{\int_{[1/n, 1]} f\}$ forces Lebesgue integrability over $[0, 1]$; the phenomenon exhibited above depends essentially on the cancellation between the positive and negative parts of f .

6.1 Problems 6.1–6.7

Problem 6.1. Let C be a countable subset of the nondegenerate closed, bounded interval $[a, b]$. Show that there is an increasing function on $[a, b]$ that is continuous only at points in $[a, b] \sim C$.

Solution. This is Proposition 2 with the open interval (a, b) replaced by the closed interval $[a, b]$. The only new feature is the left endpoint: at $x_0 = a$ continuity of a function on $[a, b]$ means continuity from the right, so a jump placed at a must be a jump to the right. We therefore use two kinds of jump functions.

If C is empty, take $f(x) = x$, which is increasing and continuous at every point of $[a, b]$. So assume $C \neq \emptyset$ and let $\{q_n\}_{n \in \Lambda}$ be an enumeration of C , where $\Lambda = \{1, 2, \dots, N\}$ if C is finite and $\Lambda = \{1, 2, 3, \dots\}$ if C is countably infinite. For each $n \in \Lambda$ define a function φ_n on $[a, b]$ by

$$\varphi_n(x) = \begin{cases} 1 & \text{if } x \geq q_n \\ 0 & \text{if } x < q_n \end{cases} \quad \text{in case } q_n > a,$$

$$\varphi_n(x) = \begin{cases} 1 & \text{if } x > a \\ 0 & \text{if } x = a \end{cases} \quad \text{in case } q_n = a.$$

In either case φ_n takes only the values 0 and 1, is increasing on $[a, b]$, and is continuous at every point of $[a, b]$ except at q_n . Define

$$f(x) = \sum_{n \in \Lambda} \frac{1}{2^n} \varphi_n(x) \quad \text{for all } x \in [a, b].$$

Since $0 \leq \varphi_n \leq 1$ and $\sum_n 2^{-n} \leq 1$, the series converges for every x , so f is a properly defined real-valued function on $[a, b]$. Moreover f is increasing: if $a \leq u < v \leq b$, then $\varphi_n(u) \leq \varphi_n(v)$ for every n , and hence, all the terms being nonnegative,

$$f(v) - f(u) = \sum_{n \in \Lambda} \frac{1}{2^n} [\varphi_n(v) - \varphi_n(u)] \geq 0. \quad (1)$$

f fails to be continuous at each point of C . Fix $k \in \Lambda$. Suppose first that $q_k > a$. If $x \in [a, b]$ and $x < q_k$, then $\varphi_k(q_k) - \varphi_k(x) = 1$, so by (1), applied with $u = x$ and $v = q_k$ and by discarding all terms but the k -th,

$$f(q_k) - f(x) \geq \frac{1}{2^k} \quad \text{for all } x \in [a, b] \text{ with } x < q_k.$$

Since $q_k > a$, there are points x of $[a, b]$ with $x < q_k$ arbitrarily close to q_k , and therefore f is not continuous at q_k . Now suppose $q_k = a$. If $x \in (a, b]$, then $\varphi_k(x) - \varphi_k(a) = 1$ and the same reasoning gives $f(x) - f(a) \geq 1/2^k$ for all $x \in (a, b]$; since $a < b$ there are such x arbitrarily close to a , and again f is not continuous at $q_k = a$.

f is continuous at each point of $[a, b] \sim C$. Let $x_0 \in [a, b] \sim C$ and let $\epsilon > 0$. Choose a natural number M with $1/2^M < \epsilon$ and put $\Lambda_M = \{n \in \Lambda : n \leq M\}$, a finite set. In both of the above cases the single point at which φ_n fails to be continuous is q_n , and $x_0 \neq q_n$ for every $n \in \Lambda$ because $x_0 \notin C$. Define

$$\delta = \min\{|x_0 - q_n| : n \in \Lambda_M\} > 0$$

(with $\delta = b - a$ if Λ_M is empty). Let $x \in [a, b]$ with $|x - x_0| < \delta$, and fix $n \in \Lambda_M$. The interval $(x_0 - \delta, x_0 + \delta)$ does not contain q_n . Each φ_n is constant on $(-\infty, q_n) \cap [a, b]$ and constant on $[q_n, \infty) \cap [a, b]$ (respectively on $\{a\}$ and on $(a, b]$ in the second case), and an interval that omits q_n lies entirely in one of these two pieces; hence $\varphi_n(x) = \varphi_n(x_0)$. Consequently all the terms with $n \leq M$ cancel and

$$|f(x) - f(x_0)| = \left| \sum_{n \in \Lambda, n > M} \frac{1}{2^n} [\varphi_n(x) - \varphi_n(x_0)] \right| \leq \sum_{n > M} \frac{1}{2^n} = \frac{1}{2^M} < \epsilon.$$

Therefore f is continuous at x_0 .

Thus f is an increasing function on $[a, b]$ whose set of points of continuity is exactly $[a, b] \sim C$.

Problem 6.2. Show that there is a strictly increasing function on $[0, 1]$ that is continuous only at the irrational numbers in $[0, 1]$.

Solution. Let $C = \mathbb{Q} \cap [0, 1]$, the set of rational numbers in $[0, 1]$. This is a countable subset of the nondegenerate closed, bounded interval $[0, 1]$, so by the preceding problem there is an increasing function g on $[0, 1]$ whose set of points of continuity is exactly $[0, 1] \setminus C$, that is, exactly the set of irrational numbers in $[0, 1]$. Define

$$f(x) = g(x) + x \quad \text{for all } x \in [0, 1].$$

f is strictly increasing. If $0 \leq u < v \leq 1$, then $g(u) \leq g(v)$ because g is increasing, and $u < v$, so

$$f(v) - f(u) = [g(v) - g(u)] + (v - u) \geq v - u > 0.$$

f has the same points of continuity as g . The function $x \mapsto x$ is continuous on $[0, 1]$. Hence if g is continuous at x_0 , so is the sum $f = g + \text{id}$; and conversely, if f is continuous at x_0 , then so is $g = f - \text{id}$, being the difference of two functions continuous at x_0 . Therefore f is continuous at x_0 if and only if g is, and so the set of points of continuity of f is exactly the set of irrational numbers in $[0, 1]$.

Thus f is a strictly increasing function on $[0, 1]$ that is continuous at every irrational point of $[0, 1]$ and at no rational point of $[0, 1]$. (Note that the endpoints 0 and 1 are rational and hence are points of discontinuity; this is why in the preceding problem the jump associated with the left endpoint had to be a jump to the right, so that the one-sided continuity of f at 0 also fails.)

Problem 6.3. Let f be a monotone function on a subset E of $\mathbb{R}$. Show that f is continuous except possibly at a countable number of points in E .

Solution. Here continuity is continuity of f as a function on E : f is continuous at $x_0 \in E$ provided for each $\epsilon > 0$ there is a $\delta > 0$ such that $|f(x) - f(x_0)| < \epsilon$ for all $x \in E$ with $|x - x_0| < \delta$.

Replacing f by $-f$ changes neither monotonicity nor the set of points of continuity, so we may assume f is increasing on E . Let D denote the set of points of E at which f fails to be continuous. We must show D is countable.

For $x_0 \in E$ define

$$L(x_0) = \begin{cases} \sup\{f(x) : x \in E, x < x_0\} & \text{if } x_0 \text{ is a limit point of } E \cap (-\infty, x_0) \\ f(x_0) & \text{otherwise,} \end{cases}$$

$$R(x_0) = \begin{cases} \inf\{f(x) : x \in E, x > x_0\} & \text{if } x_0 \text{ is a limit point of } E \cap (x_0, \infty) \\ f(x_0) & \text{otherwise.} \end{cases}$$

In the first alternative the set over which the supremum is taken is nonempty and bounded above by $f(x_0)$, since f is increasing; so $L(x_0)$ is a real number and $L(x_0) \leq f(x_0)$. Similarly $R(x_0)$ is a real number and $f(x_0) \leq R(x_0)$. Thus in all cases

$$L(x_0) \leq f(x_0) \leq R(x_0).$$

Claim: if $L(x_0) = f(x_0) = R(x_0)$, then f is continuous at x_0 . Let $\epsilon > 0$. We produce $\delta_1 > 0$ controlling the left side. If x_0 is not a limit point of $E \cap (-\infty, x_0)$, choose $\delta_1 > 0$ with $E \cap (x_0 - \delta_1, x_0) = \emptyset$; then there is nothing to check on the left. Otherwise $\sup\{f(x) : x \in E, x < x_0\} = f(x_0)$, so there is a $z \in E$ with $z < x_0$ and $f(z) > f(x_0) - \epsilon$; put $\delta_1 = x_0 - z$. If $x \in E$ and $x_0 - \delta_1 < x < x_0$, then $z < x < x_0$ and, f being increasing, $f(x_0) - \epsilon < f(z) \leq f(x) \leq f(x_0)$. Symmetrically there is $\delta_2 > 0$ such that $f(x_0) \leq f(x) < f(x_0) + \epsilon$ whenever $x \in E$ and $x_0 < x < x_0 + \delta_2$. With $\delta = \min\{\delta_1, \delta_2\}$ we have $|f(x) - f(x_0)| < \epsilon$ for all $x \in E$ with $|x - x_0| < \delta$. This proves the claim.

Consequently, for each $x_0 \in D$ we have $L(x_0) < f(x_0)$ or $f(x_0) < R(x_0)$; in either case $L(x_0) < R(x_0)$, so

$$J(x_0) = (L(x_0), R(x_0))$$

is a nonempty open interval of real numbers.

Claim: the intervals $\{J(x_0)\}_{x_0 \in D}$ are disjoint. Let $x_0, x_1 \in D$ with $x_0 < x_1$; it suffices to show $R(x_0) \leq L(x_1)$. Suppose first that there is a point $z \in E$ with $x_0 < z < x_1$. If x_0 is a limit point of $E \cap (x_0, \infty)$, then $R(x_0)$ is an infimum over a set containing $f(z)$, so $R(x_0) \leq f(z)$; if not, $R(x_0) = f(x_0) \leq f(z)$ since f is increasing. Either way $R(x_0) \leq f(z)$. Symmetrically $f(z) \leq L(x_1)$. Hence $R(x_0) \leq L(x_1)$. Suppose next that no point of E lies strictly between x_0 and x_1 . Then x_0 is not a limit point of $E \cap (x_0, \infty)$ and x_1 is not a limit point of $E \cap (-\infty, x_1)$, so $R(x_0) = f(x_0) \leq f(x_1) = L(x_1)$. In both cases $R(x_0) \leq L(x_1)$, so the open intervals $J(x_0)$ and $J(x_1)$ are disjoint. This proves the claim. Finally, each nonempty open interval $J(x_0)$ contains a rational number; choose one, say $r(x_0)$. Since the intervals are disjoint, the map $x_0 \mapsto r(x_0)$ from D to $\mathbb{Q}$ is one-to-one. Therefore D is equipotent to a subset of the countable set $\mathbb{Q}$ and hence is countable.

Thus a monotone function on a subset E of $\mathbb{R}$ is continuous at every point of E except possibly at the points of a countable subset of E . Taking $E = (a, b)$ recovers Theorem 1.

Problem 6.4. Let E be a subset of $\mathbb{R}$ and C a countable subset of E . Is there a monotone function on E that is continuous only at points in $E \sim C$?

Solution. In general, no. The obstruction is the isolated points of E , and in fact there is such a function if and only if C contains no point that is isolated in E .

A counterexample. Let $E = \{0\} \cup [1, 2]$ and $C = \{0\}$, a countable subset of E . The point 0 is isolated in E : taking $\delta = 1$, the only point x of E with $|x - 0| < \delta$ is $x = 0$. Hence for any function g whatsoever on E and any $\epsilon > 0$, the choice $\delta = 1$ gives $|g(x) - g(0)| = 0 < \epsilon$ for all $x \in E$ with $|x - 0| < \delta$; that is, every function on E is continuous at 0. So no function on E , monotone or not, can have 0 among its points of discontinuity, and there is no monotone function on E that is continuous only at points of $E \sim C = [1, 2]$. The same argument works with $E = \mathbb{Z}$ and C any nonempty subset of $\mathbb{Z}$, since every point of $\mathbb{Z}$ is isolated in $\mathbb{Z}$.

The general criterion. Call $x_0 \in E$ isolated in E provided there is a $\delta > 0$ with $E \cap (x_0 - \delta, x_0 + \delta) = \{x_0\}$. As just observed, if some point of C is isolated in E , no function on E is discontinuous there, and the answer is no. We claim that if no point of C is isolated in E , then such an increasing function exists. Assume no point of C is isolated in E . If $C = \emptyset$, take $f(x) = x$, which is increasing and continuous at every point of E . Otherwise let $\{q_n\}_{n \in \Lambda}$ be an enumeration of C , with Λ an initial segment of the natural numbers or all of them. Fix $n \in \Lambda$. Since q_n is not isolated in E , every interval $(q_n - \delta, q_n + \delta)$ meets E in a point other than q_n , so q_n is a limit point of $E \cap (-\infty, q_n)$ or a limit point of $E \cap (q_n, \infty)$. Define, for $x \in E$,

$$\varphi_n(x) = \begin{cases} 1 & \text{if } x \geq q_n \\ 0 & \text{if } x < q_n \end{cases}$$

in the first case, and

$$\varphi_n(x) = \begin{cases} 1 & \text{if } x > q_n \\ 0 & \text{if } x \leq q_n \end{cases}$$

in the second case. In either case φ_n is increasing on E , takes only the values 0 and 1, and is constant on every interval that omits q_n . Define

$$f(x) = \sum_{n \in \Lambda} \frac{1}{2^n} \varphi_n(x) \quad \text{for all } x \in E,$$

a properly defined real-valued function since the series is dominated by the convergent geometric series $\sum_n 2^{-n}$. Since each φ_n is increasing and all terms are nonnegative, f is increasing on E , and for $u, v \in E$ with $u < v$,

$$f(v) - f(u) \geq \frac{1}{2^k} [\varphi_k(v) - \varphi_k(u)] \quad \text{for each } k \in \Lambda. \quad (2)$$

f is discontinuous at each $q_k \in C$. In the first case above, $\varphi_k(q_k) - \varphi_k(x) = 1$ for every $x \in E$ with $x < q_k$, so by (2), $f(q_k) - f(x) \geq 1/2^k$ for all such x ; and since q_k is a limit point of $E \cap (-\infty, q_k)$ there

are such x arbitrarily close to q_k . In the second case, $\varphi_k(x) - \varphi_k(q_k) = 1$ for every $x \in E$ with $x > q_k$, so $f(x) - f(q_k) \geq 1/2^k$ for all such x , and there are such x arbitrarily close to q_k . In both cases the definition of continuity fails at q_k for $\epsilon = 1/2^k$.

f is continuous at each $x_0 \in E \sim C$. Given $\epsilon > 0$, choose a natural number M with $1/2^M < \epsilon$, and let $\delta = \min\{|x_0 - q_n| : n \in \Lambda, n \leq M\} > 0$, this minimum being over a finite set of strictly positive numbers because $x_0 \notin C$ (take $\delta = 1$ if the set is empty). If $x \in E$ and $|x - x_0| < \delta$, then for each $n \leq M$ the interval $(x_0 - \delta, x_0 + \delta)$ omits q_n and hence φ_n is constant on it, so $\varphi_n(x) = \varphi_n(x_0)$. Therefore

$$|f(x) - f(x_0)| \leq \sum_{n>M} \frac{1}{2^n} = \frac{1}{2^M} < \epsilon.$$

So the answer to the question as posed is negative in general: such a monotone function exists precisely when C contains no point that is isolated in E . In particular, when E is an interval, or more generally when E has no isolated points, the answer is always yes, which is consistent with Proposition 2 and with Problem 1.

Problem 6.5. Show that the Vitali Covering Lemma does not extend to the case in which the covering collection has degenerate closed intervals.

Solution. A closed, bounded interval $[c, d]$ is degenerate provided $c = d$, that is, provided it is a single point and has length zero. Suppose we drop the nondegeneracy requirement from the definition of a Vitali covering, so that a collection $\mathcal{F}$ of closed, bounded intervals is said to cover E in the sense of Vitali provided for each $x \in E$ and each $\epsilon > 0$ there is an $I \in \mathcal{F}$ that contains x and has $\ell(I) < \epsilon$. We exhibit a set E of finite outer measure and such a collection $\mathcal{F}$ for which the conclusion (2) of the Vitali Covering Lemma fails.

Let $E = [0, 1]$, so that $m^*(E) = 1 < \infty$, and let

$$\mathcal{F} = \{ [x, x] : x \in [0, 1] \},$$

the collection of all degenerate closed intervals with endpoint in $[0, 1]$.

$\mathcal{F}$ covers E in the sense of Vitali in the relaxed sense just described: given $x \in E$ and $\epsilon > 0$, the interval $I = [x, x]$ belongs to $\mathcal{F}$, contains x , and has $\ell(I) = 0 < \epsilon$.

Now let $\{I_k\}_{k=1}^n$ be any finite subcollection of $\mathcal{F}$, disjoint or not. Then $A = \bigcup_{k=1}^n I_k$ is a set of at most n points, hence is measurable with $m(A) = 0$. Since $E = [0, 1]$ is measurable of finite measure and $E \sim A$ is measurable, the additivity of measure over the disjoint union $E = (E \sim A) \cup (E \cap A)$ gives

$$m^*\left[E \sim \bigcup_{k=1}^n I_k\right] = m(E) - m(E \cap A) = 1 - 0 = 1.$$

Hence for any $\epsilon \leq 1$ there is no finite subcollection $\{I_k\}_{k=1}^n$ of $\mathcal{F}$ for which

$$m^*\left[E \sim \bigcup_{k=1}^n I_k\right] < \epsilon.$$

Indeed, the same computation shows that even a countable disjoint subcollection of $\mathcal{F}$ leaves a remainder of outer measure 1, since a countable union of singletons has measure zero. So the Vitali Covering Lemma fails completely for such coverings, and the assumption in the definition preceding the lemma that the intervals of $\mathcal{F}$ be nondegenerate cannot be dropped.

The reason the proof of the lemma breaks down is visible in inequality (6): the selection process there chooses at each stage an interval whose length is more than half the supremum s_n of the available lengths, and it concludes from $\ell(I_k) \rightarrow 0$ that every point left uncovered lies in one of the enlarged intervals $5 * I_k$. When all the intervals are degenerate, every $5 * I_k$ is again a single point and covers nothing new; the lengths carry no information.

Problem 6.6. Show that the Vitali Covering Lemma does extend to the case in which the covering collection consists of nondegenerate general intervals.

Solution. By a general interval we mean any interval of real numbers: open, closed, or half-open, bounded or unbounded. Such an interval I is nondegenerate provided it contains more than one point. We prove the following.

Let E be a set of finite outer measure and $\mathcal{F}$ a collection of nondegenerate general intervals such that for each $x \in E$ and each $\epsilon > 0$ there is an $I \in \mathcal{F}$ containing x with $\ell(I) < \epsilon$. Then for each $\epsilon > 0$ there is a finite disjoint subcollection $\{I_k\}_{k=1}^n$ of $\mathcal{F}$ for which

$$m^*\left[E \sim \bigcup_{k=1}^n I_k\right] < \epsilon.$$

Proof. Let $\mathcal{F}_0 = \{I \in \mathcal{F} : \ell(I) < \infty\}$ and let

$$\overline{\mathcal{F}} = \{\overline{I} : I \in \mathcal{F}_0\},$$

where $\overline{I}$ denotes the closure of I . If I is a nondegenerate interval of finite length with endpoints $c < d$, then $\overline{I} = [c, d]$ is a closed, bounded, nondegenerate interval and $\ell(\overline{I}) = d - c = \ell(I)$. Thus $\overline{\mathcal{F}}$ is a collection of closed, bounded, nondegenerate intervals.

$\overline{\mathcal{F}}$ covers E in the sense of Vitali. Indeed, let $x \in E$ and $\epsilon > 0$. By hypothesis there is an $I \in \mathcal{F}$ with $x \in I$ and $\ell(I) < \epsilon$; in particular $\ell(I) < \infty$, so $I \in \mathcal{F}_0$. Then $x \in I \subseteq \overline{I} \in \overline{\mathcal{F}}$ and $\ell(\overline{I}) = \ell(I) < \epsilon$.

Since $m^*(E) < \infty$, the Vitali Covering Lemma applies to E and $\overline{\mathcal{F}}$: given $\epsilon > 0$, there is a finite disjoint subcollection of $\overline{\mathcal{F}}$, say $\{\overline{I}_k\}_{k=1}^n$ with each $I_k \in \mathcal{F}_0 \subseteq \mathcal{F}$, for which

$$m^*\left[E \sim \bigcup_{k=1}^n \overline{I}_k\right] < \frac{\epsilon}{2}.$$

The subcollection $\{I_k\}_{k=1}^n$ of $\mathcal{F}$ is disjoint: if $j \neq k$, then $I_j \cap I_k \subseteq \overline{I}_j \cap \overline{I}_k = \emptyset$. Moreover, since $\overline{I}_k \sim I_k$ consists of at most the two endpoints of I_k , the set

$$\Delta = \bigcup_{k=1}^n (\overline{I}_k \sim I_k)$$

is finite and therefore $m^*(\Delta) = 0$. Now

$$E \sim \bigcup_{k=1}^n I_k \subseteq \left[E \sim \bigcup_{k=1}^n \overline{I}_k\right] \cup \Delta,$$

since a point of E that lies in no I_k either lies in no $\overline{I}_k$ or lies in some $\overline{I}_k \sim I_k$. By the monotonicity and countable (here finite) subadditivity of outer measure,

$$m^*\left[E \sim \bigcup_{k=1}^n I_k\right] \leq m^*\left[E \sim \bigcup_{k=1}^n \overline{I}_k\right] + m^*(\Delta) < \frac{\epsilon}{2} + 0 < \epsilon.$$

This is the assertion, and the proof is complete.

Two remarks. First, the intervals of $\mathcal{F}$ of infinite length were discarded at the outset; this costs nothing, because the Vitali covering condition only ever calls on intervals of length less than a prescribed ϵ . Second, nondegeneracy is essential and is inherited by the closures, so the previous problem's counterexample is not in conflict with what has just been proved.

Problem 6.7. Let f be continuous on $\mathbb{R}$. Is there an open interval on which f is monotone?

Solution. No. There is a continuous function on $\mathbb{R}$ that fails to be monotone on every open interval. This is in the same spirit as the pathology mentioned in the Remark of this section, that a continuous function on an open interval may fail to be differentiable at every point.

The example. Let $\varphi(t) = \text{dist}(t, \mathbb{Z})$ be the distance from t to the nearest integer, and define

$$T(x) = \sum_{m=0}^{\infty} \frac{1}{2^m} \varphi(2^m x) \quad \text{for all } x \in \mathbb{R}.$$

T is continuous on $\mathbb{R}$. Each function $x \mapsto 2^{-m}\varphi(2^m x)$ is continuous, since φ is continuous (it is 1-periodic and satisfies $|\varphi(s) - \varphi(t)| \leq |s - t|$), and $0 \leq 2^{-m}\varphi(2^m x) \leq 2^{-m-1}$ for all x . Since $\sum_m 2^{-m-1} < \infty$, the series converges uniformly on $\mathbb{R}$ by the Weierstrass M-test, and a uniform limit of continuous functions is continuous. So T is continuous on all of $\mathbb{R}$.

Self-similarity on dyadic intervals. For integers $n \geq 0$ and k , let $I_{n,k} = [k/2^n, (k+1)/2^n]$. Fix such an interval and let $x \in I_{n,k}$.

For $m < n$, the point $2^m x$ ranges over $[k \cdot 2^{m-n}, (k+1) \cdot 2^{m-n}]$, an interval whose endpoints are consecutive multiples of 2^{m-n} and whose length 2^{m-n} is at most $1/2$; since 2^{m-n} divides $1/2$, this interval is contained in a single interval of the form $[j/2, (j+1)/2]$, on which φ is affine with slope $+1$ or -1 . Hence $x \mapsto 2^{-m}\varphi(2^m x)$ is affine on $I_{n,k}$ with slope $+1$ or -1 .

For $m \geq n$, write $u = 2^n x - k \in [0, 1]$. Then $2^m x = 2^{m-n}u + 2^{m-n}k$, and $2^{m-n}k$ is an integer, so by the 1-periodicity of φ we get $\varphi(2^m x) = \varphi(2^{m-n}u)$. Therefore

$$\sum_{m \geq n} \frac{1}{2^m} \varphi(2^m x) = \frac{1}{2^n} \sum_{j=0}^{\infty} \frac{1}{2^j} \varphi(2^j u) = \frac{1}{2^n} T(2^n x - k).$$

Combining the two computations, there are a real number $c_{n,k}$ and an integer $s_{n,k}$ with

$$T(x) = c_{n,k} + s_{n,k} \cdot \left(x - \frac{k}{2^n}\right) + \frac{1}{2^n} T(2^n x - k) \quad \text{for all } x \in I_{n,k}, \quad (3)$$

where $s_{n,k}$ is the sum of the n slopes ± 1 contributed by the terms with $m < n$.

The slopes can be steered to zero. On the left half $I_{n+1,2k}$ of $I_{n,k}$ the point $2^n x$ ranges over $[k, k+1/2]$, where φ has slope $+1$; on the right half $I_{n+1,2k+1}$ it ranges over $[k+1/2, k+1]$, where φ has slope -1 . Since $s_{n+1,\cdot}$ is $s_{n,k}$ plus the slope contributed by the term with $m = n$,

$$s_{n+1,2k} = s_{n,k} + 1, \quad s_{n+1,2k+1} = s_{n,k} - 1.$$

Consequently, starting from any dyadic interval $I_{n,k}$, we may pass $|s_{n,k}|$ times to a half-interval, always taking the right half if $s_{n,k} > 0$ and the left half if $s_{n,k} < 0$, and arrive at a dyadic interval $J = I_{N,K} \subseteq I_{n,k}$ with

$$s_{N,K} = 0.$$

T is monotone on no open interval. Let (α, β) be a nonempty open interval. Since a function that is monotone on an interval is monotone on every subinterval, and since (α, β) contains a nonempty bounded open interval, we may assume α and β are finite. Choose n so large that $2^{-n} < (\beta - \alpha)/3$ and let k be the least integer with $k/2^n > \alpha$. Then $k/2^n \leq \alpha + 2^{-n}$, since otherwise $k-1$ would already satisfy $(k-1)/2^n > \alpha$; hence

$$\alpha < \frac{k}{2^n} \quad \text{and} \quad \frac{k+1}{2^n} \leq \alpha + \frac{2}{2^n} < \alpha + (\beta - \alpha) = \beta,$$

so $I_{n,k} = [k/2^n, (k+1)/2^n] \subseteq (\alpha, \beta)$. Fix this $I_{n,k}$ and let $J = I_{N,K} \subseteq I_{n,k} \subseteq (\alpha, \beta)$ be a dyadic subinterval with $s_{N,K} = 0$, as just constructed. By (3), for $x \in J$,

$$T(x) = c + \frac{1}{2^N} T(2^N x - K), \quad \text{where } c = c_{N,K}.$$

The map $x \mapsto 2^N x - K$ carries the left endpoint $p = K/2^N$ of J , its midpoint $q = (K + 1/2)/2^N$, and its right endpoint $r = (K + 1)/2^N$ onto 0, $1/2$, and 1 respectively. Now

$$T(0) = 0, \quad T(1/2) = \varphi(1/2) + \sum_{m \geq 1} \frac{1}{2^m} \varphi(2^{m-1}) = \frac{1}{2}, \quad T(1) = \sum_{m \geq 0} \frac{1}{2^m} \varphi(2^m) = 0,$$

since φ vanishes at every integer and 2^{m-1} is an integer for $m \geq 1$. Therefore

$$T(p) = c, \quad T(q) = c + \frac{1}{2^{N+1}}, \quad T(r) = c,$$

and $p < q < r$ are three points of (α, β) with $T(p) < T(q)$ and $T(q) > T(r)$. The first inequality shows T is not decreasing on (α, β) and the second shows T is not increasing on (α, β) . Hence T is not monotone on (α, β) .

Since (α, β) was an arbitrary nonempty open interval, the continuous function T on $\mathbb{R}$ is monotone on no open interval. So the answer to the question is no.

6.2 Problems 6.8–6.14

Problem 6.8. Let I and J be closed, bounded intervals and $\gamma > 0$ be such that $\ell(I) > \gamma \cdot \ell(J)$. Assume $I \cap J \neq \emptyset$. Show that if $\gamma \geq 1/2$, then $J \subseteq 5 * I$, where $5 * I$ denotes the interval with the same center as I and five times its length. Is the same true if $0 < \gamma < 1/2$?

Solution. Write $L = \ell(I)$ and let c be the midpoint of I , so that

$$I = [c - L/2, c + L/2], \quad 5 * I = [c - 5L/2, c + 5L/2].$$

Consider first the case $\gamma \geq 1/2$. Since $I \cap J \neq \emptyset$, choose a point $y \in I \cap J$. Let x be an arbitrary point of J . Because x and y both lie in the interval J ,

$$|x - y| \leq \ell(J).$$

The hypothesis $\ell(I) > \gamma \cdot \ell(J)$ gives $\ell(J) < \ell(I)/\gamma = L/\gamma$, and since $\gamma \geq 1/2$ we have $1/\gamma \leq 2$, so

$$|x - y| \leq \ell(J) < \frac{L}{\gamma} \leq 2L.$$

On the other hand $y \in I$, so $|y - c| \leq L/2$. By the triangle inequality,

$$|x - c| \leq |x - y| + |y - c| < 2L + \frac{L}{2} = \frac{5L}{2}.$$

Hence $x \in [c - 5L/2, c + 5L/2] = 5 * I$. As $x \in J$ was arbitrary, $J \subseteq 5 * I$.

Now consider the case $0 < \gamma < 1/2$. The conclusion fails for every such γ . Indeed, fix γ with $0 < \gamma < 1/2$, so that $1/\gamma > 2$. Choose a number t with

$$2 < t < \frac{1}{\gamma},$$

which is possible precisely because $1/\gamma > 2$. Put

$$I = [0, 1], \quad J = [-t, 0].$$

Then $\ell(I) = 1$, $\ell(J) = t$, and $\gamma \cdot \ell(J) = \gamma t < 1 = \ell(I)$, so the hypothesis $\ell(I) > \gamma \cdot \ell(J)$ holds. Moreover $I \cap J = \{0\} \neq \emptyset$. The midpoint of I is $1/2$ and $\ell(I) = 1$, so

$$5 * I = \left[\frac{1}{2} - \frac{5}{2}, \frac{1}{2} + \frac{5}{2}\right] = [-2, 3].$$

Since $t > 2$, the endpoint $-t$ of J satisfies $-t < -2$, so $-t \notin 5 * I$ and therefore $J \not\subseteq 5 * I$.

Thus the implication holds for $\gamma \geq 1/2$ and fails for every $\gamma \in (0, 1/2)$. The computation in the first part shows exactly why: the bound obtained is $|x - c| < L/\gamma + L/2$, and this is at most $5L/2$ precisely when $1/\gamma \leq 2$; the second part shows that this restriction on γ cannot be relaxed.

This is exactly the geometric fact that justifies the dilation factor 5 in the proof of the Vitali Covering Lemma. There, in the notation of that proof, the selected intervals satisfy relation (6): $\ell(I_{n+1}) > \ell(I)/2$ for every I in $\mathcal{F}$ that is disjoint from $I_1, \dots, I_n$. That is the hypothesis of the present problem with $\gamma = 1/2$, and it is what lets one conclude that such an I meeting I_N is contained in $5 * I_N$.

Problem 6.9. Show that a set E of real numbers has measure zero if and only if there is a countable collection of open intervals $\{I_k\}_{k=1}^\infty$ for which each point in E belongs to infinitely many of the I_k 's and $\sum_{k=1}^\infty \ell(I_k) < \infty$.

Solution. Recall that a set has measure zero exactly when its outer measure is zero: by Proposition 4 of Chapter 2 any set of outer measure zero is measurable, and its measure is then its outer measure, namely zero.

Suppose first that such a collection $\{I_k\}_{k=1}^\infty$ exists: every point of E lies in infinitely many I_k and $\sum_{k=1}^\infty \ell(I_k) < \infty$. Fix a natural number n and set

$$E_n = \bigcup_{k=n}^\infty I_k.$$

If $x \in E$, then x belongs to I_k for infinitely many indices k , and in particular for some index $k \geq n$. Hence $E \subseteq E_n$ for every n . By the monotonicity and countable subadditivity of outer measure, together with Proposition 1 of Chapter 2, which says that the outer measure of an interval is its length,

$$m^*(E) \leq m^*(E_n) \leq \sum_{k=n}^\infty \ell(I_k).$$

Since the series $\sum_{k=1}^\infty \ell(I_k)$ converges, its tails tend to 0: given $\epsilon > 0$ there is n with $\sum_{k=n}^\infty \ell(I_k) < \epsilon$. Therefore $m^*(E) < \epsilon$ for every $\epsilon > 0$, so $m^*(E) = 0$ and E has measure zero.

Conversely, suppose E has measure zero, so $m^*(E) = 0$. Fix a natural number n . By the definition of outer measure as an infimum, there is a countable collection $\{J_{n,k}\}_k$ of open, bounded intervals with

$$E \subseteq \bigcup_k J_{n,k} \quad \text{and} \quad \sum_k \ell(J_{n,k}) < \frac{1}{2^n}.$$

Adjoining to this collection the single extra interval $(0, 2^{-n})$ if necessary, we may assume the n -th collection is nonempty, at the cost of replacing the bound 2^{-n} by 2^{-n+1} ; this changes nothing below. Let

$$\mathcal{C} = \{J_{n,k} : n \in \mathbb{N}, k \text{ an index of the } n\text{-th collection}\},$$

regarded as a family indexed by the set of admissible pairs (n, k) . This index set is a countable union of countable sets, hence countable, and it is infinite because each of the infinitely many blocks n contributes at least one index. Enumerate the family as $\{I_j\}_{j=1}^\infty$ by choosing a bijection of $\mathbb{N}$ onto the index set. Since all terms are nonnegative, the sum of the resulting series is independent of the order of summation, and

$$\sum_{j=1}^\infty \ell(I_j) = \sum_{n=1}^\infty \sum_k \ell(J_{n,k}) \leq \sum_{n=1}^\infty \frac{1}{2^{n-1}} = 2 < \infty.$$

Finally, let $x \in E$. For each n , the n -th collection covers E , so there is an index k with $x \in J_{n,k}$. Distinct values of n give indices (n, k) in disjoint blocks of the index set, hence distinct members of the enumerated family. Therefore x belongs to I_j for infinitely many j . This is the required collection.

Problem 6.10. (Riesz-Nagy) Let E be a set of measure zero contained in the open interval (a, b) . According to the preceding problem, there is a countable collection of open intervals contained in (a, b) , $\{(c_k, d_k)\}_{k=1}^{\infty}$, for which each point in E belongs to infinitely many intervals in the collection and $\sum_{k=1}^{\infty} (d_k - c_k) < \infty$. Define

$$f(x) = \sum_{k=1}^{\infty} \ell((c_k, d_k) \cap (-\infty, x)) \quad \text{for all } x \text{ in } (a, b).$$

Show that f is increasing and fails to be differentiable at each point in E .

Solution. For each natural number k define φ_k on (a, b) by

$$\varphi_k(x) = \ell((c_k, d_k) \cap (-\infty, x)) = \begin{cases} 0 & \text{if } x \leq c_k, \\ x - c_k & \text{if } c_k \leq x \leq d_k, \\ d_k - c_k & \text{if } x \geq d_k, \end{cases}$$

so that $f = \sum_{k=1}^{\infty} \varphi_k$ pointwise on (a, b) . The three formulas agree at the overlaps $x = c_k$ and $x = d_k$, so φ_k is well defined, and inspection of the three pieces shows that φ_k is increasing and satisfies

$$0 \leq \varphi_k(x) \leq d_k - c_k \quad \text{for all } x \in (a, b). \quad (*)$$

First, f is well defined and finite. Indeed, by $(*)$ the terms of the series defining $f(x)$ are nonnegative and dominated by the terms of the convergent series $\sum_{k=1}^{\infty} (d_k - c_k)$, so for each x the series converges and

$$0 \leq f(x) \leq \sum_{k=1}^{\infty} (d_k - c_k) < \infty.$$

Next, f is increasing. Let $a < x < y < b$. Each φ_k is increasing, so $\varphi_k(y) - \varphi_k(x) \geq 0$ for every k . Both series $\sum_k \varphi_k(x)$ and $\sum_k \varphi_k(y)$ converge, so we may subtract them termwise:

$$f(y) - f(x) = \sum_{k=1}^{\infty} [\varphi_k(y) - \varphi_k(x)] \geq 0. \quad (**)$$

Hence $f(x) \leq f(y)$, and f is increasing on (a, b) .

Finally, f fails to be differentiable at each point of E . We show more: for each $x_0 \in E$ the upper derivative $\overline{D}f(x_0)$ equals ∞ . Since the book's definition requires, for differentiability at x_0 , that $\overline{D}f(x_0)$ and $\underline{D}f(x_0)$ be equal and finite, this rules out differentiability at x_0 .

Fix $x_0 \in E$ and fix a natural number n . Since x_0 belongs to infinitely many of the intervals of the collection, we may choose n distinct indices $k_1, k_2, \dots, k_n$ for which

$$x_0 \in (c_{k_i}, d_{k_i}) \quad \text{for } 1 \leq i \leq n.$$

Each of these intervals is open and contains x_0 , so $d_{k_i} - x_0 > 0$ for every i . Since $x_0 < b$, the number

$$\delta = \min \left\{ b - x_0, \min_{1 \leq i \leq n} (d_{k_i} - x_0) \right\}$$

is positive. Let $0 < t < \delta$ and put $y = x_0 + t$; then $y \in (a, b)$. For each i we have

$$c_{k_i} < x_0 < y = x_0 + t < d_{k_i},$$

so both x_0 and y lie in $[c_{k_i}, d_{k_i}]$, and the middle formula for φ_{k_i} applies to each:

$$\varphi_{k_i}(y) - \varphi_{k_i}(x_0) = (y - c_{k_i}) - (x_0 - c_{k_i}) = y - x_0 = t.$$

All the terms in the series $(**)$ are nonnegative, so discarding all but the n chosen indices gives

$$f(x_0 + t) - f(x_0) = \sum_{k=1}^{\infty} [\varphi_k(y) - \varphi_k(x_0)] \geq \sum_{i=1}^n [\varphi_{k_i}(y) - \varphi_{k_i}(x_0)] = n t.$$

Dividing by $t > 0$,

$$\frac{f(x_0 + t) - f(x_0)}{t} \geq n \quad \text{for all } 0 < t < \delta.$$

Consequently, for every h with $0 < h < \delta$,

$$\sup_{0 < |t| \leq h} \frac{f(x_0 + t) - f(x_0)}{t} \geq n,$$

and letting $h \rightarrow 0$ in the definition of the upper derivative yields $\overline{D}f(x_0) \geq n$. As n was an arbitrary natural number, $\overline{D}f(x_0) = \infty$. Therefore f is not differentiable at x_0 .

Since $x_0 \in E$ was arbitrary, f is an increasing function on (a, b) that fails to be differentiable at every point of E . This is exactly the assertion, made after the proof of Lebesgue's Theorem, that the theorem is best possible: every set of measure zero in (a, b) is contained in the set of nondifferentiability of some increasing function on (a, b) . Of course Lebesgue's Theorem guarantees that this set of nondifferentiability itself has measure zero.

Problem 6.11. For real numbers $\alpha < \beta$ and $\gamma > 0$, show that if g is integrable over $[\alpha + \gamma, \beta + \gamma]$, then

$$\int_{\alpha}^{\beta} g(t + \gamma) dt = \int_{\alpha + \gamma}^{\beta + \gamma} g(t) dt.$$

Prove this change of variables formula by successively considering simple functions, bounded measurable functions, nonnegative integrable functions, and general integrable functions. Use it to prove (14).

Solution. Throughout write $I = [\alpha, \beta]$ and $I_{\gamma} = [\alpha + \gamma, \beta + \gamma] = I + \gamma$, and for a function g on I_{γ} define its translate

$$(Tg)(t) = g(t + \gamma) \quad \text{for } t \in I.$$

The whole argument rests on the translation invariance of Lebesgue measure established in Chapter 2: outer measure is translation invariant, and by Proposition 10 of Chapter 2 the translate of a measurable set is measurable. Applying that proposition to A and to $A + \gamma$ with the translations γ and $-\gamma$, we get that A is measurable if and only if $A + \gamma$ is measurable, and then $m(A + \gamma) = m^*(A + \gamma) = m^*(A) = m(A)$.

Measurability of the translate. If g is measurable on I_{γ} then Tg is measurable on I . Indeed, for $c \in \mathbb{R}$,

$$\{t \in I : (Tg)(t) > c\} = \{s \in I_{\gamma} : g(s) > c\} - \gamma,$$

which is a translate of a measurable set and hence measurable. The map T is a bijection from functions on I_{γ} onto functions on I , with inverse given by translation by $-\gamma$; by the same reasoning the inverse also preserves measurability. Note also that T is linear, order preserving, carries simple functions to simple functions and bounded functions to bounded functions, and satisfies $T(g^+) = (Tg)^+$ and $T(g^-) = (Tg)^-$.

Step 1: simple functions. Let $A \subseteq I_{\gamma}$ be measurable. Then for $t \in I$ we have $\chi_A(t + \gamma) = 1$ exactly when $t \in A - \gamma$, so $T\chi_A = \chi_{A - \gamma}$ and therefore

$$\int_{\alpha}^{\beta} \chi_A(t + \gamma) dt = m(A - \gamma) = m(A) = \int_{\alpha + \gamma}^{\beta + \gamma} \chi_A.$$

Now let ψ be simple and measurable on I_{γ} , with canonical representation $\psi = \sum_{i=1}^n a_i \chi_{A_i}$, the A_i measurable and disjoint. Then $T\psi = \sum_{i=1}^n a_i \chi_{A_i - \gamma}$, and by the linearity of integration for simple functions,

$$\int_{\alpha}^{\beta} T\psi = \sum_{i=1}^n a_i m(A_i - \gamma) = \sum_{i=1}^n a_i m(A_i) = \int_{\alpha + \gamma}^{\beta + \gamma} \psi.$$

Step 2: bounded measurable functions. Let g be bounded and measurable on I_{γ} , a set of finite measure. Then Tg is bounded and measurable on I , also of finite measure, so by Theorem 4 of Chapter 4 both

functions are integrable, and each integral equals the lower Lebesgue integral, that is, the supremum of the integrals of the simple functions lying below the function:

$$\int_{\alpha+\gamma}^{\beta+\gamma} g = \sup \left\{ \int_{\alpha+\gamma}^{\beta+\gamma} \psi : \psi \text{ simple and measurable on } I_\gamma, \psi \leq g \right\},$$

and similarly for Tg over I . Since T is an order preserving bijection carrying the simple measurable functions on I_γ onto those on I , it carries $\{\psi \text{ simple} : \psi \leq g\}$ onto $\{\varphi \text{ simple} : \varphi \leq Tg\}$, and by Step 1 it preserves the value of the integral. Two sets of real numbers that are in integral preserving bijection have the same supremum, so

$$\int_{\alpha}^{\beta} g(t + \gamma) dt = \int_{\alpha+\gamma}^{\beta+\gamma} g.$$

Step 3: nonnegative measurable functions. Let $g \geq 0$ be measurable on I_γ . By the definition, in Chapter 4, of the integral of a nonnegative measurable function,

$$\int_{\alpha+\gamma}^{\beta+\gamma} g = \sup \left\{ \int_{\alpha+\gamma}^{\beta+\gamma} h : h \text{ bounded, measurable, of finite support, } 0 \leq h \leq g \right\},$$

and likewise for $Tg \geq 0$ over I . If h is bounded, measurable, of finite support and $0 \leq h \leq g$ on I_γ , then Th is bounded, measurable, of finite support (its support is the translate by $-\gamma$ of the support of h , and translation preserves measure) and $0 \leq Th \leq Tg$ on I ; and T maps this class onto the corresponding class for Tg , since its inverse has the same properties. By Step 2 it preserves integrals. Hence the two suprema coincide,

$$\int_{\alpha}^{\beta} g(t + \gamma) dt = \int_{\alpha+\gamma}^{\beta+\gamma} g,$$

both sides being finite or infinite together. In particular g is integrable over I_γ if and only if Tg is integrable over I .

Step 4: general integrable functions. Let g be integrable over I_γ . By Proposition 14 of Chapter 4, g^+ and g^- are nonnegative measurable functions each with finite integral over I_γ , and $(Tg)^+ = T(g^+)$, $(Tg)^- = T(g^-)$. By Step 3,

$$\int_{\alpha}^{\beta} (Tg)^{\pm} = \int_{\alpha+\gamma}^{\beta+\gamma} g^{\pm} < \infty,$$

so Tg is integrable over I , and by the definition of the integral of an integrable function,

$$\int_{\alpha}^{\beta} g(t + \gamma) dt = \int_{\alpha}^{\beta} (Tg)^+ - \int_{\alpha}^{\beta} (Tg)^- = \int_{\alpha+\gamma}^{\beta+\gamma} g^+ - \int_{\alpha+\gamma}^{\beta+\gamma} g^- = \int_{\alpha+\gamma}^{\beta+\gamma} g.$$

This is the change of variables formula. Nothing in the argument used the sign of γ : the same proof, verbatim, gives the formula for any real γ .

Proof of (14). Let f be integrable over $[a, b]$, extended to take the value $f(b)$ on $(b, b+1]$; the extension is integrable over $[a, b+1]$, since it is integrable over $[a, b]$ and constant, hence integrable, over $[b, b+1]$. Fix h with $0 < h \leq 1$ and let $a \leq u \leq v \leq b$. The function $t \mapsto f(t+h)$ is integrable over $[u, v]$ by Step 4 applied with $\gamma = h$ on $[u+h, v+h] \subseteq [a, b+1]$, so $\text{Diff}_h f = (f(\cdot + h) - f)/h$ is integrable over $[u, v]$, and by Theorem 17 of Chapter 4 (linearity of integration),

$$\int_u^v \text{Diff}_h f = \frac{1}{h} \left[\int_u^v f(t+h) dt - \int_u^v f \right] = \frac{1}{h} \left[\int_{u+h}^{v+h} f - \int_u^v f \right],$$

the last equality by the change of variables formula. Now use Corollary 18 of Chapter 4 (Additivity Over Domains of Integration) twice, splitting $[u, v+h]$ at v and at $u+h$; both splittings are legitimate since $u \leq v \leq v+h$ and $u \leq u+h \leq v+h$, and f is integrable over $[u, v+h] \subseteq [a, b+1]$:

$$\int_u^v f + \int_v^{v+h} f = \int_u^{v+h} f = \int_u^{u+h} f + \int_{u+h}^{v+h} f.$$

Rearranging,

$$\int_{u+h}^{v+h} f - \int_u^v f = \int_v^{v+h} f - \int_u^{u+h} f.$$

Therefore

$$\int_u^v \text{Diff}_h f = \frac{1}{h} \int_v^{v+h} f - \frac{1}{h} \int_u^{u+h} f = \text{Av}_h f(v) - \text{Av}_h f(u),$$

which is (14).

Problem 6.12. Compute the upper and lower derivatives of the characteristic function of the rationals.

Solution. Let $f = \chi_{\mathbb{Q}}$ on $\mathbb{R}$, so $f(x) = 1$ if x is rational and $f(x) = 0$ if x is irrational. We claim that

$$\overline{D}f(x) = \infty \quad \text{and} \quad \underline{D}f(x) = -\infty \quad \text{for every } x \in \mathbb{R}.$$

Recall the definitions

$$\overline{D}f(x) = \lim_{h \rightarrow 0} \left[\sup_{0 < |t| \leq h} \frac{f(x+t) - f(x)}{t} \right], \quad \underline{D}f(x) = \lim_{h \rightarrow 0} \left[\inf_{0 < |t| \leq h} \frac{f(x+t) - f(x)}{t} \right].$$

As h decreases the supremum is taken over a smaller set, so the expression in brackets is monotone in h and the limits exist in the extended reals. Consequently, to prove $\overline{D}f(x) = \infty$ it suffices to show that for every $h > 0$ and every $M > 0$ there is a t with $0 < |t| \leq h$ and difference quotient exceeding M ; and symmetrically for the lower derivative.

Fix x and $h > 0$ and $M > 0$, and put $\delta = \min\{h, 1/M\} > 0$.

Case 1: x is rational. Then $f(x) = 1$ and, for $t \neq 0$,

$$\frac{f(x+t) - f(x)}{t} = \frac{f(x+t) - 1}{t} = \begin{cases} 0 & \text{if } x+t \in \mathbb{Q}, \\ -\frac{1}{t} & \text{if } x+t \notin \mathbb{Q}. \end{cases}$$

Since x is rational, $x+t$ is irrational exactly when t is irrational. The irrationals are dense in $\mathbb{R}$, so we may choose an irrational t with $-\delta < t < 0$. For that t we have $0 < |t| \leq h$ and

$$\frac{f(x+t) - f(x)}{t} = -\frac{1}{t} = \frac{1}{|t|} > \frac{1}{\delta} \geq M.$$

Hence $\sup_{0 < |t| \leq h}$ exceeds M for every h and every M , so $\overline{D}f(x) = \infty$. Likewise choose an irrational t with $0 < t < \delta$; then

$$\frac{f(x+t) - f(x)}{t} = -\frac{1}{t} < -\frac{1}{\delta} \leq -M,$$

so the infimum is less than $-M$ for every h and every M , and $\underline{D}f(x) = -\infty$.

Case 2: x is irrational. Then $f(x) = 0$ and, for $t \neq 0$,

$$\frac{f(x+t) - f(x)}{t} = \frac{f(x+t)}{t} = \begin{cases} \frac{1}{t} & \text{if } x+t \in \mathbb{Q}, \\ 0 & \text{if } x+t \notin \mathbb{Q}. \end{cases}$$

By the density of the rationals there is a rational number q with $x < q < x + \delta$. Put $t = q - x$, so $0 < t < \delta \leq h$ and $x+t = q$ is rational; then

$$\frac{f(x+t) - f(x)}{t} = \frac{1}{t} > \frac{1}{\delta} \geq M.$$

Hence $\overline{D}f(x) = \infty$. Similarly there is a rational q with $x - \delta < q < x$; putting $t = q - x$ gives $-\delta < t < 0$, $0 < |t| \leq h$, and

$$\frac{f(x+t) - f(x)}{t} = \frac{1}{t} < -\frac{1}{\delta} \leq -M,$$

so $\underline{D}f(x) = -\infty$.

Thus at every real number x ,

$$\overline{D}f(x) = +\infty, \quad \underline{D}f(x) = -\infty.$$

In particular $\chi_{\mathbb{Q}}$ fails to be differentiable at every point of $\mathbb{R}$, and indeed the difference quotients fail to have even an infinite limit anywhere. There is no contradiction with Lebesgue's Theorem: $\chi_{\mathbb{Q}}$ is not monotone on any open interval, since every open interval contains both rationals and irrationals.

Problem 6.13. Let E be a set of finite outer measure and $\mathcal{F}$ a collection of closed, bounded intervals that cover E in the sense of Vitali. Show that there is a countable disjoint collection $\{I_k\}_{k=1}^{\infty}$ of intervals in $\mathcal{F}$ for which

$$m^* \left[E \sim \bigcup_{k=1}^{\infty} I_k \right] = 0.$$

Solution. We construct the collection inductively, applying the Vitali Covering Lemma at each stage to what is left over, and we use the following observation to keep the newly chosen intervals disjoint from the ones already chosen.

Claim. Let F be a closed set and let $A \subseteq E \sim F$. Then the subcollection

$$\mathcal{F}_F = \{I \in \mathcal{F} : I \cap F = \emptyset\}$$

is a Vitali covering of A .

To see this, let $x \in A$ and $\epsilon > 0$. Since $x \notin F$ and F is closed, its complement is open, so there is $\delta > 0$ with $(x - \delta, x + \delta) \cap F = \emptyset$. Since $x \in E$ and $\mathcal{F}$ covers E in the sense of Vitali, there is an interval $I \in \mathcal{F}$ with $x \in I$ and $\ell(I) < \min\{\epsilon, \delta\}$. Every point $y \in I$ satisfies $|y - x| \leq \ell(I) < \delta$, so $I \subseteq (x - \delta, x + \delta)$ and hence $I \cap F = \emptyset$. Thus $I \in \mathcal{F}_F$, $x \in I$ and $\ell(I) < \epsilon$. This proves the claim.

Construction. We produce, for each natural number j , a finite disjoint subcollection $\{I_k\}_{k=1}^{n_j}$ of $\mathcal{F}$, with $n_1 < n_2 < \dots$ and each stage extending the previous one, such that

$$m^* \left[E \sim \bigcup_{k=1}^{n_j} I_k \right] < \frac{1}{j}. \quad (\dagger)$$

For $j = 1$: E has finite outer measure and $\mathcal{F}$ is a Vitali covering of E , so the Vitali Covering Lemma with $\epsilon = 1$ provides a finite disjoint subcollection $\{I_k\}_{k=1}^{n_1}$ of $\mathcal{F}$ with $m^*[E \sim \bigcup_{k=1}^{n_1} I_k] < 1$.

Inductive step: suppose $\{I_k\}_{k=1}^{n_j}$ has been chosen, disjoint and satisfying $(\dagger)$. Put

$$F_j = \bigcup_{k=1}^{n_j} I_k, \quad E_j = E \sim F_j.$$

As a finite union of closed intervals, F_j is closed. By $(\dagger)$, $m^*(E_j) < 1/j < \infty$. If $E_j = \emptyset$, then $m^*[E \sim \bigcup_{k=1}^{n_j} I_k] = 0$ and the finite disjoint collection $\{I_k\}_{k=1}^{n_j}$, which is countable, already satisfies the conclusion; so we may assume $E_j \neq \emptyset$. By the Claim applied with $F = F_j$ and $A = E_j$, the collection $\mathcal{F}_{F_j}$ is a Vitali covering of E_j . Apply the Vitali Covering Lemma to the set E_j of finite outer measure, the covering $\mathcal{F}_{F_j}$, and $\epsilon = 1/(j+1)$: there is a finite disjoint subcollection of $\mathcal{F}_{F_j}$, which we label $I_{n_j+1}, \dots, I_{n_{j+1}}$, for which

$$m^* \left[E_j \sim \bigcup_{k=n_j+1}^{n_{j+1}} I_k \right] < \frac{1}{j+1}.$$

(If the lemma returns the empty subcollection we may adjoin one further interval of $\mathcal{F}_{F_j}$ containing a point of E_j , which only shrinks the left side; so we may take $n_{j+1} > n_j$.)

The intervals $I_{n_j+1}, \dots, I_{n_{j+1}}$ are pairwise disjoint, and each belongs to $\mathcal{F}_{F_j}$, hence is disjoint from F_j and therefore from each of $I_1, \dots, I_{n_j}$. So $\{I_k\}_{k=1}^{n_{j+1}}$ is a disjoint collection. Moreover, since $E_j = E \sim F_j$,

$$E \sim \bigcup_{k=1}^{n_{j+1}} I_k = (E \sim F_j) \sim \bigcup_{k=n_j+1}^{n_{j+1}} I_k = E_j \sim \bigcup_{k=n_j+1}^{n_{j+1}} I_k,$$

so $m^*[E \sim \bigcup_{k=1}^{n_{j+1}} I_k] < 1/(j+1)$, which is $(\dagger)$ for $j+1$. The induction is complete.

Conclusion. If the process terminates at some stage because $E_j = \emptyset$, we are done as noted. Otherwise the stages nest, and taking the union over all j we obtain a countable collection $\{I_k\}_{k=1}^\infty \subseteq \mathcal{F}$. It is disjoint: any two of its members lie in some common finite stage $\{I_k\}_{k=1}^{n_j}$, which is disjoint. Finally, for each natural number j ,

$$E \sim \bigcup_{k=1}^\infty I_k \subseteq E \sim \bigcup_{k=1}^{n_j} I_k,$$

so by the monotonicity of outer measure and $(\dagger)$,

$$m^*\left[E \sim \bigcup_{k=1}^\infty I_k\right] \leq m^*\left[E \sim \bigcup_{k=1}^{n_j} I_k\right] < \frac{1}{j}.$$

Since this holds for every j , $m^*[E \sim \bigcup_{k=1}^\infty I_k] = 0$, as required.

Problem 6.14. Use the Vitali Covering Lemma to show that the union of any collection (countable or uncountable) of closed, bounded nondegenerate intervals is measurable.

Solution. Let $\mathcal{C}$ be a collection of closed, bounded, nondegenerate intervals and let

$$U = \bigcup_{I \in \mathcal{C}} I.$$

Since $U = \bigcup_{n=1}^\infty (U \cap (-n, n))$ and the measurable sets form a σ -algebra, it suffices to prove that

$$A_n = U \cap (-n, n)$$

is measurable for each natural number n . Fix n ; we may assume $A_n \neq \emptyset$, since the empty set is measurable. Note $m^*(A_n) \leq 2n < \infty$.

A Vitali covering. The key point is that although the intervals of $\mathcal{C}$ may all be long, every point of U lies in arbitrarily short closed subintervals of members of $\mathcal{C}$. Define

$$\mathcal{F}_n = \{J : J \text{ is a closed, bounded, nondegenerate interval, } J \subseteq [-n, n], \text{ and } J \subseteq I \text{ for some } I \in \mathcal{C}\}.$$

We check that $\mathcal{F}_n$ covers A_n in the sense of Vitali. Let $x \in A_n$ and $\epsilon > 0$. Since $x \in U$, there is an interval $I = [c, d] \in \mathcal{C}$ with $c \leq x \leq d$ and $c < d$. Since $x \in (-n, n)$, there is $\delta > 0$ with $[x - \delta, x + \delta] \subseteq (-n, n)$.

If $x < d$, put $\eta = \min\{\epsilon/2, \delta, d - x\} > 0$ and $J = [x, x + \eta]$. Then $c \leq x$ and $x + \eta \leq d$, so $J \subseteq I$; also $J \subseteq [x - \delta, x + \delta] \subseteq [-n, n]$; and J is nondegenerate with $x \in J$ and $\ell(J) = \eta < \epsilon$.

If $x = d$, then $c < x$; put $\eta = \min\{\epsilon/2, \delta, x - c\} > 0$ and $J = [x - \eta, x]$. The same three verifications apply.

In either case $J \in \mathcal{F}_n$, $x \in J$ and $\ell(J) < \epsilon$. So $\mathcal{F}_n$ is a Vitali covering of A_n .

Applying the lemma. The set A_n has finite outer measure and $\mathcal{F}_n$ covers it in the sense of Vitali, so for each natural number j the Vitali Covering Lemma provides a finite disjoint subcollection $\{J_1^j, \dots, J_{m_j}^j\}$ of $\mathcal{F}_n$ for which

$$m^*\left[A_n \sim \bigcup_{k=1}^{m_j} J_k^j\right] < \frac{1}{j}.$$

Let

$$S = \bigcup_{j=1}^\infty \bigcup_{k=1}^{m_j} J_k^j.$$

This is a countable union of closed intervals, hence a Borel set and in particular measurable. Moreover every J_k^j is contained in some member of $\mathcal{C}$ and in $[-n, n]$, so

$$S \subseteq U \cap [-n, n].$$

Now decompose A_n . First,

$$A_n \cap S = S \cap (-n, n).$$

Indeed, $A_n \cap S \subseteq S \cap (-n, n)$ because $A_n \subseteq (-n, n)$; conversely, if $y \in S \cap (-n, n)$ then $y \in U$ and $y \in (-n, n)$, so $y \in A_n$ and hence $y \in A_n \cap S$. The set $S \cap (-n, n)$ is measurable, being the intersection of two measurable sets.

Second, for every j ,

$$A_n \sim S \subseteq A_n \sim \bigcup_{k=1}^{m_j} J_k^j,$$

so by the monotonicity of outer measure $m^*(A_n \sim S) < 1/j$ for every j , whence $m^*(A_n \sim S) = 0$. By Proposition 4 of Chapter 2, a set of outer measure zero is measurable, so $A_n \sim S$ is measurable.

Therefore

$$A_n = (A_n \cap S) \cup (A_n \sim S) = [S \cap (-n, n)] \cup (A_n \sim S)$$

is the union of two measurable sets and hence measurable. Since this holds for every n ,

$$U = \bigcup_{n=1}^{\infty} A_n$$

is measurable, being a countable union of measurable sets.

Observe where nondegeneracy was used: it is what guarantees that each $x \in U$ has, on at least one side, room inside a member of $\mathcal{C}$ for arbitrarily short closed nondegenerate subintervals, and hence that $\mathcal{F}_n$ is a genuine Vitali covering. For degenerate intervals the statement is false: if E is any nonmeasurable set, then $E = \bigcup_{x \in E} [x, x]$ is a union of degenerate closed intervals.

6.3 Problems 6.15–6.21

Problem 6.15. Define f on $\mathbb{R}$ by

$$f(x) = \begin{cases} x \sin(1/x) & \text{if } x \neq 0, \\ 0 & \text{if } x = 0. \end{cases}$$

Find the upper and lower derivatives of f at $x = 0$.

Solution. Since $f(0) = 0$, for $t \neq 0$ the difference quotient at 0 is

$$\frac{f(0+t) - f(0)}{t} = \frac{t \sin(1/t)}{t} = \sin(1/t).$$

So, with the definitions of Section 6.2,

$$\overline{D}f(0) = \lim_{h \rightarrow 0} \left[\sup_{0 < |t| \leq h} \sin(1/t) \right], \quad \underline{D}f(0) = \lim_{h \rightarrow 0} \left[\inf_{0 < |t| \leq h} \sin(1/t) \right].$$

Fix $h > 0$. Choose a natural number k so large that

$$t_k = \frac{1}{\pi/2 + 2k\pi} \leq h.$$

Then $0 < t_k \leq h$ and $\sin(1/t_k) = \sin(\pi/2 + 2k\pi) = 1$. Since $|\sin| \leq 1$ always,

$$\sup_{0 < |t| \leq h} \sin(1/t) = 1 \quad \text{for every } h > 0,$$

and therefore $\overline{D}f(0) = 1$.

Similarly, for $h > 0$ choose k so large that

$$s_k = \frac{1}{-\pi/2 + 2k\pi} \leq h.$$

Then $0 < s_k \leq h$ and $\sin(1/s_k) = \sin(2k\pi - \pi/2) = -1$, so

$$\inf_{0 < |t| \leq h} \sin(1/t) = -1 \quad \text{for every } h > 0,$$

and therefore $\underline{D}f(0) = -1$.

Thus

$$\underline{D}f(0) = -1 < 1 = \overline{D}f(0),$$

and in particular f fails to be differentiable at $x = 0$, although both derivatives are finite there. (Observe also that f is continuous at 0, since $|f(x)| \leq |x|$ for all x ; continuity at a point is of course no guarantee of differentiability there.)

Problem 6.16. Let g be integrable over $[a, b]$. Define the antiderivative of g to be the function f defined on $[a, b]$ by

$$f(x) = \int_a^x g \quad \text{for all } x \in [a, b].$$

Show that f is differentiable almost everywhere on (a, b) .

Solution. Write $g = g^+ - g^-$, where $g^+ = \max\{g, 0\}$ and $g^- = \max\{-g, 0\}$ are nonnegative measurable functions. Since $|g^\pm| \leq |g|$ and g is integrable over $[a, b]$, both g^+ and g^- are integrable over $[a, b]$, and hence over every measurable subset of $[a, b]$. Define, for $x \in [a, b]$,

$$f_1(x) = \int_a^x g^+, \quad f_2(x) = \int_a^x g^-.$$

By the linearity of integration, $f = f_1 - f_2$ on $[a, b]$.

Each f_i is increasing on $[a, b]$. Indeed, let $a \leq x < y \leq b$. By the additivity of integration over domains (Chapter 4),

$$f_1(y) - f_1(x) = \int_a^y g^+ - \int_a^x g^+ = \int_x^y g^+ \geq 0,$$

because $g^+ \geq 0$ and the integral of a nonnegative integrable function is nonnegative. Hence $f_1(x) \leq f_1(y)$, and the same computation with g^- in place of g^+ shows f_2 is increasing.

Now apply Lebesgue's Theorem to each of the monotone functions f_1 and f_2 on the open interval (a, b) : there are sets $E_1, E_2 \subseteq (a, b)$ of measure zero such that f_1 is differentiable at every point of $(a, b) \sim E_1$ and f_2 is differentiable at every point of $(a, b) \sim E_2$. The set $E = E_1 \cup E_2$ has measure zero, by the countable subadditivity of measure.

Let $x \in (a, b) \sim E$. Then both limits

$$f'_1(x) = \lim_{t \rightarrow 0} \frac{f_1(x+t) - f_1(x)}{t}, \quad f'_2(x) = \lim_{t \rightarrow 0} \frac{f_2(x+t) - f_2(x)}{t}$$

exist and are finite, and therefore, since

$$\frac{f(x+t) - f(x)}{t} = \frac{f_1(x+t) - f_1(x)}{t} - \frac{f_2(x+t) - f_2(x)}{t}$$

for all $t \neq 0$ with $x+t \in [a, b]$, the limit as $t \rightarrow 0$ of the left-hand side exists and equals $f'_1(x) - f'_2(x)$. Thus f is differentiable at x , with

$$f'(x) = f'_1(x) - f'_2(x).$$

Since E has measure zero, f is differentiable at almost every point of (a, b) .

Problem 6.17. Let f be an increasing bounded function on the open, bounded interval (a, b) . Verify (15).

Solution. Recall that (15) is the conclusion of Corollary 4: for an increasing function on a closed, bounded interval $[a, b]$, the derivative f' is integrable over $[a, b]$ and

$$\int_a^b f' \leq f(b) - f(a).$$

For f increasing and bounded on the open interval (a, b) the endpoint values are to be read as the one-sided limits, and the assertion to be verified is: f' , which by Lebesgue's Theorem is defined almost everywhere on (a, b) , is integrable over (a, b) and

$$\int_a^b f' \leq \lim_{x \rightarrow b^-} f(x) - \lim_{x \rightarrow a^+} f(x).$$

Since f is bounded on (a, b) , the numbers

$$A = \inf_{x \in (a, b)} f(x), \quad B = \sup_{x \in (a, b)} f(x)$$

are finite, and since f is increasing, monotone convergence of the values gives

$$A = \lim_{x \rightarrow a^+} f(x), \quad B = \lim_{x \rightarrow b^-} f(x).$$

Indeed, for $\epsilon > 0$ there is $x_0 \in (a, b)$ with $f(x_0) < A + \epsilon$, and then $A \leq f(x) \leq f(x_0) < A + \epsilon$ for all $x \in (a, x_0)$; the argument at b is symmetric.

Define $\tilde{f}$ on the closed interval $[a, b]$ by

$$\tilde{f}(a) = A, \quad \tilde{f}(x) = f(x) \text{ for } x \in (a, b), \quad \tilde{f}(b) = B.$$

Then $\tilde{f}$ is increasing on $[a, b]$: if $a < x < y < b$ then $\tilde{f}(x) = f(x) \leq f(y) = \tilde{f}(y)$ since f is increasing; and $\tilde{f}(a) = A \leq f(x) \leq B = \tilde{f}(b)$ for every $x \in (a, b)$ by the definition of infimum and supremum; finally $A \leq B$.

Apply Corollary 4 to the increasing function $\tilde{f}$ on $[a, b]$: $\tilde{f}'$ is integrable over $[a, b]$ and

$$\int_a^b \tilde{f}' \leq \tilde{f}(b) - \tilde{f}(a) = B - A.$$

Finally, $\tilde{f}$ and f agree on (a, b) , and differentiability at a point $x \in (a, b)$ together with the value of the derivative there depends only on the values of the function in a neighbourhood of x contained in (a, b) . Hence for every $x \in (a, b)$, $\tilde{f}$ is differentiable at x if and only if f is, and then $\tilde{f}'(x) = f'(x)$. Both derivatives exist for almost all $x \in (a, b)$, by Lebesgue's Theorem. Since $\{a, b\}$ has measure zero, the two integrals agree, and we conclude that f' is integrable over (a, b) with

$$\int_a^b f' = \int_a^b \tilde{f}' \leq B - A = \sup_{x \in (a, b)} f(x) - \inf_{x \in (a, b)} f(x) = \lim_{x \rightarrow b^-} f(x) - \lim_{x \rightarrow a^+} f(x).$$

This is (15) for f on (a, b) ; note that, since A and B are respectively the largest and the smallest values that an increasing extension of f to $[a, b]$ may take at a and at b , the bound obtained is the sharp form (18) of the inequality.

Problem 6.18. Show that if f is defined on (a, b) and $c \in (a, b)$ is a local minimizer for f , then $\underline{D}f(c) \leq 0 \leq \overline{D}f(c)$.

Solution. That c is a local minimizer for f means that there is a $\delta > 0$ such that

$$(c - \delta, c + \delta) \subseteq (a, b) \quad \text{and} \quad f(x) \geq f(c) \text{ for all } x \in (c - \delta, c + \delta).$$

For $0 < h \leq \delta/2$ put

$$S(h) = \sup_{0 < |t| \leq h} \frac{f(c+t) - f(c)}{t}, \quad I(h) = \inf_{0 < |t| \leq h} \frac{f(c+t) - f(c)}{t},$$

so that $\overline{D}f(c) = \lim_{h \rightarrow 0} S(h)$ and $\underline{D}f(c) = \lim_{h \rightarrow 0} I(h)$. As h decreases the supremum is taken over a smaller set of values of t , so S is nondecreasing in h and I is nonincreasing in h ; consequently both limits exist in the extended real numbers, and

$$\overline{D}f(c) = \inf_{0 < h \leq \delta/2} S(h), \quad \underline{D}f(c) = \sup_{0 < h \leq \delta/2} I(h).$$

Fix h with $0 < h \leq \delta/2$.

Take $t = h$. Then $0 < |t| \leq h$ and $c + t \in (c - \delta, c + \delta)$, so $f(c + t) - f(c) \geq 0$; since $t > 0$,

$$\frac{f(c + h) - f(c)}{h} \geq 0, \quad \text{hence } S(h) \geq 0.$$

As this holds for every such h , taking the infimum over h gives $\overline{D}f(c) \geq 0$.

Now take $t = -h$. Then $0 < |t| \leq h$ and $c + t \in (c - \delta, c + \delta)$, so again $f(c + t) - f(c) \geq 0$; since now $t = -h < 0$,

$$\frac{f(c - h) - f(c)}{-h} \leq 0, \quad \text{hence } I(h) \leq 0.$$

As this holds for every such h , taking the supremum over h gives $\underline{D}f(c) \leq 0$.

Therefore

$$\underline{D}f(c) \leq 0 \leq \overline{D}f(c),$$

as asserted. (In particular, if f happens to be differentiable at the local minimizer c , then $\underline{D}f(c) = \overline{D}f(c) = f'(c)$, and the two inequalities force $f'(c) = 0$: this is the familiar interior extremum theorem. The same argument applied to $-f$ shows that at a local maximizer one again has $\underline{D}f(c) \leq 0 \leq \overline{D}f(c)$, since $\overline{D}(-f) = -\underline{D}f$ and $\underline{D}(-f) = -\overline{D}f$.)

Problem 6.19. Let f be continuous on $[a, b]$ with $\overline{D}f \geq 0$ on (a, b) . Show that f is increasing on $[a, b]$. (Hint: First show this for a function g for which $\overline{D}g \geq \epsilon > 0$ on (a, b) . Apply this to the function $g(x) = f(x) + \epsilon x$.)

Solution. Throughout, “increasing” means $f(u) \leq f(v)$ whenever $u < v$, as in Section 6.1. It is convenient to split the upper derivative into its one-sided parts. For $c \in (a, b)$ set

$$D^+f(c) = \limsup_{t \rightarrow 0^+} \frac{f(c+t) - f(c)}{t}, \quad D^-f(c) = \limsup_{s \rightarrow 0^+} \frac{f(c) - f(c-s)}{s}.$$

For $h > 0$,

$$\sup_{0 < |t| \leq h} \frac{f(c+t) - f(c)}{t} = \max \left\{ \sup_{0 < t \leq h} \frac{f(c+t) - f(c)}{t}, \sup_{0 < s \leq h} \frac{f(c) - f(c-s)}{s} \right\},$$

because the substitution $t = -s$ turns a quotient with $t < 0$ into $(f(c) - f(c-s))/s$. Each of the two suprema is nondecreasing in h , so letting $h \rightarrow 0$ gives

$$\overline{D}f(c) = \max\{D^+f(c), D^-f(c)\}.$$

The proof below establishes the theorem for the hypothesis $D^+f \geq 0$ on (a, b) (and, by reflection, for $D^-f \geq 0$); a closing remark shows that the two-sided derivate $\overline{D}f = \max\{D^+f, D^-f\}$, which is what Section 6.2 denotes by $\overline{D}f$, does not suffice, so that the hypothesis has to be read one-sidedly.

Step 1, the reduction supplied by the hint. Suppose it is known that

(L) if g is continuous on $[a, b]$ and $D^+g \geq \epsilon > 0$ on (a, b) , then g is increasing on $[a, b]$.
Let f be continuous on $[a, b]$ with $D^+f \geq 0$ on (a, b) , and let $\epsilon > 0$. Put $g(x) = f(x) + \epsilon x$; g is continuous on $[a, b]$. For $c \in (a, b)$ and $t \neq 0$,

$$\frac{g(c+t) - g(c)}{t} = \frac{f(c+t) - f(c)}{t} + \epsilon,$$

so the supremum over $0 < t \leq h$ of the left side is ϵ more than that of the first term on the right; letting $h \rightarrow 0$,

$$D^+g(c) = D^+f(c) + \epsilon \geq \epsilon > 0.$$

By (L), g is increasing on $[a, b]$: if $a \leq u < v \leq b$ then $f(u) + \epsilon u \leq f(v) + \epsilon v$, that is,

$$f(v) - f(u) \geq \epsilon(u - v) \geq -\epsilon(b - a).$$

Since $\epsilon > 0$ is arbitrary, $f(v) - f(u) \geq 0$. Thus f is increasing on $[a, b]$, and it remains only to prove (L).

Step 2, the crossing-point argument, which proves (L). Assume g is continuous on $[a, b]$ and $D^+g \geq \epsilon > 0$ on (a, b) , and suppose, to get a contradiction, that g is not increasing: there are u, v with $a \leq u < v \leq b$ and $g(u) > g(v)$. Fix λ with $g(v) < \lambda < g(u)$ and set

$$S = \{x \in [u, v] : g(x) \geq \lambda\}, \quad c = \sup S.$$

S is nonempty ($u \in S$) and closed in $[u, v]$ by the continuity of g , so $c \in S$, i.e. $g(c) \geq \lambda$; and $c < v$ since $g(v) < \lambda$. By the definition of c ,

$$g(x) < \lambda \quad \text{for all } x \in (c, v].$$

Letting $x \rightarrow c^+$ and using continuity gives $g(c) \leq \lambda$, hence $g(c) = \lambda$; in particular $c \neq u$, since $g(u) > \lambda$, so $c > u$ and $c \in (u, v) \subseteq (a, b)$. Consequently, for $0 < t \leq v - c$,

$$\frac{g(c+t) - g(c)}{t} = \frac{g(c+t) - \lambda}{t} < 0,$$

so that

$$D^+g(c) \leq 0.$$

Since $c \in (a, b)$, the hypothesis gives $D^+g(c) \geq \epsilon > 0$, and this contradicts $D^+g(c) \leq 0$. Hence no such pair $u < v$ exists and g is increasing on $[a, b]$. This proves (L), and with Step 1 it proves if f is continuous on $[a, b]$ and $D^+f \geq 0$ on (a, b) , then f is increasing on $[a, b]$.

The same holds with D^- in place of D^+ . Indeed, put $\tilde{f}(x) = -f(-x)$ on $[-b, -a]$; for $s > 0$,

$$\frac{\tilde{f}(x+s) - \tilde{f}(x)}{s} = \frac{f(-x) - f(-x-s)}{s},$$

so $D^+\tilde{f}(x) = D^-f(-x)$, and $\tilde{f}$ is increasing precisely when f is; so the statement for D^- follows from the one just proved.

Why the hypothesis must be read one-sidedly. With the two-sided derivate of Section 6.2 the assertion is false. Observe first where the argument above breaks down: at the crossing point c we obtained only $D^+g(c) \leq 0$, and $\overline{D}g(c) = \max\{D^+g(c), D^-g(c)\} \geq \epsilon$ then forces $D^-g(c) \geq \epsilon$, which merely says that g dips below λ arbitrarily near c on the left as well. That is not absurd, and in fact no argument can rule it out.

Take $\alpha = 1/2$ and $\beta = 13$, so that β is an odd integer and $\alpha\beta = 13/2 > 1 + 3\pi/2$, and let

$$W(x) = \sum_{n=0}^{\infty} \alpha^n \cos(\beta^n \pi x).$$

The series is dominated by the convergent geometric series $\sum \alpha^n$, so it converges uniformly on $\mathbb{R}$ and W is continuous. Because β^n is odd, $\cos(\beta^n \pi) = -1$, so

$$W(0) = \sum_{n=0}^{\infty} \alpha^n = 2, \quad W(1) = -\sum_{n=0}^{\infty} \alpha^n = -2,$$

and W is not increasing on $[0, 1]$. We claim that nevertheless $\overline{DW}(x) = +\infty$ for every $x \in (0, 1)$, so that W satisfies the hypothesis as printed.

Fix x and a natural number m . Write $\beta^m x = k_m + \xi_m$ with k_m an integer and $-1/2 < \xi_m \leq 1/2$, and put

$$y_m^+ = \frac{k_m + 1}{\beta^m}, \quad y_m^- = \frac{k_m - 1}{\beta^m}.$$

Then $y_m^+ - x = (1 - \xi_m)/\beta^m$ and $y_m^- - x = -(1 + \xi_m)/\beta^m$, so

$$\frac{1}{2\beta^m} \leq y_m^+ - x \leq \frac{3}{2\beta^m}, \quad -\frac{3}{2\beta^m} \leq y_m^- - x \leq -\frac{1}{2\beta^m},$$

and both points tend to x ; discard the finitely many m for which they fall outside $(0, 1)$. Split the series at $n = m$.

For $n < m$, the Mean Value Theorem applied to the cosine gives $|\cos(\beta^n \pi y) - \cos(\beta^n \pi x)| \leq \beta^n \pi |y - x|$, so for either choice of sign,

$$\left| \frac{1}{y_m^\pm - x} \sum_{n=0}^{m-1} \alpha^n [\cos(\beta^n \pi y_m^\pm) - \cos(\beta^n \pi x)] \right| \leq \pi \sum_{n=0}^{m-1} (\alpha\beta)^n \leq \frac{\pi}{\alpha\beta - 1} (\alpha\beta)^m.$$

For $n \geq m$, use that β is odd: $\beta^{n-m}(k_m \pm 1)$ has the parity of $k_m + 1$ and $\beta^{n-m}k_m$ has the parity of k_m , whence

$$\cos(\beta^n \pi y_m^\pm) = (-1)^{k_m+1}, \quad \cos(\beta^n \pi x) = (-1)^{k_m} \cos(\beta^{n-m} \pi \xi_m).$$

Therefore, for both choices of sign,

$$\sum_{n=m}^{\infty} \alpha^n [\cos(\beta^n \pi y_m^\pm) - \cos(\beta^n \pi x)] = -(-1)^{k_m} \Sigma_m, \quad \Sigma_m = \sum_{n=m}^{\infty} \alpha^n [1 + \cos(\beta^{n-m} \pi \xi_m)].$$

Every term of Σ_m is nonnegative, and its $n = m$ term is $\alpha^m(1 + \cos(\pi \xi_m)) \geq \alpha^m$ because $|\xi_m| \leq 1/2$; hence $\Sigma_m \geq \alpha^m$. Dividing by $y_m^+ - x > 0$ produces a quantity of sign $-(-1)^{k_m}$ and absolute value at least $\alpha^m \cdot \frac{2\beta^m}{3} = \frac{2}{3}(\alpha\beta)^m$; dividing by $y_m^- - x < 0$ produces a quantity of the opposite sign $(-1)^{k_m}$ and again of absolute value at least $\frac{2}{3}(\alpha\beta)^m$.

Set $\kappa = \frac{2}{3} - \frac{\pi}{\alpha\beta-1} = \frac{2}{3} - \frac{\pi}{5.5} > 0$. Combining the two estimates, the difference quotients

$$\frac{W(y_m^+) - W(x)}{y_m^+ - x} \quad \text{and} \quad \frac{W(y_m^-) - W(x)}{y_m^- - x}$$

have opposite signs and each has absolute value at least $\kappa(\alpha\beta)^m$. In particular, for each m at least one of the two is $\geq \kappa(\alpha\beta)^m$. Since $y_m^\pm \rightarrow x$ and $\alpha\beta > 1$, this gives

$$\overline{DW}(x) = \limsup_{t \rightarrow 0} \frac{W(x+t) - W(x)}{t} = +\infty$$

at every x . (The other member of each pair shows likewise that $\underline{DW}(x) = -\infty$; this is Weierstrass's classical proof that W is nowhere differentiable.)

So W is continuous on $[0, 1]$, satisfies $\overline{DW} \geq 0$ on $(0, 1)$, and is not increasing. Accordingly the hypothesis of the problem is to be read as a hypothesis on one fixed one-sided derivate, and under that reading Steps 1 and 2 above are a complete proof.

Problem 6.20. Let f and g be real-valued functions on (a, b) . Show that

$$\underline{D}f + \underline{D}g \leq \underline{D}(f + g) \leq \overline{D}(f + g) \leq \overline{D}f + \overline{D}g \quad \text{on } (a, b).$$

Solution. Fix $c \in (a, b)$ and choose $h_0 > 0$ with $(c - h_0, c + h_0) \subseteq (a, b)$. For $0 < h \leq h_0$ and for a real-valued function φ on (a, b) write

$$Q_\varphi(t) = \frac{\varphi(c+t) - \varphi(c)}{t} \quad (0 < |t| \leq h_0), \quad S_\varphi(h) = \sup_{0 < |t| \leq h} Q_\varphi(t), \quad I_\varphi(h) = \inf_{0 < |t| \leq h} Q_\varphi(t),$$

so that, by definition, $\overline{D}\varphi(c) = \lim_{h \rightarrow 0} S_\varphi(h)$ and $\underline{D}\varphi(c) = \lim_{h \rightarrow 0} I_\varphi(h)$. Each $Q_\varphi(t)$ is a real number and the index set is nonempty, so $S_\varphi(h) \in (-\infty, +\infty]$ and $I_\varphi(h) \in [-\infty, +\infty]$; in particular the sums $S_f(h) + S_g(h)$ and $I_f(h) + I_g(h)$ are unambiguously defined in the extended reals. Moreover S_φ is nondecreasing and I_φ is nonincreasing in h , so the two limits above exist in $[-\infty, +\infty]$; as usual, the outer inequalities of the problem are asserted whenever the sums on their outer sides are defined, i.e. are not of the form $+\infty + (-\infty)$.

The whole proof rests on the identity

$$Q_{f+g}(t) = \frac{(f(c+t) + g(c+t)) - (f(c) + g(c))}{t} = Q_f(t) + Q_g(t), \quad 0 < |t| \leq h_0.$$

The upper estimate. Fix $h \in (0, h_0]$. For every t with $0 < |t| \leq h$,

$$Q_{f+g}(t) = Q_f(t) + Q_g(t) \leq S_f(h) + S_g(h),$$

since each term is dominated by the corresponding supremum (the inequality is trivially true if the right-hand side is $+\infty$). Taking the supremum over such t ,

$$S_{f+g}(h) \leq S_f(h) + S_g(h) \quad \text{for all } 0 < h \leq h_0.$$

Now let $h \rightarrow 0$. All three quantities are monotone in h , so all three limits exist in $[-\infty, +\infty]$, and if $\overline{D}f(c) + \overline{D}g(c)$ is defined then $\lim_{h \rightarrow 0} [S_f(h) + S_g(h)] = \overline{D}f(c) + \overline{D}g(c)$. Hence

$$\overline{D}(f + g)(c) \leq \overline{D}f(c) + \overline{D}g(c).$$

The lower estimate. Fix $h \in (0, h_0]$. For every t with $0 < |t| \leq h$,

$$Q_{f+g}(t) = Q_f(t) + Q_g(t) \geq I_f(h) + I_g(h),$$

and taking the infimum over such t ,

$$I_{f+g}(h) \geq I_f(h) + I_g(h) \quad \text{for all } 0 < h \leq h_0.$$

Letting $h \rightarrow 0$ exactly as before,

$$\underline{D}(f + g)(c) \geq \underline{D}f(c) + \underline{D}g(c).$$

The middle estimate. For each $h \in (0, h_0]$ the infimum of a nonempty set of real numbers does not exceed its supremum, so $I_{f+g}(h) \leq S_{f+g}(h)$; letting $h \rightarrow 0$ gives

$$\underline{D}(f + g)(c) \leq \overline{D}(f + g)(c).$$

(This is the inequality $\underline{D}\varphi \leq \overline{D}\varphi$ recorded in Section 6.2 for every φ .)

Since $c \in (a, b)$ was arbitrary, the chain

$$\underline{D}f + \underline{D}g \leq \underline{D}(f + g) \leq \overline{D}(f + g) \leq \overline{D}f + \overline{D}g$$

holds at every point of (a, b) .

Both outer inequalities may be strict. First observe that for any real-valued φ and any $h > 0$, $Q_{-\varphi}(t) = -Q_\varphi(t)$, so $S_{-\varphi}(h) = -I_\varphi(h)$ and $I_{-\varphi}(h) = -S_\varphi(h)$; letting $h \rightarrow 0$,

$$\overline{D}(-\varphi) = -\underline{D}\varphi, \quad \underline{D}(-\varphi) = -\overline{D}\varphi.$$

Now take $(a, b) = (-1, 1)$, let f be the function of Problem 15, $f(x) = x \sin(1/x)$ for $x \neq 0$ and $f(0) = 0$, let $g = -f$, and evaluate at $c = 0$. By Problem 15, $\overline{D}f(0) = 1$ and $\underline{D}f(0) = -1$, so by the displayed identities $\overline{D}g(0) = 1$ and $\underline{D}g(0) = -1$. Since $f + g \equiv 0$ we have $\underline{D}(f + g)(0) = \overline{D}(f + g)(0) = 0$. Thus the right-hand end of the chain is 2 and the left-hand end is -2 , while both middle terms are 0.

Problem 6.21. Let f be defined on $[a, b]$ and g a continuous function on $[\alpha, \beta]$ that is differentiable at $\gamma \in (\alpha, \beta)$ with $g(\gamma) = c \in (a, b)$. Verify the following.

(i) If $g'(\gamma) > 0$, then $\overline{D}(f \circ g)(\gamma) = \overline{D}f(c) \cdot g'(\gamma)$.

(ii) If $g'(\gamma) = 0$ and the upper and lower derivatives of f at c are finite, then $\overline{D}(f \circ g)(\gamma) = 0$.

Solution. Throughout put

$$\sigma(t) = g(\gamma + t) - g(\gamma) = g(\gamma + t) - c, \quad Q(\tau) = \frac{f(c + \tau) - f(c)}{\tau} \quad (\tau \neq 0, c + \tau \in [a, b]),$$

and, writing $r_0 = \min\{c - a, b - c\} > 0$ (positive because c is an interior point of $[a, b]$), put $S(r) = \sup_{0 < |\tau| \leq r} Q(\tau)$ for $0 < r \leq r_0$; every τ occurring here has $c + \tau \in [a, b]$, so $S(r)$ is well defined in $(-\infty, +\infty]$, S is nondecreasing in r , and $\overline{D}f(c) = \lim_{r \rightarrow 0+} S(r) = \inf_{0 < r \leq r_0} S(r)$. Since c is interior to $[a, b]$ and g is continuous at γ , there is $\delta_1 > 0$ with $(\gamma - \delta_1, \gamma + \delta_1) \subseteq (\alpha, \beta)$ and $g((\gamma - \delta_1, \gamma + \delta_1)) \subseteq (a, b)$; so $f \circ g$ is defined on $(\gamma - \delta_1, \gamma + \delta_1)$ and its upper derivative at γ makes sense. Note that σ is continuous, $\sigma(0) = 0$, and $\sigma(t)/t \rightarrow g'(\gamma)$ as $t \rightarrow 0$. Whenever $\sigma(t) \neq 0$,

$$\frac{(f \circ g)(\gamma + t) - (f \circ g)(\gamma)}{t} = \frac{f(c + \sigma(t)) - f(c)}{\sigma(t)} \cdot \frac{\sigma(t)}{t} = Q(\sigma(t)) \cdot \frac{\sigma(t)}{t}. \quad (\dagger)$$

We use twice the following elementary fact about upper limits.

Lemma. Let u and v be real-valued on a punctured neighbourhood of 0, with $v(t) \rightarrow m > 0$ as $t \rightarrow 0$, and let $L = \limsup_{t \rightarrow 0} u(t) \in [-\infty, +\infty]$. Then $\limsup_{t \rightarrow 0} u(t)v(t) = mL$.

Proof of the Lemma. Fix $\eta \in (0, m)$; for all small $t \neq 0$ we have $m - \eta < v(t) < m + \eta$, and in particular $v(t) > 0$.

We first show $\limsup_{t \rightarrow 0} u(t)v(t) \leq mL$. Suppose L is finite. For all small $t \neq 0$ we also have $u(t) < L + \eta$, and multiplying by $v(t) > 0$ gives

$$u(t)v(t) < (L + \eta)v(t) \leq \max\{(L + \eta)(m - \eta), (L + \eta)(m + \eta)\},$$

the last step because $(L + \eta)v(t)$ lies between the two displayed products according to the sign of $L + \eta$. Hence $\limsup_{t \rightarrow 0} uv \leq \max\{(L + \eta)(m - \eta), (L + \eta)(m + \eta)\}$, and both products tend to mL as $\eta \rightarrow 0$, so $\limsup_{t \rightarrow 0} uv \leq mL$. If $L = -\infty$, then for each $M > 0$ we have $u(t) < -M$ for all small $t \neq 0$, whence $u(t)v(t) < -M(m - \eta)$; as M is arbitrary and $m - \eta > 0$, $\limsup_{t \rightarrow 0} uv = -\infty = mL$. If $L = +\infty$ the inequality $\limsup_{t \rightarrow 0} uv \leq mL$ is vacuous.

For the reverse inequality choose $t_n \rightarrow 0$ with $t_n \neq 0$ and $u(t_n) \rightarrow L$. Since $v(t_n) \rightarrow m > 0$, we get $u(t_n)v(t_n) \rightarrow mL$, this also when $L = \pm\infty$. Hence $\limsup_{t \rightarrow 0} uv \geq mL$, and the Lemma is proved.

Part (i). Let $m = g'(\gamma) > 0$. Since $\sigma(t)/t \rightarrow m$, there is $\delta_2 \in (0, \delta_1]$ such that

$$\frac{m}{2} \leq \frac{\sigma(t)}{t} \leq 2m \quad \text{for } 0 < |t| \leq \delta_2,$$

and, shrinking δ_2 further, we may also require $2m\delta_2 \leq r_0$, so that $S(2mh)$ is defined for every $h \in (0, \delta_2]$. In particular $\sigma(t) \neq 0$ for $0 < |t| \leq \delta_2$, $\sigma(t)$ has the same sign as t , and $|\sigma(t)| \leq 2m|t|$. Thus $(\dagger)$ is available for all such t , and by the Lemma (with $u(t) = Q(\sigma(t))$ and $v(t) = \sigma(t)/t \rightarrow m > 0$),

$$\overline{D}(f \circ g)(\gamma) = \limsup_{t \rightarrow 0} Q(\sigma(t)) \cdot \frac{\sigma(t)}{t} = m \cdot \limsup_{t \rightarrow 0} Q(\sigma(t)).$$

It remains to prove that

$$\limsup_{t \rightarrow 0} Q(\sigma(t)) = \overline{D}f(c),$$

and for this we compare the suprema of the two families of difference quotients.

First, let $0 < h \leq \delta_2$. For $0 < |t| \leq h$ we have $0 < |\sigma(t)| \leq 2mh$, so $Q(\sigma(t))$ belongs to the family $\{Q(\tau) : 0 < |\tau| \leq 2mh\}$, and therefore

$$\sup_{0 < |t| \leq h} Q(\sigma(t)) \leq S(2mh).$$

Letting $h \rightarrow 0^+$ gives $\limsup_{t \rightarrow 0} Q(\sigma(t)) \leq \overline{D}f(c)$.
 Second, again let $0 < h \leq \delta_2$ and put

$$\rho(h) = \min\{\sigma(h), -\sigma(-h)\}.$$

Both entries are positive, because $\sigma(h) \geq (m/2)h > 0$ and $\sigma(-h) \leq (m/2)(-h) < 0$; also $\rho(h) \leq 2mh$, so $\rho(h) \rightarrow 0^+$ as $h \rightarrow 0^+$. The function σ is continuous on $[-h, h]$ with $\sigma(-h) < 0 < \sigma(h)$, so by the Intermediate Value Theorem it attains every value in $[\sigma(-h), \sigma(h)] \supseteq [-\rho(h), \rho(h)]$. Hence every τ with $0 < |\tau| \leq \rho(h)$ equals $\sigma(t)$ for some $t \in [-h, h]$, and such t is nonzero because $\sigma(0) = 0 \neq \tau$. Consequently

$$\sup_{0 < |t| \leq h} Q(\sigma(t)) \geq \sup_{0 < |\tau| \leq \rho(h)} Q(\tau) = S(\rho(h)).$$

Since $\rho(h) \rightarrow 0^+$ as $h \rightarrow 0^+$ and $S(r)$ has the limit $\overline{D}f(c)$ as $r \rightarrow 0^+$, letting $h \rightarrow 0^+$ gives $\limsup_{t \rightarrow 0} Q(\sigma(t)) \geq \overline{D}f(c)$.

Combining the two estimates, $\limsup_{t \rightarrow 0} Q(\sigma(t)) = \overline{D}f(c)$, and therefore

$$\overline{D}(f \circ g)(\gamma) = \overline{D}f(c) \cdot g'(\gamma),$$

this being an equality in the extended reals (both sides are simultaneously $+\infty$ or $-\infty$, since $g'(\gamma) > 0$). Part (ii). Now let $g'(\gamma) = 0$ and suppose $\overline{D}f(c)$ and $\underline{D}f(c)$ are finite. Since $S(r) \downarrow \overline{D}f(c)$ as $r \rightarrow 0^+$ and the limit is finite, there is $r_1 \in (0, r_0]$ with $S(r_1) \leq \overline{D}f(c) + 1 < \infty$; likewise, since the infima $\inf_{0 < |\tau| \leq r} Q(\tau)$ increase to the finite number $\underline{D}f(c)$ as r decreases to 0, there is $r_2 \in (0, r_0]$ with $\inf_{0 < |\tau| \leq r_2} Q(\tau) \geq \underline{D}f(c) - 1 > -\infty$. Put $\delta_0 = \min\{r_1, r_2\}$ and

$$M = \max\{|\overline{D}f(c)| + 1, |\underline{D}f(c)| + 1\},$$

so that

$$|Q(\tau)| \leq M \quad \text{for all } \tau \text{ with } 0 < |\tau| \leq \delta_0.$$

Let $\eta > 0$. Since g is continuous at γ , there is $\delta' \in (0, \delta_1]$ with $|\sigma(t)| \leq \delta_0$ for $|t| \leq \delta'$; and since $\sigma(t)/t \rightarrow g'(\gamma) = 0$, we may shrink δ' so that in addition

$$\frac{|\sigma(t)|}{|t|} < \frac{\eta}{M} \quad \text{for } 0 < |t| \leq \delta'.$$

Fix t with $0 < |t| \leq \delta'$. If $\sigma(t) = 0$ then $(f \circ g)(\gamma + t) = f(c) = (f \circ g)(\gamma)$ and the difference quotient of $f \circ g$ at γ vanishes. If $\sigma(t) \neq 0$ then, by $(\dagger)$,

$$\left| \frac{(f \circ g)(\gamma + t) - (f \circ g)(\gamma)}{t} \right| = |Q(\sigma(t))| \cdot \frac{|\sigma(t)|}{|t|} \leq M \cdot \frac{\eta}{M} = \eta.$$

In both cases the difference quotient of $f \circ g$ at γ has absolute value at most η for $0 < |t| \leq \delta'$. As $\eta > 0$ was arbitrary,

$$\lim_{t \rightarrow 0} \frac{(f \circ g)(\gamma + t) - (f \circ g)(\gamma)}{t} = 0,$$

so $f \circ g$ is in fact differentiable at γ with $(f \circ g)'(\gamma) = 0$; in particular

$$\overline{D}(f \circ g)(\gamma) = 0 = \underline{D}(f \circ g)(\gamma).$$

The finiteness hypothesis in (ii) cannot be dropped. Take $[a, b] = [\alpha, \beta] = [-1, 1]$, $\gamma = 0$, $g(t) = t^2$, and

$$f(s) = \begin{cases} \sqrt{s} & \text{if } 0 \leq s \leq 1, \\ 0 & \text{if } -1 \leq s < 0. \end{cases}$$

Then g is continuous on $[-1, 1]$ and differentiable at 0 with $g'(0) = 0$, and $c = g(0) = 0 \in (-1, 1)$. The difference quotients of f at 0 are $Q(\tau) = 1/\sqrt{\tau}$ for $\tau > 0$ and $Q(\tau) = 0$ for $\tau < 0$, so $\overline{D}f(0) = +\infty$ (while $\underline{D}f(0) = 0$). Here $(f \circ g)(t) = \sqrt{t^2} = |t|$, whose difference quotients at 0 are $|t|/t = \pm 1$, so

$$\overline{D}(f \circ g)(0) = 1 \neq 0.$$

Thus the conclusion of (ii) fails when the upper derivative of f at c is infinite: the unboundedness of Q near 0 is picked up exactly along the values $\tau = \sigma(t)$, at a rate that compensates for $\sigma(t)/t \rightarrow 0$.

6.4 Problems 6.22–6.28

Problem 6.22. Show that a strictly increasing function that is defined on an interval is measurable and then use this to show that a monotone function that is defined on an interval is measurable.

Solution. Throughout, I denotes an interval of real numbers (bounded or unbounded, open, closed or half-open) and a real-valued function f on I is measurable provided $\{x \in I : f(x) > c\}$ is a measurable set for every $c \in \mathbb{R}$; this is the criterion of Proposition 1 of Chapter 3. Every interval is a Borel set, hence measurable.

Step 1: a strictly increasing function on an interval is measurable.

Let f be strictly increasing on I and fix $c \in \mathbb{R}$. Put

$$E_c = \{x \in I : f(x) > c\}.$$

If $E_c = \emptyset$ it is measurable, so assume $E_c \neq \emptyset$ and set $\alpha = \inf E_c$, an element of $[-\infty, \infty)$.

By the definition of infimum, $E_c \subseteq [\alpha, \infty) \cap I$ (interpreting $[-\infty, \infty)$ as $\mathbb{R}$ when $\alpha = -\infty$).

Conversely, let $x \in I$ with $x > \alpha$. Since α is the infimum of E_c , there is a point $y \in E_c$ with $\alpha \leq y < x$. As f is strictly increasing and $y < x$, we have $f(x) > f(y) > c$, so $x \in E_c$. Thus

$$(\alpha, \infty) \cap I \subseteq E_c \subseteq [\alpha, \infty) \cap I.$$

Consequently E_c is either $(\alpha, \infty) \cap I$ or $((\alpha, \infty) \cap I) \cup \{\alpha\}$, and the latter can occur only when $\alpha \in I$, in which case it equals $[\alpha, \infty) \cap I$. In either case E_c is the intersection of two intervals and hence is an interval, therefore a Borel set and so measurable. Since $c \in \mathbb{R}$ was arbitrary, f is measurable on I .

Step 2: a monotone function on an interval is measurable.

First suppose f is increasing on I , that is, $f(u) \leq f(v)$ whenever $u, v \in I$ and $u < v$. Define

$$g(x) = f(x) + x \quad \text{for all } x \in I.$$

If $u < v$ are points of I , then $f(u) \leq f(v)$ and $u < v$, so $g(u) = f(u) + u < f(v) + v = g(v)$. Hence g is strictly increasing on I , and therefore measurable by Step 1. The identity function $x \mapsto x$ is continuous on I , hence measurable. By Theorem 6 of Chapter 3 (linear combinations of measurable real-valued functions are measurable),

$$f(x) = g(x) - x \quad \text{for all } x \in I$$

is measurable on I .

Now suppose f is decreasing on I . Then $-f$ is increasing on I , hence measurable by the preceding paragraph, and therefore $f = -(-f)$ is measurable.

Thus every monotone real-valued function defined on an interval is measurable.

Problem 6.23. Show that a continuous function f on $[a, b]$ is Lipschitz if its upper and lower derivatives are bounded on (a, b) .

Solution. Recall the definitions of Section 6.2: for x in (a, b) ,

$$\overline{D}f(x) = \lim_{h \rightarrow 0^+} \left[\sup_{0 < |t| \leq h} \frac{f(x+t) - f(x)}{t} \right], \quad \underline{D}f(x) = \lim_{h \rightarrow 0^+} \left[\inf_{0 < |t| \leq h} \frac{f(x+t) - f(x)}{t} \right],$$

the supremum and infimum being taken over those t with $x+t$ in $[a, b]$. By hypothesis there is a number $M \geq 0$ with

$$|\overline{D}f(x)| \leq M \quad \text{and} \quad |\underline{D}f(x)| \leq M \quad \text{for all } x \in (a, b).$$

In particular $-M \leq \underline{D}f(x)$ and $\overline{D}f(x) \leq M$ on (a, b) . We show $|f(u) - f(v)| \leq M|u - v|$ for all u, v in $[a, b]$, so that f is Lipschitz with Lipschitz constant M .

Step 1: a local estimate at each interior point.

Fix $\epsilon > 0$ and put $K = M + \epsilon$. Let $x \in (a, b)$. Since

$$\limsup_{t \rightarrow 0} \frac{f(x+t) - f(x)}{t} = \overline{D}f(x) \leq M < K \quad \text{and} \quad \liminf_{t \rightarrow 0} \frac{f(x+t) - f(x)}{t} = \underline{D}f(x) \geq -M > -K,$$

there is a $\delta_x > 0$ such that

$$-K < \frac{f(x+t) - f(x)}{t} < K \quad \text{whenever } 0 < |t| < \delta_x \text{ and } x+t \in [a, b].$$

The two inequalities together say $\left| \frac{f(x+t) - f(x)}{t} \right| < K$, and multiplying by $|t|$ (which is legitimate for t of either sign) gives $|f(x+t) - f(x)| < K|t|$. Writing $y = x+t$, and noting that the case $y = x$ is trivial, this says exactly

$$|f(y) - f(x)| \leq K|y - x| \quad \text{for all } y \in [a, b] \text{ with } |y - x| < \delta_x. \quad (*)$$

Step 2: from the local estimate to a global one on (a, b) .

Let u, w satisfy $a < u < w < b$. Put

$$S = \{v \in [u, w] : |f(v) - f(u)| \leq K(v - u)\}.$$

Then $u \in S$, so $S \neq \emptyset$, and S is closed in $[u, w]$ because f is continuous and both sides of the defining inequality are continuous in v . Let $s = \sup S$; since S is closed and bounded, $s \in S$.

Suppose $s < w$. Then $s \in [u, w] \subseteq (a, b)$, so $(*)$ holds at s with some $\delta_s > 0$. Choose v with $s < v < \min\{w, s + \delta_s\}$. Then, using $(*)$ at s and $s \in S$,

$$|f(v) - f(u)| \leq |f(v) - f(s)| + |f(s) - f(u)| \leq K(v - s) + K(s - u) = K(v - u),$$

so $v \in S$ and $v > s$, contradicting $s = \sup S$. Hence $s = w$, that is,

$$|f(w) - f(u)| \leq K(w - u) \quad \text{for all } a < u < w < b. \quad (**)$$

Step 3: including the endpoints, and letting ϵ tend to 0.

Let $u, v \in [a, b]$ with $u < v$. For each natural number n set

$$u_n = \max \left\{ u, a + \frac{1}{n} \right\}, \quad v_n = \min \left\{ v, b - \frac{1}{n} \right\}.$$

Then $a < u_n$ and $v_n < b$ for every n with $1/n < b - a$, while $u_n \rightarrow u$ and $v_n \rightarrow v$ (if $u > a$ then $u_n = u$ once $1/n < u - a$, and if $u = a$ then $u_n = a + 1/n$; similarly for v_n). Since $u < v$, we have $u_n < v_n$ for all sufficiently large n . For such n , $(**)$ applies and gives $|f(v_n) - f(u_n)| \leq K(v_n - u_n)$. Since f is continuous on $[a, b]$, letting $n \rightarrow \infty$ gives

$$|f(v) - f(u)| \leq K(v - u) = (M + \epsilon)(v - u).$$

This holds for every $\epsilon > 0$, so letting $\epsilon \rightarrow 0^+$ we obtain

$$|f(v) - f(u)| \leq M|v - u| \quad \text{for all } u, v \in [a, b].$$

Therefore f is Lipschitz on $[a, b]$, with Lipschitz constant M .

Problem 6.24. Show that for f defined in the last remark of this section, f' is not integrable over $[0, 1]$. [That remark reads: for a continuous function f on a closed, bounded interval $[a, b]$ that is differentiable on the open interval (a, b) , in the absence of a monotonicity assumption on f we cannot infer that its derivative f' is integrable over $[a, b]$. We leave it as an exercise to show that for

f defined on $[0, 1]$ by

$$f(x) = \begin{cases} x^2 \sin(1/x^2) & \text{for } 0 < x \leq 1, \\ 0 & \text{for } x = 0, \end{cases}$$

f' is not integrable over $[0, 1]$.

Solution. The function is differentiable on all of $[0, 1]$.

For $0 < x \leq 1$ the chain and product rules give

$$f'(x) = 2x \sin\left(\frac{1}{x^2}\right) - \frac{2}{x} \cos\left(\frac{1}{x^2}\right),$$

and this expression is continuous on $(0, 1]$. At $x = 0$, for $0 < x \leq 1$,

$$\left| \frac{f(x) - f(0)}{x - 0} \right| = \left| x \sin\left(\frac{1}{x^2}\right) \right| \leq x \rightarrow 0,$$

so $f'(0)$ exists and equals 0. Also $|f(x)| \leq x^2$ shows f is continuous at 0, so f is continuous on $[0, 1]$ and differentiable at every point of $[0, 1]$, as asserted in the remark. Since f' is continuous on $(0, 1]$ it is measurable there, and $\{0\}$ has measure zero, so f' is a measurable function on $[0, 1]$. Thus f' is integrable over $[0, 1]$ if and only if $\int_0^1 |f'| < \infty$.

A sequence of disjoint intervals on which f oscillates.

For each natural number n set

$$a_n = \left[(2n + \tfrac{1}{2})\pi\right]^{-1/2}, \quad b_n = \left[(2n - \tfrac{1}{2})\pi\right]^{-1/2}.$$

Since $2n - \frac{1}{2} < 2n + \frac{1}{2}$ we have $0 < a_n < b_n$, and $b_1 = (3\pi/2)^{-1/2} < 1$, so $b_n \leq b_1 < 1$ for all n and each $[a_n, b_n]$ is contained in $(0, 1)$. Moreover

$$b_{n+1} = \left[(2n + \tfrac{3}{2})\pi\right]^{-1/2} < \left[(2n + \tfrac{1}{2})\pi\right]^{-1/2} = a_n,$$

so the intervals $[a_n, b_n]$, $n = 1, 2, \dots$, are pairwise disjoint.

Because $1/a_n^2 = (2n + \frac{1}{2})\pi$ and $1/b_n^2 = (2n - \frac{1}{2})\pi$,

$$\sin\left(\frac{1}{a_n^2}\right) = \sin \frac{\pi}{2} = 1, \quad \sin\left(\frac{1}{b_n^2}\right) = \sin\left(-\frac{\pi}{2}\right) = -1,$$

and therefore

$$f(a_n) = a_n^2 = \frac{1}{(2n + \frac{1}{2})\pi}, \quad f(b_n) = -b_n^2 = -\frac{1}{(2n - \frac{1}{2})\pi}.$$

Lower bound for the integral.

On the closed interval $[a_n, b_n] \subset (0, 1]$ the derivative f' is continuous, so its Riemann and Lebesgue integrals agree (by Theorem 3 of Chapter 4) and the Fundamental Theorem of Calculus applies:

$$\int_{a_n}^{b_n} f' = f(b_n) - f(a_n).$$

Hence

$$\int_{a_n}^{b_n} |f'| \geq \left| \int_{a_n}^{b_n} f' \right| = |f(b_n) - f(a_n)| = a_n^2 + b_n^2 = \frac{1}{(2n + \frac{1}{2})\pi} + \frac{1}{(2n - \frac{1}{2})\pi} > \frac{2}{(2n + 1)\pi}.$$

Now $|f'|$ is nonnegative and measurable on $[0, 1]$, and the intervals $[a_n, b_n]$ are disjoint measurable subsets of $[0, 1]$. By Theorem 11 of Chapter 4 (Additivity Over Domains of Integration for nonnegative measurable functions), applied $N - 1$ times, $\int_{A_N} |f'| = \sum_{n=1}^N \int_{a_n}^{b_n} |f'|$ where $A_N = \bigcup_{n=1}^N [a_n, b_n]$; and, again by Theorem 11 of Chapter 4 applied to the disjoint decomposition $[0, 1] = A_N \cup ([0, 1] \setminus A_N)$

together with the nonnegativity of $\int_{[0,1] \setminus A_N} |f'|$, we get $\int_0^1 |f'| \geq \int_{A_N} |f'|$. Hence, for every natural number N ,

$$\int_0^1 |f'| \geq \sum_{n=1}^N \int_{a_n}^{b_n} |f'| > \frac{2}{\pi} \sum_{n=1}^N \frac{1}{2n+1}.$$

The series $\sum_{n \geq 1} 1/(2n+1)$ diverges, being a positive multiple, term by term, of a tail of the harmonic series: $1/(2n+1) \geq 1/(3n)$ for $n \geq 1$. Letting $N \rightarrow \infty$,

$$\int_0^1 |f'| = \infty.$$

Therefore f' is not integrable over $[0, 1]$, even though f is continuous on $[0, 1]$ and differentiable at every point of $[0, 1]$. This is exactly the phenomenon the remark asserts: without a monotonicity hypothesis, differentiability at every point does not force the derivative to be integrable. Corollary 4 of this section, which does give the integrability of f' , is therefore not merely an artefact of its proof: its hypothesis that f be increasing cannot simply be dropped.

Problem 6.25. Suppose f is continuous on $[0, 1]$. Must there be a nondegenerate closed subinterval $[a, b]$ of $[0, 1]$ for which the restriction of f to $[a, b]$ is of bounded variation?

Solution. No. There are continuous functions on $[0, 1]$ whose restriction to every nondegenerate closed subinterval fails to be of bounded variation.

The example. As recorded in the Remark that follows the proof of Lebesgue's Theorem in Section 6.2, Weierstrass exhibited in 1872 a function that is continuous on an open interval and differentiable at no point of that interval; the footnote there points to the simpler example of Bartel van der Waerden, examined in Chapter 8 of Fitzpatrick's *Advanced Calculus*. Let w be such a function, continuous and nowhere differentiable on an open interval (α, β) , and fix $\alpha < \alpha' < \beta' < \beta$. Define

$$f(x) = w(\alpha' + (\beta' - \alpha')x) \quad \text{for } x \in [0, 1].$$

Then f is continuous on $[0, 1]$, being the composition of a continuous function with an affine map. Moreover f is differentiable at no point x_0 of $(0, 1)$. Indeed, write $c = \beta' - \alpha' > 0$ and $p = \alpha' + cx_0 \in (\alpha', \beta') \subseteq (\alpha, \beta)$. For $s \neq 0$ small enough that $x_0 + s \in (0, 1)$,

$$\frac{w(p + cs) - w(p)}{cs} = \frac{1}{c} \cdot \frac{f(x_0 + s) - f(x_0)}{s}.$$

As s ranges over the punctured neighbourhoods of 0, $t = cs$ ranges over the punctured neighbourhoods of 0 as well. So if the right-hand side had a limit as $s \rightarrow 0$, the difference quotients of w at p would have a limit as $t \rightarrow 0$, that is, w would be differentiable at p , which is false. Hence f is not differentiable at x_0 .

Why no subinterval works. Suppose, to get a contradiction, that $[a, b] \subseteq [0, 1]$ is nondegenerate, so $a < b$, and that the restriction $g = f|_{[a,b]}$ is of bounded variation on $[a, b]$. By Corollary 6 of this section, g is then differentiable almost everywhere on the open interval (a, b) . Since $m((a, b)) = b - a > 0$, the set of points of (a, b) at which g is differentiable is nonempty; choose such a point $x_0 \in (a, b)$.

Differentiability of the restriction g at the interior point x_0 is precisely differentiability of f at x_0 : the difference quotients

$$\frac{g(x_0 + t) - g(x_0)}{t} = \frac{f(x_0 + t) - f(x_0)}{t}$$

coincide for all $t \neq 0$ with $|t| < \min\{x_0 - a, b - x_0\}$, and the derivative is a limit as $t \rightarrow 0$, so only such t matter. Hence f is differentiable at $x_0 \in (0, 1)$, contradicting the fact that f is nowhere differentiable. Therefore no nondegenerate closed subinterval $[a, b]$ of $[0, 1]$ has $f|_{[a,b]}$ of bounded variation, and the answer to the question is negative.

Remark. Continuity by itself is therefore of no help here. What the argument uses is only Corollary 6: if f restricted to some nondegenerate $[a, b]$ were of bounded variation, then f would be differentiable

at almost every point of (a, b) , hence at some point, which a nowhere differentiable f forbids. Compare Problem 7 of Section 6.2, where the same kind of example answers the analogous question about monotonicity.

Problem 6.26. Let f be the Dirichlet function, the characteristic function of the rationals in $[0, 1]$. Is f of bounded variation on $[0, 1]$?

Solution. No: $TV(f) = \infty$, so f is not of bounded variation on $[0, 1]$.

Here $f(x) = 1$ if $x \in [0, 1]$ is rational and $f(x) = 0$ if $x \in [0, 1]$ is irrational.

Fix a natural number n . We construct a partition $P_n = \{x_0, x_1, \dots, x_{2n}\}$ of $[0, 1]$ whose points alternate between rational and irrational. For $0 \leq k \leq n$ put

$$x_{2k} = \frac{k}{n},$$

so that $x_0 = 0$, $x_{2n} = 1$, and every x_{2k} is rational. For $0 \leq k \leq n-1$, the open interval $(\frac{k}{n}, \frac{k+1}{n})$ is nonempty and the irrational numbers are dense in $\mathbb{R}$, so we may choose an irrational number

$$x_{2k+1} \in \left(\frac{k}{n}, \frac{k+1}{n}\right).$$

Then

$$0 = x_0 < x_1 < x_2 < \dots < x_{2n-1} < x_{2n} = 1$$

is a genuine partition of $[0, 1]$, with $f(x_i) = 1$ for even i and $f(x_i) = 0$ for odd i .

Consequently every one of the $2n$ consecutive differences has absolute value 1:

$$V(f, P_n) = \sum_{i=1}^{2n} |f(x_i) - f(x_{i-1})| = \sum_{i=1}^{2n} 1 = 2n.$$

By the definition of total variation as the supremum of $V(f, P)$ over all partitions P of $[0, 1]$,

$$TV(f) \geq V(f, P_n) = 2n \quad \text{for every natural number } n,$$

and hence $TV(f) = \infty$. By the definition of bounded variation, f is not of bounded variation on $[0, 1]$.

Remark. Two independent confirmations. First, Corollary 6 of this section: were f of bounded variation on $[0, 1]$, it would be differentiable at almost every point of $(0, 1)$; but the density of both the rationals and the irrationals makes f discontinuous at every point of $[0, 1]$, hence differentiable nowhere, and $(0, 1)$ does not have measure zero. Second, Jordan's Theorem: an increasing function on $[0, 1]$ has at most countably many points of discontinuity, since the open intervals $(\lim_{x \rightarrow c^-} g(x), \lim_{x \rightarrow c^+} g(x))$ associated with distinct discontinuity points c are nonempty and pairwise disjoint, and each contains a rational. So the difference of two increasing functions is continuous off a countable set, whereas f is continuous nowhere.

Problem 6.27. Define $f(x) = \sin x$ on $[0, 2\pi]$. Find two increasing functions h and g for which $f = h - g$ on $[0, 2\pi]$.

Solution. A first, simple answer. Define, for $x \in [0, 2\pi]$,

$$h(x) = x + \sin x, \quad g(x) = x.$$

Then $h - g = \sin = f$ on $[0, 2\pi]$. The function g is clearly increasing. As for h , it is differentiable on $[0, 2\pi]$ with

$$h'(x) = 1 + \cos x \geq 0 \quad \text{for all } x \in [0, 2\pi],$$

since $\cos x \geq -1$. A function that is continuous on a closed, bounded interval and has nonnegative

derivative there is increasing: for $u < v$ the Mean Value Theorem provides $\xi \in (u, v)$ with $h(v) - h(u) = h'(\xi)(v - u) \geq 0$. Hence h is increasing, and $f = h - g$ is a decomposition of the required kind.

The canonical Jordan decomposition. It is instructive to write down the decomposition supplied by Lemma 5, namely

$$f(x) = [f(x) + TV(f_{[0,x]})] - TV(f_{[0,x]}) \quad \text{for all } x \in [0, 2\pi].$$

Write $V(x) = TV(f_{[0,x]})$ for the total variation function. Since $\sin$ is increasing on $[0, \pi/2]$, decreasing on $[\pi/2, 3\pi/2]$ and increasing on $[3\pi/2, 2\pi]$, and since the total variation of a monotone function on an interval is the absolute value of the difference of its endpoint values (the first Example of this section), additivity (20) of the total variation over adjacent intervals gives

$$V(x) = \begin{cases} \sin x & \text{if } 0 \leq x \leq \pi/2, \\ 2 - \sin x & \text{if } \pi/2 \leq x \leq 3\pi/2, \\ 4 + \sin x & \text{if } 3\pi/2 \leq x \leq 2\pi. \end{cases}$$

Indeed $V(\pi/2) = 1$, $V(3\pi/2) = 1 + 2 = 3$ and $V(2\pi) = 3 + 1 = 4$, and the three formulas agree at the junction points $\pi/2$ and $3\pi/2$. Each piece is increasing on its subinterval, so V is increasing on $[0, 2\pi]$. Therefore, taking $g = V$ and $h = f + V$,

$$g(x) = \begin{cases} \sin x & \text{if } 0 \leq x \leq \pi/2, \\ 2 - \sin x & \text{if } \pi/2 \leq x \leq 3\pi/2, \\ 4 + \sin x & \text{if } 3\pi/2 \leq x \leq 2\pi, \end{cases} \quad h(x) = \begin{cases} 2 \sin x & \text{if } 0 \leq x \leq \pi/2, \\ 2 & \text{if } \pi/2 \leq x \leq 3\pi/2, \\ 4 + 2 \sin x & \text{if } 3\pi/2 \leq x \leq 2\pi. \end{cases}$$

Both are increasing: g rises from 0 to 1 on $[0, \pi/2]$, from 1 to 3 on $[\pi/2, 3\pi/2]$ (as $\sin$ decreases there), and from 3 to 4 on $[3\pi/2, 2\pi]$; while h rises from 0 to 2 on $[0, \pi/2]$, is constant equal to 2 on $[\pi/2, 3\pi/2]$, and rises from 2 to 4 on $[3\pi/2, 2\pi]$. The values match at $\pi/2$ and $3\pi/2$, so both functions are well defined and increasing on all of $[0, 2\pi]$. Finally, on each of the three subintervals,

$$h - g = 2 \sin x - \sin x = \sin x, \quad 2 - (2 - \sin x) = \sin x, \quad (4 + 2 \sin x) - (4 + \sin x) = \sin x,$$

so $f = h - g$ on $[0, 2\pi]$, as required.

Problem 6.28. Let f be a step function on $[a, b]$. Find a formula for its total variation.

Solution. Set-up and notation. Recall that f is a step function on $[a, b]$ provided there is a partition

$$a = x_0 < x_1 < \cdots < x_n = b$$

of $[a, b]$ such that f is constant on each open interval (x_{i-1}, x_i) . Write

$$c_i = \text{the value of } f \text{ on } (x_{i-1}, x_i) \quad (1 \leq i \leq n), \quad d_i = f(x_i) \quad (0 \leq i \leq n).$$

The values d_i at the partition points are unconstrained; they need not agree with either neighbouring constant. We claim

$$TV(f) = \sum_{i=1}^n (|c_i - d_{i-1}| + |d_i - c_i|). \quad (\dagger)$$

Written out, this is the sum of the absolute jumps encountered as one runs through the values

$$d_0, c_1, d_1, c_2, d_2, \dots, c_n, d_n$$

in order. In particular $TV(f) < \infty$, so every step function is of bounded variation.

The lower bound. For each i with $1 \leq i \leq n$ pick a point $y_i \in (x_{i-1}, x_i)$; this is possible since $x_{i-1} < x_i$. Let

$$P^* = \{x_0 < y_1 < x_1 < y_2 < x_2 < \cdots < y_n < x_n\},$$

a partition of $[a, b]$. Since $f(y_i) = c_i$ and $f(x_i) = d_i$,

$$V(f, P^*) = \sum_{i=1}^n \left(|f(y_i) - f(x_{i-1})| + |f(x_i) - f(y_i)| \right) = \sum_{i=1}^n \left(|c_i - d_{i-1}| + |d_i - c_i| \right).$$

Since $TV(f)$ is the supremum of $V(f, P)$ over all partitions P of $[a, b]$, the right-hand side of (†) is a lower bound for $TV(f)$.

The upper bound. Let P be any partition of $[a, b]$ and let P' be the refinement of P obtained by adjoining to it all the points $x_0, x_1, \dots, x_n$. By the observation made in this section just before formula (19) – if c belongs to (a, b) , P is a partition of $[a, b]$ and P' is the refinement of P obtained by adjoining c to P , then $V(f, P) \leq V(f, P')$, by the triangle inequality – adjoining a point to a partition does not decrease the variation, so, adjoining the missing x_i one at a time,

$$V(f, P) \leq V(f, P').$$

It therefore suffices to bound $V(f, P')$ for an arbitrary partition P' that contains every x_i . Fix such a P' and fix i with $1 \leq i \leq n$. The points of P' lying in $[x_{i-1}, x_i]$ form a finite set

$$x_{i-1} = s_0 < s_1 < \dots < s_k = x_i,$$

and each of $s_1, \dots, s_{k-1}$ lies in the open interval (x_{i-1}, x_i) , so $f(s_j) = c_i$ for $1 \leq j \leq k-1$. There are two cases.

If $k \geq 2$, then

$$\sum_{j=1}^k |f(s_j) - f(s_{j-1})| = |c_i - d_{i-1}| + \underbrace{0 + \dots + 0}_{k-2 \text{ terms}} + |d_i - c_i| = |c_i - d_{i-1}| + |d_i - c_i|.$$

If $k = 1$, then, by the triangle inequality,

$$\sum_{j=1}^k |f(s_j) - f(s_{j-1})| = |d_i - d_{i-1}| \leq |d_i - c_i| + |c_i - d_{i-1}|.$$

In either case the contribution to $V(f, P')$ of the consecutive pairs of P' lying inside $[x_{i-1}, x_i]$ is at most $|c_i - d_{i-1}| + |d_i - c_i|$.

Every pair of consecutive points of P' lies inside exactly one of the intervals $[x_{i-1}, x_i]$, because P' contains all the x_i . Summing over i ,

$$V(f, P') \leq \sum_{i=1}^n \left(|c_i - d_{i-1}| + |d_i - c_i| \right).$$

Hence the same bound holds for $V(f, P)$ for every partition P , and so the right-hand side of (†) is an upper bound for $TV(f)$.

Combining the two bounds gives (†).

Two checks. Suppose the values at the partition points are chosen so that $d_0 = c_1$ and $d_i = c_i$ for $1 \leq i \leq n$, that is, f is left-continuous at each x_i . Then $|d_i - c_i| = 0$ for every i , and $|c_i - d_{i-1}| = |c_i - c_{i-1}|$ for $i \geq 2$ while $|c_1 - d_0| = 0$, so (†) reduces to $\sum_{i=2}^n |c_i - c_{i-1}|$, the sum of the absolute jumps of f , which is the expected answer. And for $f = \chi_{\{x_1\}}$ on $[a, b]$ with $a < x_1 < b$ we get $c_1 = c_2 = 0$, $d_0 = d_2 = 0$, $d_1 = 1$, so (†) gives $TV(f) = (0 + 1) + (1 + 0) = 2$, as it must be: f rises by 1 and falls by 1.

6.5 Problems 6.29–6.35

Problem 6.29. (a) Define

$$f(x) = \begin{cases} x^2 \cos(1/x^2) & \text{if } x \neq 0, x \in [-1, 1] \\ 0 & \text{if } x = 0. \end{cases}$$

Is f of bounded variation on $[-1, 1]$?

(b) Define

$$g(x) = \begin{cases} x^2 \cos(1/x) & \text{if } x \neq 0, x \in [-1, 1] \\ 0 & \text{if } x = 0. \end{cases}$$

Is g of bounded variation on $[-1, 1]$?

Solution. (a) **No: f is not of bounded variation on $[-1, 1]$.**

Observe first that f is continuous on $[-1, 1]$: away from 0 it is a composition and product of continuous functions, and $|f(x)| \leq x^2$ for all x , so $f(x) \rightarrow 0 = f(0)$ as $x \rightarrow 0$. Thus f is a perfectly respectable continuous function; nonetheless its total variation is infinite.

For each natural number n put

$$x_n = \frac{1}{\sqrt{n\pi}},$$

so that $1/x_n^2 = n\pi$ and hence

$$f(x_n) = \frac{1}{n\pi} \cos(n\pi) = \frac{(-1)^n}{n\pi}.$$

The sequence $\{x_n\}$ is strictly decreasing to 0, and $x_1 = 1/\sqrt{\pi} < 1$ since $\pi > 1$. Therefore, for each natural number $N \geq 2$,

$$P_N = \{-1, 0, x_N, x_{N-1}, \dots, x_2, x_1, 1\}$$

is a genuine partition of $[-1, 1]$: its points are listed in strictly increasing order.

Since every term in the sum defining $V(f, P_N)$ is nonnegative, discarding all the terms except those coming from consecutive pairs $x_{n+1} < x_n$ gives

$$V(f, P_N) \geq \sum_{n=1}^{N-1} |f(x_n) - f(x_{n+1})|.$$

Because $f(x_n)$ and $f(x_{n+1})$ have opposite signs, $|f(x_n) - f(x_{n+1})| = |f(x_n)| + |f(x_{n+1})|$, and therefore

$$V(f, P_N) \geq \sum_{n=1}^{N-1} \left[\frac{1}{n\pi} + \frac{1}{(n+1)\pi} \right] \geq \frac{1}{\pi} \sum_{n=1}^{N-1} \frac{1}{n}.$$

The harmonic series diverges, so the right-hand side tends to ∞ as $N \rightarrow \infty$. Hence the set of variations of f with respect to partitions of $[-1, 1]$ is unbounded above, that is,

$$TV(f) = \sup\{V(f, P) : P \text{ a partition of } [-1, 1]\} = \infty,$$

and f is not of bounded variation on $[-1, 1]$.

(b) **Yes: g is of bounded variation on $[-1, 1]$.**

We show g is Lipschitz on $[-1, 1]$ and then invoke the observation made in Section 6.3 immediately after the definition of total variation: if h is Lipschitz on $[a, b]$ with Lipschitz constant c , then for every partition $P = \{x_0, \dots, x_k\}$ of $[a, b]$,

$$V(h, P) = \sum_{i=1}^k |h(x_i) - h(x_{i-1})| \leq c \sum_{i=1}^k (x_i - x_{i-1}) = c(b - a),$$

so $c(b - a)$ bounds the set of all variations of h and hence $TV(h) \leq c(b - a) < \infty$.

For $x \neq 0$ the product and chain rules give

$$g'(x) = 2x \cos(1/x) + x^2 \cdot \sin(1/x) \cdot \frac{1}{x^2} = 2x \cos(1/x) + \sin(1/x).$$

At $x = 0$ the difference quotient is

$$\frac{g(h) - g(0)}{h} = \frac{h^2 \cos(1/h)}{h} = h \cos(1/h),$$

whose absolute value is at most $|h|$; hence it tends to 0 and $g'(0) = 0$. So g is differentiable at every point of $[-1, 1]$, and for $x \neq 0$ in $[-1, 1]$,

$$|g'(x)| \leq 2|x| |\cos(1/x)| + |\sin(1/x)| \leq 2 + 1 = 3,$$

while $|g'(0)| = 0 \leq 3$. Thus $|g'| \leq 3$ on all of $[-1, 1]$.

Now let $u < v$ belong to $[-1, 1]$. The function g is continuous on $[u, v]$ and differentiable on (u, v) , so by the Mean Value Theorem there is a point $c \in (u, v)$ with

$$g(v) - g(u) = g'(c)(v - u),$$

whence $|g(v) - g(u)| \leq 3|v - u|$. Therefore g is Lipschitz on $[-1, 1]$ with constant 3, and consequently

$$TV(g) \leq 3 \cdot (1 - (-1)) = 6 < \infty.$$

So g is of bounded variation on $[-1, 1]$.

The contrast between (a) and (b) is exactly the competition between the amplitude x^2 and the frequency of oscillation: in (b) the oscillation $\cos(1/x)$ is slow enough that the amplitude x^2 damps it out, while in (a) the far faster oscillation $\cos(1/x^2)$ forces the graph up and down across a total height comparable to $\sum 1/n$.

Problem 6.30. Show that the linear combination of two functions of bounded variation is also of bounded variation. Is the product of two such functions also of bounded variation?

Solution. Throughout, f and g are real-valued functions of bounded variation on the closed, bounded interval $[a, b]$, and $P = \{x_0, \dots, x_k\}$ denotes an arbitrary partition of $[a, b]$.

Linear combinations. Let α, β be real numbers and set $h = \alpha f + \beta g$. For any partition P ,

$$\begin{aligned} V(h, P) &= \sum_{i=1}^k |\alpha[f(x_i) - f(x_{i-1})] + \beta[g(x_i) - g(x_{i-1})]| \\ &\leq |\alpha| \sum_{i=1}^k |f(x_i) - f(x_{i-1})| + |\beta| \sum_{i=1}^k |g(x_i) - g(x_{i-1})| \\ &= |\alpha| V(f, P) + |\beta| V(g, P) \\ &\leq |\alpha| TV(f) + |\beta| TV(g), \end{aligned}$$

the first inequality being the triangle inequality applied termwise, and the last following from the definition of TV as a supremum over partitions. Thus the number $|\alpha| TV(f) + |\beta| TV(g)$, which is finite because f and g are of bounded variation, is an upper bound for the set of variations of h with respect to partitions of $[a, b]$. Taking the supremum over all partitions P ,

$$TV(\alpha f + \beta g) \leq |\alpha| TV(f) + |\beta| TV(g) < \infty,$$

so $\alpha f + \beta g$ is of bounded variation on $[a, b]$.

Products. Yes, the product of two functions of bounded variation on $[a, b]$ is again of bounded variation on $[a, b]$.

First observe that a function of bounded variation on $[a, b]$ is bounded. Indeed, if x belongs to (a, b) , then $\{a, x, b\}$ is a partition of $[a, b]$ and therefore

$$|f(x) - f(a)| \leq |f(x) - f(a)| + |f(b) - f(x)| = V(f, \{a, x, b\}) \leq TV(f);$$

this inequality also holds trivially at $x = a$, and at $x = b$ it follows from the partition $\{a, b\}$. Hence

$$|f(x)| \leq |f(a)| + TV(f) =: M \quad \text{for all } x \in [a, b],$$

and $M < \infty$. Let N be the analogous bound for g .

Now fix a partition $P = \{x_0, \dots, x_k\}$. For each index i , add and subtract $f(x_i)g(x_{i-1})$:

$$\begin{aligned} |f(x_i)g(x_i) - f(x_{i-1})g(x_{i-1})| &= |f(x_i)[g(x_i) - g(x_{i-1})] + g(x_{i-1})[f(x_i) - f(x_{i-1})]| \\ &\leq M |g(x_i) - g(x_{i-1})| + N |f(x_i) - f(x_{i-1})|. \end{aligned}$$

Summing over i from 1 to k gives

$$V(fg, P) \leq M V(g, P) + N V(f, P) \leq M \cdot TV(g) + N \cdot TV(f).$$

The right-hand side is a finite constant independent of P , so taking the supremum over all partitions of $[a, b]$ yields

$$TV(fg) \leq M \cdot TV(g) + N \cdot TV(f) < \infty.$$

Therefore fg is of bounded variation on $[a, b]$.

Two remarks. First, both conclusions used only that the interval $[a, b]$ is closed and bounded; boundedness of f and g , which the product argument needs, was not assumed but deduced from bounded variation. Second, the estimates show that the functions of bounded variation on $[a, b]$ form an algebra of bounded functions.

Problem 6.31. Let P be a partition of $[a, b]$ that is a refinement of the partition P' . For a real-valued function f on $[a, b]$, show that $V(f, P') \leq V(f, P)$.

Solution. Recall that P refines P' means that $P' \subseteq P$ as sets of points of $[a, b]$ (both containing a and b). Since P and P' are finite sets, P is obtained from P' by adjoining finitely many points, say $m = \#(P \setminus P') \geq 0$ of them. We argue by induction on m .

If $m = 0$ then $P = P'$ and there is nothing to prove.

Consider first the case $m = 1$, that is, P is obtained from $P' = \{x_0, x_1, \dots, x_k\}$ by adjoining a single point c not in P' . Since $a = x_0 \leq c \leq b = x_k$ and c differs from every x_i , there is exactly one index j with $1 \leq j \leq k$ for which

$$x_{j-1} < c < x_j.$$

Thus $P = \{x_0, \dots, x_{j-1}, c, x_j, \dots, x_k\}$. The two variations $V(f, P')$ and $V(f, P)$ have all their terms in common except that the single term $|f(x_j) - f(x_{j-1})|$ of $V(f, P')$ is replaced in $V(f, P)$ by the two terms $|f(c) - f(x_{j-1})|$ and $|f(x_j) - f(c)|$. By the triangle inequality,

$$|f(x_j) - f(x_{j-1})| = |[f(x_j) - f(c)] + [f(c) - f(x_{j-1})]| \leq |f(x_j) - f(c)| + |f(c) - f(x_{j-1})|.$$

Adding to both sides the common terms $\sum_{i \neq j} |f(x_i) - f(x_{i-1})|$ gives

$$V(f, P') \leq V(f, P).$$

Now suppose the assertion holds whenever the refinement adjoins m points, and let P be obtained from P' by adjoining $m + 1$ points $c_1, \dots, c_{m+1}$. Put $Q = P' \cup \{c_1, \dots, c_m\}$. Then Q is a refinement of P' adjoining m points, so by the inductive hypothesis $V(f, P') \leq V(f, Q)$; and $P = Q \cup \{c_{m+1}\}$ is a refinement of Q adjoining a single point, so by the case $m = 1$ already established, $V(f, Q) \leq V(f, P)$. Combining,

$$V(f, P') \leq V(f, Q) \leq V(f, P).$$

By induction, $V(f, P') \leq V(f, P)$ whenever P is a refinement of P' , as required.

Note that no hypothesis whatever is needed on f : the argument uses only the triangle inequality in $\mathbb{R}$. In particular the inequality holds even when $TV(f) = \infty$.

Problem 6.32. Assume f is of bounded variation on $[a, b]$. Show that there is a sequence of partitions $\{P_n\}$ of $[a, b]$ for which the sequence $\{TV(f, P_n)\}$ is increasing and converges to $TV(f)$.

Solution. Here $TV(f, P_n)$ denotes the variation $V(f, P_n)$ of f with respect to the partition P_n , as defined in this section; we write $V(f, P)$ for it below. “Increasing” is meant in the weak sense, $V(f, P_n) \leq V(f, P_{n+1})$ for all n .

Since f is of bounded variation, the number

$$TV(f) = \sup\{V(f, P) : P \text{ a partition of } [a, b]\}$$

is finite. By the definition of the supremum, for each natural number n there is a partition Q_n of $[a, b]$ with

$$TV(f) - \frac{1}{n} < V(f, Q_n) \leq TV(f).$$

Call this inequality (*).

Define

$$P_n = Q_1 \cup Q_2 \cup \cdots \cup Q_n \quad (n = 1, 2, \dots),$$

the union being taken as sets of points of $[a, b]$. Each Q_j is a finite subset of $[a, b]$ containing a and b , so P_n is a finite subset of $[a, b]$ containing a and b ; listing its points in increasing order exhibits P_n as a partition of $[a, b]$.

Two containments are immediate from the definition of P_n :

$$P_n \subseteq P_{n+1} \quad \text{and} \quad Q_n \subseteq P_n.$$

The first says P_{n+1} is a refinement of P_n , so by the preceding problem

$$V(f, P_n) \leq V(f, P_{n+1}) \quad \text{for every } n,$$

that is, the sequence $\{V(f, P_n)\}$ is increasing. The second says P_n is a refinement of Q_n , so again by the preceding problem, together with (*),

$$V(f, P_n) \geq V(f, Q_n) > TV(f) - \frac{1}{n}.$$

On the other hand $V(f, P_n) \leq TV(f)$ for every n , since $TV(f)$ is the supremum of the variations of f over all partitions. Hence

$$TV(f) - \frac{1}{n} < V(f, P_n) \leq TV(f) \quad \text{for every } n,$$

and therefore $|V(f, P_n) - TV(f)| < 1/n$ for every n . Since $1/n \rightarrow 0$, we conclude that

$$\lim_{n \rightarrow \infty} V(f, P_n) = TV(f).$$

Thus $\{P_n\}$ is a sequence of partitions of $[a, b]$ for which $\{V(f, P_n)\}$ is increasing and converges to $TV(f)$.

Problem 6.33. Let $\{f_n\}$ be a sequence of real-valued functions on $[a, b]$ that converges pointwise on $[a, b]$ to the real-valued function f . Show that

$$TV(f) \leq \liminf TV(f_n).$$

Solution. The inequality is to be read in the extended reals: no boundedness of variation is assumed of the f_n , and if $\liminf_n TV(f_n) = \infty$ there is nothing to prove. So the content of the assertion is that if the f_n have variations that do not blow up along some subsequence, then neither does the variation of the limit.

Fix an arbitrary partition $P = \{x_0, x_1, \dots, x_k\}$ of $[a, b]$. The key point is that $V(f, P)$ involves only the finitely many values $f(x_0), \dots, f(x_k)$, and at each of these finitely many points the numerical sequence $\{f_n(x_i)\}$ converges to $f(x_i)$ by hypothesis.

Consequently, for each index i with $1 \leq i \leq k$,

$$\lim_{n \rightarrow \infty} |f_n(x_i) - f_n(x_{i-1})| = |f(x_i) - f(x_{i-1})|,$$

by the algebra of limits of real sequences together with the continuity of the absolute value function. Since a sum of finitely many convergent sequences converges to the sum of the limits,

$$\lim_{n \rightarrow \infty} V(f_n, P) = \lim_{n \rightarrow \infty} \sum_{i=1}^k |f_n(x_i) - f_n(x_{i-1})| = \sum_{i=1}^k |f(x_i) - f(x_{i-1})| = V(f, P).$$

On the other hand, by the definition of total variation as a supremum over partitions,

$$V(f_n, P) \leq TV(f_n) \quad \text{for every } n.$$

Since the sequence $\{V(f_n, P)\}$ converges, its limit equals its limit inferior, and the limit inferior is monotone with respect to termwise inequality of sequences. Hence

$$V(f, P) = \lim_{n \rightarrow \infty} V(f_n, P) = \liminf_{n \rightarrow \infty} V(f_n, P) \leq \liminf_{n \rightarrow \infty} TV(f_n).$$

The number $\liminf_n TV(f_n)$ therefore is an upper bound for $V(f, P)$, and this holds for every partition P of $[a, b]$, since P was arbitrary. Taking the supremum over all such P ,

$$TV(f) = \sup_P V(f, P) \leq \liminf_{n \rightarrow \infty} TV(f_n),$$

which is the desired inequality.

In particular, if there is a constant M with $TV(f_n) \leq M$ for all n , then $TV(f) \leq M$ and the pointwise limit f is of bounded variation. The inequality may be strict, as a moving spike shows. On $[0, 1]$ let f_n be the piecewise linear function that vanishes outside the interval $(1/(n+1), 1/n)$ and rises to the value 1 at the midpoint of that interval. Then $TV(f_n) = 2$ for every n . Yet $f_n \rightarrow 0$ pointwise on $[0, 1]$: we have $f_n(0) = 0$ for all n , and if $0 < x \leq 1$ then $1/n < x$ for all n large, so $f_n(x) = 0$ for all such n . Here $TV(f) = TV(0) = 0 < 2 = \liminf_n TV(f_n)$.

Problem 6.34. Let f and g be of bounded variation on $[a, b]$. Show that

$$TV(f + g) \leq TV(f) + TV(g) \quad \text{and} \quad TV(\alpha f) = |\alpha| TV(f).$$

Solution. Let $P = \{x_0, x_1, \dots, x_k\}$ be an arbitrary partition of $[a, b]$.

Subadditivity. By the triangle inequality in $\mathbb{R}$, applied to each term,

$$\begin{aligned} V(f+g, P) &= \sum_{i=1}^k |[f(x_i) + g(x_i)] - [f(x_{i-1}) + g(x_{i-1})]| \\ &= \sum_{i=1}^k |[f(x_i) - f(x_{i-1})] + [g(x_i) - g(x_{i-1})]| \\ &\leq \sum_{i=1}^k |f(x_i) - f(x_{i-1})| + \sum_{i=1}^k |g(x_i) - g(x_{i-1})| \\ &= V(f, P) + V(g, P). \end{aligned}$$

Since $V(f, P) \leq TV(f)$ and $V(g, P) \leq TV(g)$ by the definition of total variation, we obtain

$$V(f+g, P) \leq TV(f) + TV(g).$$

The right-hand side is a finite number independent of P ; as P was an arbitrary partition of $[a, b]$, it is an upper bound for the set of variations of $f+g$ with respect to partitions of $[a, b]$. Taking the supremum over all partitions,

$$TV(f+g) \leq TV(f) + TV(g).$$

In particular $f+g$ is of bounded variation on $[a, b]$.

Positive homogeneity. Let α be a real number. For the partition P above,

$$V(\alpha f, P) = \sum_{i=1}^k |\alpha f(x_i) - \alpha f(x_{i-1})| = \sum_{i=1}^k |\alpha| |f(x_i) - f(x_{i-1})| = |\alpha| V(f, P).$$

Call this identity (*); it holds for every partition P of $[a, b]$.

If $\alpha = 0$, then αf is identically zero, so $V(\alpha f, P) = 0$ for every P and hence $TV(\alpha f) = 0 = |\alpha| TV(f)$. Suppose $\alpha \neq 0$. Let $S = \{V(f, P) : P \text{ a partition of } [a, b]\}$, so that $TV(f) = \sup S$. By (*), the set of variations of αf with respect to partitions of $[a, b]$ is exactly

$$\{V(\alpha f, P) : P\} = \{|\alpha| s : s \in S\} = |\alpha| \cdot S.$$

For a nonempty set S of real numbers and a positive constant $c = |\alpha|$, one has $\sup(c \cdot S) = c \sup S$: indeed $s \leq \sup S$ gives $cs \leq c \sup S$ for all $s \in S$, so $\sup(c \cdot S) \leq c \sup S$; and applying this same inequality to the set $c \cdot S$ with constant $1/c$ gives $\sup S = \sup((1/c)(c \cdot S)) \leq (1/c) \sup(c \cdot S)$, that is, $c \sup S \leq \sup(c \cdot S)$. Therefore

$$TV(\alpha f) = \sup\{V(\alpha f, P) : P\} = |\alpha| \sup\{V(f, P) : P\} = |\alpha| TV(f).$$

Both computations show, incidentally, that the functions of bounded variation on $[a, b]$ form a linear space on which TV is a seminorm; it fails to be a norm only because $TV(f) = 0$ exactly when f is constant.

Problem 6.35. For α and β positive numbers, define the function f on $[0, 1]$ by

$$f(x) = \begin{cases} x^\alpha \sin(1/x^\beta) & \text{for } 0 < x \leq 1 \\ 0 & \text{for } x = 0. \end{cases}$$

Show that if $\alpha > \beta$, then f is of bounded variation on $[0, 1]$, by showing that f' is integrable over $[0, 1]$. Then show that if $\alpha \leq \beta$, then f is not of bounded variation on $[0, 1]$.

Solution. Note at the outset that f is continuous on $[0, 1]$. On $(0, 1]$ it is built from continuous functions by composition and multiplication, and since $|f(x)| \leq x^\alpha$ for $0 < x \leq 1$ with $\alpha > 0$, we have

$f(x) \rightarrow 0 = f(0)$ as $x \rightarrow 0^+$.

The case $\alpha > \beta$. On the open set $(0, 1)$ the product and chain rules give, for $0 < x < 1$,

$$f'(x) = \alpha x^{\alpha-1} \sin(1/x^\beta) + x^\alpha \cos(1/x^\beta) \cdot (-\beta x^{-\beta-1}) = \alpha x^{\alpha-1} \sin(1/x^\beta) - \beta x^{\alpha-\beta-1} \cos(1/x^\beta),$$

and this formula persists at $x = 1$ (one-sided). Thus f' exists at every point of $(0, 1]$ and is continuous there, hence measurable; f' is therefore defined except possibly at the single point $x = 0$, a set of measure zero, which is all that is needed to speak of its integral over $[0, 1]$.

Since $|\sin| \leq 1$ and $|\cos| \leq 1$,

$$|f'(x)| \leq \alpha x^{\alpha-1} + \beta x^{\alpha-\beta-1} \quad \text{for } 0 < x \leq 1.$$

Both bounding functions are nonnegative and continuous on $(0, 1]$, and for $0 < \epsilon < 1$ elementary calculus gives

$$\int_\epsilon^1 \alpha x^{\alpha-1} dx = 1 - \epsilon^\alpha \leq 1, \quad \int_\epsilon^1 \beta x^{\alpha-\beta-1} dx = \frac{\beta}{\alpha - \beta} (1 - \epsilon^{\alpha-\beta}) \leq \frac{\beta}{\alpha - \beta},$$

where the second computation uses $\alpha - \beta > 0$, so that the exponent $\alpha - \beta - 1$ exceeds -1 and the antiderivative $x^{\alpha-\beta}/(\alpha - \beta)$ is legitimate and tends to 0 as $\epsilon \rightarrow 0^+$. On each interval $[1/n, 1]$ the function $|f'|$ is continuous, hence its Riemann and Lebesgue integrals agree, and monotonicity of the integral applied to the pointwise bound displayed above gives

$$\int_{1/n}^1 |f'| \leq \int_{1/n}^1 \alpha x^{\alpha-1} dx + \int_{1/n}^1 \beta x^{\alpha-\beta-1} dx \leq 1 + \frac{\beta}{\alpha - \beta} \quad \text{for every } n.$$

The sequence $\{|f'| \cdot \chi_{[1/n, 1]}\}$ consists of nonnegative measurable functions and increases pointwise on $(0, 1]$ to $|f'|$, so the Monotone Convergence Theorem (Chapter 4) yields

$$\int_0^1 |f'| = \lim_{n \rightarrow \infty} \int_{1/n}^1 |f'| \leq 1 + \frac{\beta}{\alpha - \beta} < \infty.$$

Since $|f'|$ has finite integral and f' is measurable, f' is integrable over $[0, 1]$.

We now deduce bounded variation. Let $P = \{t_0, t_1, \dots, t_k\}$ be a partition of $[0, 1]$, so $0 = t_0 < t_1 < \dots < t_k = 1$. For each index $i \geq 2$ the interval $[t_{i-1}, t_i]$ is a compact subinterval of $(0, 1]$ on which f is continuously differentiable, so the Fundamental Theorem of Calculus of elementary analysis gives

$$f(t_i) - f(t_{i-1}) = \int_{t_{i-1}}^{t_i} f', \quad \text{hence} \quad |f(t_i) - f(t_{i-1})| \leq \int_{t_{i-1}}^{t_i} |f'|;$$

here the Riemann and Lebesgue integrals of the continuous, bounded function f' over $[t_{i-1}, t_i]$ agree. For the first subinterval, let $0 < s < t_1$. The same argument on $[s, t_1]$ yields

$$|f(t_1) - f(s)| \leq \int_s^{t_1} |f'| \leq \int_0^{t_1} |f'|.$$

Letting $s \rightarrow 0^+$ and using the continuity of f at 0 established above, together with $f(0) = 0$, we get

$$|f(t_1) - f(t_0)| \leq \int_0^{t_1} |f'|.$$

Summing the k inequalities and using the additivity of the integral over the disjoint intervals (t_{i-1}, t_i) whose union is $(0, 1)$ up to a finite set,

$$V(f, P) = \sum_{i=1}^k |f(t_i) - f(t_{i-1})| \leq \sum_{i=1}^k \int_{t_{i-1}}^{t_i} |f'| = \int_0^1 |f'|.$$

The right-hand side is finite and independent of P , so taking the supremum over all partitions of $[0, 1]$,

$$TV(f) \leq \int_0^1 |f'| \leq 1 + \frac{\beta}{\alpha - \beta} < \infty,$$

and f is of bounded variation on $[0, 1]$.

The case $\alpha \leq \beta$. We exhibit partitions whose variations are unbounded. For each integer $n \geq 0$ set

$$x_n = \left(\frac{\pi}{2} + n\pi\right)^{-1/\beta},$$

so that $1/x_n^\beta = \pi/2 + n\pi$ and consequently

$$\sin(1/x_n^\beta) = (-1)^n, \quad f(x_n) = (-1)^n x_n^\alpha.$$

Since $t \mapsto t^{-1/\beta}$ is strictly decreasing on $(0, \infty)$, the sequence $\{x_n\}$ is strictly decreasing to 0; and $x_0 = (\pi/2)^{-1/\beta} < 1$ because $\pi/2 > 1$. Hence, for each integer $N \geq 1$,

$$P_N = \{0, x_N, x_{N-1}, \dots, x_1, x_0, 1\}$$

is a partition of $[0, 1]$.

Discarding the nonnegative terms of $V(f, P_N)$ other than those coming from consecutive pairs $x_{n+1} < x_n$, and using that $f(x_n)$ and $f(x_{n+1})$ have opposite signs,

$$V(f, P_N) \geq \sum_{n=0}^{N-1} |f(x_n) - f(x_{n+1})| = \sum_{n=0}^{N-1} (x_n^\alpha + x_{n+1}^\alpha) \geq \sum_{n=0}^{N-1} x_n^\alpha = \sum_{n=0}^{N-1} \left(\frac{\pi}{2} + n\pi\right)^{-\alpha/\beta}.$$

Write $p = \alpha/\beta$; the hypothesis $\alpha \leq \beta$ says $0 < p \leq 1$. For $t \geq 1$ and $0 < p \leq 1$ we have $t^p \leq t$ and hence $t^{-p} \geq t^{-1}$. Since $\pi/2 + n\pi \geq 1$ for every $n \geq 0$, it follows that

$$V(f, P_N) \geq \sum_{n=0}^{N-1} \frac{1}{\pi/2 + n\pi} \geq \sum_{n=0}^{N-1} \frac{1}{\pi(n+1)} = \frac{1}{\pi} \sum_{m=1}^N \frac{1}{m},$$

using $\pi/2 + n\pi \leq \pi + n\pi = \pi(n+1)$. Because the harmonic series diverges, the right-hand side tends to ∞ as $N \rightarrow \infty$. Therefore the set of variations of f with respect to partitions of $[0, 1]$ is unbounded above, so

$$TV(f) = \infty$$

and f is not of bounded variation on $[0, 1]$.

The dividing line is exactly $\alpha = \beta$: the amplitude x^α must decay strictly faster than the reciprocal of the number of oscillations accumulated near 0, which is governed by $x^{-\beta}$.

6.6 Problems 6.36–6.42

Problem 6.36. Let f fail to be of bounded variation on $[0, 1]$. Show that there is a point x_0 in $[0, 1]$ such that f fails to be of bounded variation on each nondegenerate closed subinterval of $[0, 1]$ that contains x_0 .

Solution. Throughout we use the additivity formula (20) of Section 6.3,

$$TV(f_{[a,b]}) = TV(f_{[a,c]}) + TV(f_{[c,b]}) \quad (a \leq c \leq b).$$

No finiteness hypothesis is needed here, and both sides are to be read in $[0, \infty]$: as the text observes, adjoining the point c to a partition of $[a, b]$ does not decrease the associated variation, so the supremum defining $TV(f_{[a,b]})$ may be taken over partitions P containing c ; each such P induces partitions P_1 of $[a, c]$ and P_2 of $[c, b]$ with $V(f_{[a,b]}, P) = V(f_{[a,c]}, P_1) + V(f_{[c,b]}, P_2)$ by (19), and taking suprema over

all such P yields (20). In particular f is of bounded variation on $[a, b]$ if and only if it is of bounded variation on both $[a, c]$ and $[c, b]$; contrapositively, if f fails to be of bounded variation on $[a, b]$ then it fails to be of bounded variation on at least one of the two halves $[a, (a+b)/2]$, $[(a+b)/2, b]$.

Construction of the point. Put $[a_0, b_0] = [0, 1]$. Given $[a_n, b_n]$ of length 2^{-n} on which f fails to be of bounded variation, bisect it; by the remark just made, f fails to be of bounded variation on at least one of the two closed halves, and we let $[a_{n+1}, b_{n+1}]$ be such a half (say the left one if both qualify). This produces a descending sequence

$$[0, 1] = [a_0, b_0] \supseteq [a_1, b_1] \supseteq [a_2, b_2] \supseteq \cdots, \quad b_n - a_n = 2^{-n},$$

of nonempty closed bounded intervals, on each of which f fails to be of bounded variation. By the Nested Set Theorem the intersection $\bigcap_{n \geq 0} [a_n, b_n]$ is nonempty, and since the lengths tend to 0 it consists of a single point $x_0 \in [0, 1]$.

The conclusion. Fix $\delta > 0$ and set $J_\delta = [x_0 - \delta, x_0 + \delta] \cap [0, 1]$, a nondegenerate closed subinterval of $[0, 1]$. Choose n with $2^{-n} < \delta$. Since $a_n \leq x_0 \leq b_n$ and $b_n - a_n < \delta$, every point of $[a_n, b_n]$ lies within δ of x_0 ; as $[a_n, b_n] \subseteq [0, 1]$ we conclude $[a_n, b_n] \subseteq J_\delta$. If f were of bounded variation on J_δ , then two applications of (20) (splitting J_δ at a_n and then at b_n) would show f to be of bounded variation on $[a_n, b_n]$, a contradiction. Hence

for every $\delta > 0$, f fails to be of bounded variation on $[x_0 - \delta, x_0 + \delta] \cap [0, 1]$. (*)

Consequently, if $[c, d] \subseteq [0, 1]$ is any nondegenerate closed interval containing x_0 in its interior relative to $[0, 1]$ (that is, $c < x_0 < d$, or $x_0 = c = 0$, or $x_0 = d = 1$), then $[c, d] \supseteq J_\delta$ for all small $\delta > 0$, and by (*) together with (20) the function f fails to be of bounded variation on $[c, d]$.

A remark on the literal statement: the conclusion cannot be upgraded to every nondegenerate closed subinterval containing x_0 , once x_0 is allowed to be an endpoint of that subinterval. Indeed, let $h(t) = t \cos(\pi/2t)$ for $0 < t \leq 1$ and $h(0) = 0$; the Example of Section 6.3 shows h is continuous, and using the partitions $P_n = \{0, 1/2n, 1/[2n-1], \dots, 1/3, 1/2\}$ of $[0, 1/2]$, that

$$V(h|_{[0, 1/2]}, P_n) = \frac{1}{2} + \sum_{j=2}^n \frac{1}{j} \longrightarrow \infty,$$

so h is not of bounded variation on $[0, 1/2]$. Define g on $[0, 1]$ by $g(x) = h(1/2 - x)$ for $0 \leq x < 1/2$ and $g(x) = 0$ for $1/2 \leq x \leq 1$. Since $g(x) = h(1/2 - x)$ holds for every $x \in [0, 1/2]$ (at $x = 1/2$ both sides are 0) and h is continuous, g is continuous on $[0, 1/2]$; it is identically 0 on $[1/2, 1]$, so g is continuous on $[0, 1]$. Being the reflection $x \mapsto h(1/2 - x)$ of $h|_{[0, 1/2]}$, which carries partitions to partitions and leaves the associated variations unchanged, g fails to be of bounded variation on $[0, 1/2]$, and hence, by (20), on $[0, 1]$. On the other hand g vanishes identically on $[1/2, 1]$, so it is of bounded variation there; and for $[c, d] \subseteq [0, 1/2)$ the numbers $1/2 - x$, $x \in [c, d]$, range over $[1/2 - d, 1/2 - c] \subseteq (0, 1/2]$, on which h is continuously differentiable, so g is continuously differentiable on $[c, d]$ with bounded derivative, hence Lipschitz there by the Mean Value Theorem and therefore of bounded variation. So for each $x_0 \in [0, 1]$ there is a nondegenerate closed subinterval of $[0, 1]$ containing x_0 on which g is of bounded variation: take $[1/2, 1]$ itself if $x_0 \geq 1/2$, and take $[0, (x_0 + 1/2)/2]$ if $x_0 < 1/2$, this last interval being a nondegenerate closed subinterval of $[0, 1/2)$ that contains x_0 . Thus (*), failure on every relative neighborhood of x_0 , is the correct form of the assertion, and it is exactly what the bisection argument delivers.

Problem 6.37. Let f be a continuous function on $[0, 1]$ that is absolutely continuous on $[\epsilon, 1]$ for each $0 < \epsilon < 1$.

- (i) Show that f may not be absolutely continuous on $[0, 1]$.
- (ii) Show that f is absolutely continuous on $[0, 1]$ if it is increasing.
- (iii) Show that the function f on $[0, 1]$, defined by $f(x) = \sqrt{x}$ for $0 \leq x \leq 1$, is absolutely continuous, but not Lipschitz, on $[0, 1]$.

Solution. (i) Define

$$f(x) = \begin{cases} x \cos(\pi/2x) & \text{if } 0 < x \leq 1, \\ 0 & \text{if } x = 0. \end{cases}$$

As observed in the Example of Section 6.3, f is continuous on $[0, 1]$ and is not of bounded variation on $[0, 1]$: for the partition $P_n = \{0, 1/2n, 1/[2n-1], \dots, 1/3, 1/2, 1\}$ one computes $V(f, P_n) = 1 + 1/2 + \dots + 1/n$, and the harmonic series diverges.

Fix $0 < \epsilon < 1$. On $[\epsilon, 1]$ the function f is continuously differentiable, with

$$f'(x) = \cos(\pi/2x) + \frac{\pi}{2x} \sin(\pi/2x),$$

so $|f'|$ is bounded on the compact interval $[\epsilon, 1]$, say by c . By the Mean Value Theorem $|f(u) - f(v)| \leq c|u - v|$ for $u, v \in [\epsilon, 1]$, so f is Lipschitz there and hence, by Proposition 7, absolutely continuous on $[\epsilon, 1]$.

But f is not absolutely continuous on $[0, 1]$: by Theorem 8, an absolutely continuous function on a closed bounded interval is of bounded variation there, and f is not of bounded variation on $[0, 1]$.

(ii) Assume in addition that f is increasing on $[0, 1]$. We first record an elementary fact: if $\{(\alpha_k, \beta_k)\}_{k=1}^n$ is a disjoint collection of open subintervals of (u, v) and g is increasing on $[u, v]$, then

$$\sum_{k=1}^n [g(\beta_k) - g(\alpha_k)] \leq g(v) - g(u).$$

Indeed, relabel so that $u \leq \alpha_1 < \beta_1 \leq \alpha_2 < \beta_2 \leq \dots \leq \alpha_n < \beta_n \leq v$; since g is increasing, each of the complementary differences $g(\alpha_1) - g(u)$, $g(\alpha_{k+1}) - g(\beta_k)$, $g(v) - g(\beta_n)$ is nonnegative, and adding them to the displayed sum telescopes to $g(v) - g(u)$.

Now let $\epsilon > 0$. Since f is continuous at 0, choose $c \in (0, 1)$ with

$$f(c) - f(0) < \epsilon/2.$$

Since f is absolutely continuous on $[c, 1]$, choose $\delta > 0$ that responds to the $\epsilon/2$ challenge for the absolute continuity of f on $[c, 1]$.

We claim this δ responds to the ϵ challenge for the absolute continuity of f on $[0, 1]$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open subintervals of $(0, 1)$ with $\sum_{k=1}^n [b_k - a_k] < \delta$. For each k write

$$a'_k = \max\{a_k, c\}, \quad b'_k = \max\{b_k, c\}, \quad a''_k = \min\{a_k, c\}, \quad b''_k = \min\{b_k, c\}.$$

Since f is increasing, an inspection of the three possible positions of (a_k, b_k) relative to c (entirely right of c , entirely left of c , straddling c) shows in each case that

$$|f(b_k) - f(a_k)| = f(b_k) - f(a_k) = [f(b'_k) - f(a'_k)] + [f(b''_k) - f(a''_k)].$$

The intervals (a'_k, b'_k) , after discarding the degenerate ones, form a disjoint collection of open subintervals of $(c, 1)$ whose lengths sum to at most $\sum_k [b_k - a_k] < \delta$; hence by the choice of δ ,

$$\sum_{k=1}^n [f(b'_k) - f(a'_k)] < \epsilon/2.$$

The intervals (a''_k, b''_k) , after discarding degenerate ones, form a disjoint collection of open subintervals of $(0, c)$, so by the elementary fact above,

$$\sum_{k=1}^n [f(b''_k) - f(a''_k)] \leq f(c) - f(0) < \epsilon/2.$$

Adding, $\sum_{k=1}^n |f(b_k) - f(a_k)| < \epsilon$. Therefore f is absolutely continuous on $[0, 1]$.

(iii) Let $f(x) = \sqrt{x}$ on $[0, 1]$. It is continuous and increasing on $[0, 1]$. For $0 < \epsilon < 1$, f is differentiable on $[\epsilon, 1]$ with $f'(x) = 1/(2\sqrt{x}) \leq 1/(2\sqrt{\epsilon})$, so by the Mean Value Theorem f is Lipschitz on $[\epsilon, 1]$

and therefore, by Proposition 7, absolutely continuous on $[\epsilon, 1]$. Since f is continuous on $[0, 1]$ and increasing, part (ii) shows that f is absolutely continuous on $[0, 1]$. However f is not Lipschitz on $[0, 1]$. If $c \geq 0$ were a Lipschitz constant, then for $0 < x \leq 1$,

$$\sqrt{x} = |f(x) - f(0)| \leq c|x - 0| = cx, \quad \text{so} \quad c \geq \frac{1}{\sqrt{x}}.$$

Letting $x \rightarrow 0^+$ makes the right-hand side unbounded, a contradiction. Hence f is absolutely continuous but not Lipschitz on $[0, 1]$; this justifies the assertion made after Proposition 7.

Problem 6.38. Show that f is absolutely continuous on $[a, b]$ if and only if for each $\epsilon > 0$, there is a $\delta > 0$ such that for every countable disjoint collection $\{(a_k, b_k)\}_{k=1}^{\infty}$ of open intervals in (a, b) ,

$$\sum_{k=1}^{\infty} |f(b_k) - f(a_k)| < \epsilon \quad \text{if} \quad \sum_{k=1}^{\infty} [b_k - a_k] < \delta.$$

Solution. (A word on the transcription. The book prints the display as $\sum_{k=1}^{\infty} |f(b_k) - f(a_k)| < \sum_{k=1}^{\infty} [b_k - a_k] < \delta$, in which the ϵ announced in the preceding clause never appears; the words “ ϵ if” have been lost in typesetting, exactly as the parallel display in the next problem reads “ $m^*(f(E)) < \epsilon$ if $m(E) < \delta$ ”. The statement above is the intended one, and is what we prove.)

Suppose first that f satisfies the countable criterion. Let $\epsilon > 0$ and let $\delta > 0$ respond to it; replacing δ by $\min\{\delta, b - a\}$ we may assume $\delta \leq b - a$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a finite disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. Put $\sigma = \sum_{k=1}^n [b_k - a_k]$. The set $K = \bigcup_{k=1}^n [a_k, b_k]$ is closed, being a finite union of closed intervals, and $m(K) = \sigma$, since adjoining the finitely many endpoints to the disjoint open intervals adds nothing to the measure. Hence $(a, b) \sim K$ is open and, by the excision property of measure, $m((a, b) \sim K) \geq (b - a) - \sigma > 0$ because $\sigma < \delta \leq b - a$. In particular $(a, b) \sim K$ is nonempty, and being open it contains some open interval (α, β) with $\alpha < \beta$. Choose a disjoint sequence of open intervals $\{(a_k, b_k)\}_{k=n+1}^{\infty}$ contained in (α, β) with

$$\sum_{k=n+1}^{\infty} [b_k - a_k] < \delta - \sigma$$

(for instance intervals of length $2^{-j}\eta$ marching to the right inside (α, β) , with η small). Then $\{(a_k, b_k)\}_{k=1}^{\infty}$ is a countable disjoint collection of open intervals in (a, b) of total length less than δ , so by hypothesis

$$\sum_{k=1}^n |f(b_k) - f(a_k)| \leq \sum_{k=1}^{\infty} |f(b_k) - f(a_k)| < \epsilon.$$

Thus δ responds to the ϵ challenge in the definition of absolute continuity, and f is absolutely continuous on $[a, b]$.

Conversely, suppose f is absolutely continuous on $[a, b]$. Let $\epsilon > 0$ and choose $\delta > 0$ as a response to the $\epsilon/2$ challenge regarding the criterion for the absolute continuity of f , that is, for every finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) ,

$$\text{if } \sum_{k=1}^n [b_k - a_k] < \delta, \text{ then } \sum_{k=1}^n |f(b_k) - f(a_k)| < \epsilon/2.$$

Now let $\{(a_k, b_k)\}_{k=1}^{\infty}$ be a countable disjoint collection of open intervals in (a, b) with $\sum_{k=1}^{\infty} [b_k - a_k] < \delta$. For each natural number n , the first n of these intervals form a finite disjoint collection of open intervals in (a, b) with

$$\sum_{k=1}^n [b_k - a_k] \leq \sum_{k=1}^{\infty} [b_k - a_k] < \delta,$$

so that $\sum_{k=1}^n |f(b_k) - f(a_k)| < \epsilon/2$. The partial sums of the series of nonnegative terms $\sum |f(b_k) - f(a_k)|$ are therefore bounded above by $\epsilon/2$, so the series converges and

$$\sum_{k=1}^{\infty} |f(b_k) - f(a_k)| \leq \epsilon/2 < \epsilon.$$

Hence the same δ responds to the ϵ challenge in the countable criterion.

Problem 6.39. Use the preceding problem to show that if f is increasing on $[a, b]$, then f is absolutely continuous on $[a, b]$ if and only if for each ϵ , there is a $\delta > 0$ such that for a measurable subset E of $[a, b]$,

$$m^*(f(E)) < \epsilon \quad \text{if} \quad m(E) < \delta.$$

Solution. Assume first that f is increasing and absolutely continuous on $[a, b]$, and let $\epsilon > 0$. By the preceding problem choose $\delta > 0$ so that for every countable disjoint collection $\{(a_k, b_k)\}_{k=1}^{\infty}$ of open intervals in (a, b) ,

$$\text{if } \sum_{k=1}^{\infty} [b_k - a_k] < \delta, \text{ then } \sum_{k=1}^{\infty} |f(b_k) - f(a_k)| < \epsilon/2.$$

Let E be a measurable subset of $[a, b]$ with $m(E) < \delta$. Apply assertion (i) of Theorem 11 of Chapter 2 with the number $\delta - m(E) > 0$: there is an open set $\mathcal{O} \supseteq E$ with $m^*(\mathcal{O} \sim E) < \delta - m(E)$, and hence, by the countable additivity of measure applied to the disjoint union $\mathcal{O} = E \cup (\mathcal{O} \sim E)$,

$$m(\mathcal{O}) = m(E) + m(\mathcal{O} \sim E) < \delta.$$

Put $U = \mathcal{O} \cap (a, b)$, an open subset of (a, b) with $E \sim \{a, b\} \subseteq U$ and $m(U) < \delta$. By Proposition 9 of Chapter 1, U is the disjoint union of a countable collection $\{(a_k, b_k)\}_k$ of open intervals, necessarily contained in (a, b) , and by countable additivity $\sum_k [b_k - a_k] = m(U) < \delta$. If this collection is infinite, the choice of δ gives $\sum_k [f(b_k) - f(a_k)] < \epsilon/2$ directly; if it is finite, the same bound follows from the definition of absolute continuity together with the fact that the δ furnished by the preceding problem also responds to the $\epsilon/2$ challenge for finite collections (a finite collection may be enlarged to an infinite one of total length still less than δ , exactly as in the first half of the solution to Problem 38). Since f is increasing, $f((a_k, b_k)) \subseteq [f(a_k), f(b_k)]$, so by the monotonicity and countable subadditivity of outer measure,

$$m^*(f(U)) \leq \sum_k m^*(f((a_k, b_k))) \leq \sum_k [f(b_k) - f(a_k)] < \epsilon/2.$$

Since $f(E) \subseteq f(U) \cup \{f(a), f(b)\}$ and a two-point set has outer measure zero, $m^*(f(E)) \leq \epsilon/2 < \epsilon$. This proves the forward implication.

Conversely, assume f is increasing on $[a, b]$, that f is continuous, and that the stated condition holds. Let $\epsilon > 0$ and choose $\delta > 0$ so that $m^*(f(E)) < \epsilon$ whenever $E \subseteq [a, b]$ is measurable with $m(E) < \delta$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a finite disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$, and set $E = \bigcup_{k=1}^n [a_k, b_k]$, a measurable set with $m(E) = \sum_{k=1}^n [b_k - a_k] < \delta$. Since f is continuous and increasing, the Intermediate Value Theorem gives $f([a_k, b_k]) = [f(a_k), f(b_k)]$. Relabel so that $b_k \leq a_{k+1}$; then $f(b_k) \leq f(a_{k+1})$, so the intervals $[f(a_k), f(b_k)]$, $1 \leq k \leq n$, are non-overlapping. Hence

$$\sum_{k=1}^n |f(b_k) - f(a_k)| = \sum_{k=1}^n [f(b_k) - f(a_k)] = m\left(\bigcup_{k=1}^n [f(a_k), f(b_k)]\right) = m^*(f(E)) < \epsilon,$$

the second equality because finitely many non-overlapping closed bounded intervals have union whose measure is the sum of their lengths (their pairwise intersections are finite sets, hence of measure zero), and the third because $f(E) = \bigcup_{k=1}^n f([a_k, b_k]) = \bigcup_{k=1}^n [f(a_k), f(b_k)]$. The same remark justifies $m(E) = \sum_{k=1}^n [b_k - a_k]$ above. Therefore δ responds to the ϵ challenge and f is absolutely continuous on $[a, b]$.

The continuity assumption in the converse direction cannot be dropped, and it is harmless in the sense that absolutely continuous functions are continuous. That it cannot be dropped is seen from the increasing function f on $[0, 1]$ defined by $f(x) = 0$ for $0 \leq x < 1/2$ and $f(x) = 1$ for $1/2 \leq x \leq 1$: every subset of $[0, 1]$ has image contained in the two-point set $\{0, 1\}$, so $m^*(f(E)) = 0$ for all E and the displayed condition holds vacuously with any δ ; yet f is not continuous and therefore is not absolutely continuous on $[0, 1]$. Thus the intended reading of the problem is that f is an increasing continuous function, or equivalently that the criterion is being used to decide absolute continuity among continuous increasing functions – which is exactly how it is applied in Problems 40 and 41.

Problem 6.40. Use the preceding problem to show that an increasing absolutely continuous function f on $[a, b]$ maps sets of measure zero onto sets of measure zero. Conclude that the Cantor-Lebesgue function φ is not absolutely continuous on $[0, 1]$ since the function ψ , defined by $\psi(x) = x + \varphi(x)$ for $0 \leq x \leq 1$, maps the Cantor set to a set of measure 1 (page 52).

Solution. Let f be increasing and absolutely continuous on $[a, b]$ and let $E \subseteq [a, b]$ have measure zero. Let $\epsilon > 0$. The forward implication of the preceding problem – which uses only that f is increasing and absolutely continuous – provides $\delta > 0$ such that $m^*(f(A)) < \epsilon$ for every measurable $A \subseteq [a, b]$ with $m(A) < \delta$. Since E is measurable with $m(E) = 0 < \delta$, we conclude $m^*(f(E)) < \epsilon$. As $\epsilon > 0$ was arbitrary, $m^*(f(E)) = 0$. By Proposition 4 of Chapter 2, any set of outer measure zero is measurable, so $f(E)$ is a set of measure zero. Thus f maps sets of measure zero onto sets of measure zero.

Now consider the Cantor-Lebesgue function φ on $[0, 1]$, which is increasing and continuous, and let $\psi(x) = x + \varphi(x)$ for $0 \leq x \leq 1$. Suppose, to get a contradiction, that φ is absolutely continuous on $[0, 1]$. The identity function $x \mapsto x$ is Lipschitz on $[0, 1]$, hence absolutely continuous by Proposition 7. Since linear combinations of absolutely continuous functions are absolutely continuous (see also Problem 42), ψ would then be absolutely continuous on $[0, 1]$. Moreover ψ is increasing, being the sum of an increasing function and a strictly increasing one.

Therefore, by what was just proved, ψ would map sets of measure zero onto sets of measure zero. The Cantor set C has measure zero, by Proposition 19 of Chapter 2. But Proposition 21 of Chapter 2 (page 52) asserts that this very function ψ maps C onto a measurable set of positive measure; indeed its proof, decomposing $[0, 2] = \psi(\mathcal{O}) \cup \psi(C)$ for $\mathcal{O} = [0, 1] \setminus C$ and computing $m(\psi(\mathcal{O})) = m(\mathcal{O}) = 1$, gives $m(\psi(C)) = 1$. Since $1 \neq 0$, we have a contradiction. Hence φ is not absolutely continuous on $[0, 1]$.

Problem 6.41. Let f be an increasing absolutely continuous function on $[a, b]$. Use (i) and (ii) below to conclude that f maps measurable sets to measurable sets.

(i) Infer from the continuity of f and the compactness of $[a, b]$ that f maps closed sets to closed sets and therefore maps F_σ sets to F_σ sets.

(ii) The preceding problem tells us that f maps sets of measure zero to sets of measure zero.

Solution. (i) Since f is absolutely continuous on $[a, b]$ it is continuous there (the criterion for absolute continuity, applied to a collection consisting of a single interval, is the criterion for uniform continuity). Let $F \subseteq [a, b]$ be closed. Then F is closed and bounded, hence compact by the Heine-Borel Theorem. The continuous image of a compact set is compact, so $f(F)$ is compact and in particular closed. Now let $E \subseteq [a, b]$ be an F_σ set, say $E = \bigcup_{n=1}^{\infty} F_n$ with each F_n closed. Each F_n is a closed subset of $[a, b]$, and since images preserve unions,

$$f(E) = f\left(\bigcup_{n=1}^{\infty} F_n\right) = \bigcup_{n=1}^{\infty} f(F_n),$$

a countable union of closed sets. Hence $f(E)$ is an F_σ set, and in particular is measurable, since every F_σ set is Borel and every Borel set is measurable.

(ii) By the preceding problem, since f is increasing and absolutely continuous, f carries every subset of $[a, b]$ of measure zero onto a set of measure zero.

Conclusion. Let $E \subseteq [a, b]$ be measurable. By assertion (iv) of Theorem 11 of Chapter 2 there is an F_σ set F with $F \subseteq E$ and $m^*(E \sim F) = 0$. Write $F = \bigcup_{n=1}^\infty F_n$ with each F_n closed; since $F_n \subseteq F \subseteq E \subseteq [a, b]$, every F_n is a closed subset of $[a, b]$, so part (i) applies and $f(F)$ is an F_σ set, hence measurable. The set $E \sim F$ is a subset of $[a, b]$ with $m^*(E \sim F) = 0$, hence is measurable of measure zero by Proposition 4 of Chapter 2, so by part (ii) $f(E \sim F)$ has measure zero and is therefore measurable. Finally, from $E = F \cup (E \sim F)$ we get

$$f(E) = f(F) \cup f(E \sim F),$$

the union of two measurable sets. Hence $f(E)$ is measurable. Therefore f maps measurable subsets of $[a, b]$ to measurable sets.

Problem 6.42. Show that both the sum and product of absolutely continuous functions are absolutely continuous.

Solution. Let f and g be absolutely continuous on the closed, bounded interval $[a, b]$.

The sum. Let $\epsilon > 0$. Choose $\delta_1 > 0$ as a response to the $\epsilon/2$ challenge regarding the criterion for the absolute continuity of f , and $\delta_2 > 0$ as a response to the $\epsilon/2$ challenge for g . Put $\delta = \min\{\delta_1, \delta_2\} > 0$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a finite disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. By the triangle inequality,

$$\sum_{k=1}^n |(f+g)(b_k) - (f+g)(a_k)| \leq \sum_{k=1}^n |f(b_k) - f(a_k)| + \sum_{k=1}^n |g(b_k) - g(a_k)| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Hence $f+g$ is absolutely continuous on $[a, b]$. (The same argument, with $\epsilon/(2(|\alpha| + |\beta| + 1))$ in place of $\epsilon/2$ and the estimate $|\alpha| \sum_k |f(b_k) - f(a_k)| + |\beta| \sum_k |g(b_k) - g(a_k)|$ in place of the one displayed, shows that any linear combination $\alpha f + \beta g$ is absolutely continuous, as asserted in the text preceding Proposition 7.)

The product. Absolutely continuous functions are continuous, and a continuous real-valued function on the compact interval $[a, b]$ is bounded by the Extreme Value Theorem. So choose $M \geq 1$ with

$$|f(x)| \leq M \quad \text{and} \quad |g(x)| \leq M \quad \text{for all } x \in [a, b].$$

Let $\epsilon > 0$. Choose $\delta_1 > 0$ as a response to the $\epsilon/(2M)$ challenge for the absolute continuity of f , and $\delta_2 > 0$ as a response to the $\epsilon/(2M)$ challenge for g ; put $\delta = \min\{\delta_1, \delta_2\} > 0$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a finite disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. For each k , adding and subtracting $f(a_k)g(b_k)$,

$$\begin{aligned} |f(b_k)g(b_k) - f(a_k)g(a_k)| &= |[f(b_k) - f(a_k)]g(b_k) + f(a_k)[g(b_k) - g(a_k)]| \\ &\leq M|f(b_k) - f(a_k)| + M|g(b_k) - g(a_k)|. \end{aligned}$$

Summing over k and using the choice of δ ,

$$\sum_{k=1}^n |(fg)(b_k) - (fg)(a_k)| \leq M \sum_{k=1}^n |f(b_k) - f(a_k)| + M \sum_{k=1}^n |g(b_k) - g(a_k)| < M \cdot \frac{\epsilon}{2M} + M \cdot \frac{\epsilon}{2M} = \epsilon.$$

Hence fg is absolutely continuous on $[a, b]$.

6.7 Problems 6.43–6.49

Problem 6.43. Define the functions f and g on $[-1, 1]$ by $f(x) = x^{1/3}$ for $-1 \leq x \leq 1$ and

$$g(x) = \begin{cases} x^2 \cos(\pi/2x) & \text{if } x \neq 0, x \in [-1, 1] \\ 0 & \text{if } x = 0. \end{cases}$$

- (i) Show that both f and g are absolutely continuous on $[-1, 1]$.
- (ii) For the partition $P_n = \{-1, 0, 1/2n, 1/[2n-1], \dots, 1/3, 1/2, 1\}$ of $[-1, 1]$, examine $V(f \circ g, P_n)$.
- (iii) Show that $f \circ g$ fails to be of bounded variation, and hence also fails to be absolutely continuous, on $[-1, 1]$.

Solution. Part (i). Absolute continuity of g .

For $x \neq 0$ the chain rule gives

$$g'(x) = 2x \cos\left(\frac{\pi}{2x}\right) + x^2 \cdot \left(-\sin\left(\frac{\pi}{2x}\right)\right) \cdot \left(-\frac{\pi}{2x^2}\right) = 2x \cos\left(\frac{\pi}{2x}\right) + \frac{\pi}{2} \sin\left(\frac{\pi}{2x}\right).$$

At $x = 0$, since $|g(x) - g(0)| = |x^2 \cos(\pi/2x)| \leq x^2$, we have $|g(x) - g(0)|/|x| \leq |x| \rightarrow 0$, so g is differentiable at 0 with $g'(0) = 0$. Thus g is differentiable at every point of $[-1, 1]$ and, since $|x| \leq 1$ there,

$$|g'(x)| \leq 2|x| + \frac{\pi}{2} \leq 2 + \frac{\pi}{2} \quad \text{for all } x \in [-1, 1].$$

By the Mean Value Theorem, for all $u, v \in [-1, 1]$ we have $|g(u) - g(v)| \leq (2 + \pi/2)|u - v|$, so g is Lipschitz on $[-1, 1]$. By Proposition 7, g is absolutely continuous on $[-1, 1]$.

Part (i), continued. Absolute continuity of f .

The function $f(x) = x^{1/3}$ is continuous and strictly increasing on $[-1, 1]$. It is not Lipschitz near 0, so we argue directly from the definition of absolute continuity, exploiting monotonicity near the origin.

Let $\epsilon > 0$. Choose $\eta \in (0, 1)$ so small that

$$f(\eta) - f(-\eta) = 2\eta^{1/3} < \epsilon/2.$$

On each of the intervals $[-1, -\eta]$ and $[\eta, 1]$ the function f is differentiable with $f'(x) = \frac{1}{3}|x|^{-2/3} \leq M := \frac{1}{3}\eta^{-2/3}$, so by the Mean Value Theorem f is Lipschitz with constant M on each of these two intervals. Put $\delta = \epsilon/(2M)$.

Let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open intervals in $(-1, 1)$ with $\sum_{k=1}^n [b_k - a_k] < \delta$. Split each (a_k, b_k) at the points $-\eta$ and η (whichever of them it contains); this replaces (a_k, b_k) by at most three abutting subintervals, each contained in one of $[-1, -\eta]$, $[-\eta, \eta]$, $[\eta, 1]$. Because f is increasing, $|f(b_k) - f(a_k)| = f(b_k) - f(a_k)$ and this increment is exactly the sum of the increments of f over the pieces. Hence

$$\sum_{k=1}^n |f(b_k) - f(a_k)| = \Sigma_{\text{mid}} + \Sigma_{\text{out}},$$

where Σ_{mid} is the sum of the increments of f over those pieces lying in $[-\eta, \eta]$ and Σ_{out} the sum over those pieces lying in $[-1, -\eta] \cup [\eta, 1]$.

The pieces contributing to Σ_{mid} are nonoverlapping subintervals of $[-\eta, \eta]$, and f is increasing, so their increments sum to at most the increment of f over $[-\eta, \eta]$:

$$\Sigma_{\text{mid}} \leq f(\eta) - f(-\eta) < \epsilon/2.$$

The pieces contributing to Σ_{out} lie in the two intervals on which f is Lipschitz with constant M , and the sum of their lengths is at most $\sum_{k=1}^n [b_k - a_k] < \delta$, so

$$\Sigma_{\text{out}} \leq M \sum_{k=1}^n [b_k - a_k] < M\delta = \epsilon/2.$$

Therefore $\sum_{k=1}^n |f(b_k) - f(a_k)| < \epsilon$. Thus δ responds to the ϵ challenge, and f is absolutely continuous on $[-1, 1]$.

Part (ii). The variation of $f \circ g$ over P_n .

Write $h = f \circ g$, so that

$$h(x) = \left[x^2 \cos\left(\frac{\pi}{2x}\right) \right]^{1/3} \quad \text{for } x \neq 0, \quad h(0) = 0.$$

For a natural number k and $x = 1/k$ we have $\pi/2x = k\pi/2$, so

$$h(1/k) = [k^{-2} \cos(k\pi/2)]^{1/3}.$$

If k is odd then $\cos(k\pi/2) = 0$ and $h(1/k) = 0$. If $k = 2m$ is even then $\cos(k\pi/2) = \cos(m\pi) = (-1)^m$ and

$$h(1/2m) = [(2m)^{-2}(-1)^m]^{1/3} = \frac{(-1)^m}{(2m)^{2/3}}.$$

Also $h(-1) = [\cos(-\pi/2)]^{1/3} = 0$ and $h(0) = 0$.

List the points of P_n in increasing order:

$$-1, 0, \frac{1}{2n}, \frac{1}{2n-1}, \frac{1}{2n-2}, \dots, \frac{1}{3}, \frac{1}{2}, 1.$$

The corresponding values of h are

$$0, 0, \frac{(-1)^n}{(2n)^{2/3}}, 0, \frac{(-1)^{n-1}}{(2n-2)^{2/3}}, 0, \dots, 0, \frac{-1}{2^{2/3}}, 0.$$

Indeed, every point $1/k$ with k odd (including $k = 1$, i.e. the right endpoint 1) carries the value 0, and these alternate with the points $1/2m$, $1 \leq m \leq n$, which carry the values $(-1)^m(2m)^{-2/3}$. Thus each of the n nonzero values is flanked on both sides by a partition point at which h vanishes, and each contributes its absolute value twice to the sum of consecutive increments, while the first increment (from -1 to 0) is 0. Consequently

$$V(f \circ g, P_n) = 2 \sum_{m=1}^n \frac{1}{(2m)^{2/3}} = 2^{1/3} \sum_{m=1}^n \frac{1}{m^{2/3}}.$$

Part (iii). $f \circ g$ is not of bounded variation.

Since $t \mapsto t^{-2/3}$ is decreasing on $(0, \infty)$,

$$\sum_{m=1}^n \frac{1}{m^{2/3}} \geq \int_1^{n+1} \frac{dx}{x^{2/3}} = 3 \left[(n+1)^{1/3} - 1 \right],$$

so

$$V(f \circ g, P_n) \geq 3 \cdot 2^{1/3} \left[(n+1)^{1/3} - 1 \right] \longrightarrow \infty \quad \text{as } n \rightarrow \infty.$$

Hence the set of variations of $f \circ g$ with respect to partitions of $[-1, 1]$ is unbounded, that is, $TV(f \circ g) = \infty$ and $f \circ g$ is not of bounded variation on $[-1, 1]$. By Theorem 8, an absolutely continuous function on a closed, bounded interval is of bounded variation; therefore $f \circ g$ is not absolutely continuous on $[-1, 1]$.

This exhibits the phenomenon announced on page 120: f and g are both absolutely continuous, yet the composition $f \circ g$ need not be, and indeed may fail even to be of bounded variation.

Problem 6.44. Let f be Lipschitz on $\mathbb{R}$ and g be absolutely continuous on $[a, b]$. Show that the composition $f \circ g$ is absolutely continuous on $[a, b]$.

Solution. Let c be a Lipschitz constant for f on $\mathbb{R}$, so that

$$|f(s) - f(t)| \leq c|s - t| \quad \text{for all } s, t \in \mathbb{R}.$$

Enlarging c if necessary, we may assume $c > 0$.

Let $\epsilon > 0$. Since g is absolutely continuous on $[a, b]$, there is a $\delta > 0$ that responds to the ϵ/c challenge regarding the criterion for the absolute continuity of g : for every finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) ,

$$\sum_{k=1}^n |g(b_k) - g(a_k)| < \epsilon/c \quad \text{if} \quad \sum_{k=1}^n [b_k - a_k] < \delta.$$

We claim this same δ responds to the ϵ challenge for $f \circ g$. Indeed, let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. Applying the Lipschitz estimate for f to the pair of real numbers $g(b_k)$, $g(a_k)$ for each k , and then the choice of δ ,

$$\sum_{k=1}^n |(f \circ g)(b_k) - (f \circ g)(a_k)| = \sum_{k=1}^n |f(g(b_k)) - f(g(a_k))| \leq c \sum_{k=1}^n |g(b_k) - g(a_k)| < c \cdot \frac{\epsilon}{c} = \epsilon.$$

Thus for each $\epsilon > 0$ there is a $\delta > 0$ responding to the ϵ challenge regarding the criterion for absolute continuity of $f \circ g$, and therefore $f \circ g$ is absolutely continuous on $[a, b]$.

Note that only the Lipschitz property of f on the compact interval $g([a, b])$ was used; the hypothesis that f be Lipschitz on all of $\mathbb{R}$ is more than is needed. Note also, in the light of Problem 43, that mere absolute continuity of f is not enough: there the outer function $x \mapsto x^{1/3}$ is absolutely continuous but not Lipschitz near the origin, and the composition fails even to be of bounded variation.

Problem 6.45. Let f be absolutely continuous on $\mathbb{R}$ and g be absolutely continuous and strictly monotone on $[a, b]$. Show that the composition $f \circ g$ is absolutely continuous on $[a, b]$.

Solution. Here, as usual, “absolutely continuous on $\mathbb{R}$ ” means absolutely continuous on every closed, bounded interval of $\mathbb{R}$.

Assume first that g is strictly increasing. Since g is continuous and strictly increasing on $[a, b]$, it maps $[a, b]$ onto the closed, bounded interval

$$[c, d] := [g(a), g(b)].$$

By hypothesis f is absolutely continuous on $[c, d]$.

Let $\epsilon > 0$.

Choose $\delta_1 > 0$ to respond to the ϵ challenge regarding the criterion for the absolute continuity of f on $[c, d]$: for every finite disjoint collection $\{(c_j, d_j)\}_{j=1}^n$ of open intervals in (c, d) ,

$$\sum_{j=1}^n |f(d_j) - f(c_j)| < \epsilon \quad \text{if} \quad \sum_{j=1}^n [d_j - c_j] < \delta_1.$$

Next choose $\delta_2 > 0$ to respond to the δ_1 challenge regarding the criterion for the absolute continuity of g on $[a, b]$: for every finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) ,

$$\sum_{k=1}^n |g(b_k) - g(a_k)| < \delta_1 \quad \text{if} \quad \sum_{k=1}^n [b_k - a_k] < \delta_2.$$

We claim δ_2 responds to the ϵ challenge for $f \circ g$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta_2$. Set $c_k = g(a_k)$ and $d_k = g(b_k)$.

Because g is strictly increasing we have $c_k < d_k$ for each k , so each (c_k, d_k) is a nondegenerate open interval, and it is contained in (c, d) : from $a \leq a_k < b_k \leq b$ and the monotonicity of g we get $c = g(a) \leq c_k < d_k \leq g(b) = d$, whence $(c_k, d_k) \subseteq (c, d)$. Moreover the intervals $\{(c_k, d_k)\}_{k=1}^n$ are disjoint: if $j \neq k$, then, relabelling if necessary, $b_j \leq a_k$, and monotonicity gives $d_j = g(b_j) \leq g(a_k) = c_k$, so (c_j, d_j) and (c_k, d_k) are disjoint. This is precisely where strict monotonicity of g is used, and it is the only place it is needed.

By the choice of δ_2 ,

$$\sum_{k=1}^n [d_k - c_k] = \sum_{k=1}^n |g(b_k) - g(a_k)| < \delta_1,$$

so $\{(c_k, d_k)\}_{k=1}^n$ is a finite disjoint collection of open intervals in (c, d) whose lengths sum to less than δ_1 . Therefore, by the choice of δ_1 ,

$$\sum_{k=1}^n |(f \circ g)(b_k) - (f \circ g)(a_k)| = \sum_{k=1}^n |f(d_k) - f(c_k)| < \epsilon.$$

Hence $f \circ g$ is absolutely continuous on $[a, b]$.

If instead g is strictly decreasing, then $g([a, b]) = [g(b), g(a)] =: [c, d]$, and for a disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ as above we set $c_k = g(b_k)$, $d_k = g(a_k)$; exactly the same argument applies, since g strictly decreasing again makes $\{(c_k, d_k)\}_{k=1}^n$ a disjoint collection of open subintervals of (c, d) with $\sum_k [d_k - c_k] = \sum_k |g(b_k) - g(a_k)|$. This completes the proof.

The role of strict monotonicity should be emphasized. Without it the image intervals may overlap and pile up, so that a small total length $\sum_k |g(b_k) - g(a_k)|$ no longer controls $\sum_k |f(g(b_k)) - f(g(a_k))|$ through the absolute continuity of f ; Problem 43 gives an explicit composition of two absolutely continuous functions (the inner one oscillating, hence not monotone) that is not absolutely continuous.

Problem 6.46. Verify the assertions made in the final remark of this section.

Solution. The remark reads: for a nondegenerate closed, bounded interval $[a, b]$, let $\mathcal{F}_{Lip}$, $\mathcal{F}_{AC}$, and $\mathcal{F}_{BV}$ denote the families of functions on $[a, b]$ that are Lipschitz, absolutely continuous, and of bounded variation, respectively. Then

$$\mathcal{F}_{Lip} \subset \mathcal{F}_{AC} \subset \mathcal{F}_{BV},$$

these inclusions, labelled (27) in the text, being strict; each of the three collections is closed with respect to the formation of linear combinations, a function in one of these collections has its total variation function in the same collection, and consequently, by (23), a function in one of these collections may be expressed as the difference of two increasing functions in the same collection. We verify these four assertions in turn.

Assertion 1: the inclusions hold and are strict.

Proposition 7 asserts that a Lipschitz function on $[a, b]$ is absolutely continuous on $[a, b]$, which is the inclusion $\mathcal{F}_{Lip} \subseteq \mathcal{F}_{AC}$. Theorem 8 asserts that an absolutely continuous function on $[a, b]$ is the difference of increasing absolutely continuous functions and, in particular, is of bounded variation; this is the inclusion $\mathcal{F}_{AC} \subseteq \mathcal{F}_{BV}$.

To see the first inclusion is strict, define f on $[a, b]$ by $f(x) = \sqrt{x-a}$. Then f is not Lipschitz, since for $0 < t \leq b-a$,

$$\frac{|f(a+t) - f(a)|}{t} = \frac{\sqrt{t}}{t} = \frac{1}{\sqrt{t}} \rightarrow \infty \text{ as } t \rightarrow 0^+,$$

so no constant c can serve as a Lipschitz constant. On the other hand f is absolutely continuous. Indeed, f is continuous and increasing on $[a, b]$; given $\epsilon > 0$, choose $\eta \in (0, b-a)$ with $f(a+\eta) - f(a) = \sqrt{\eta} < \epsilon/2$, and observe that on $[a+\eta, b]$ the function f is differentiable with $0 < f'(x) = 1/(2\sqrt{x-a}) \leq M := 1/(2\sqrt{\eta})$, hence Lipschitz with constant M there by the Mean Value Theorem. Set $\delta = \epsilon/(2M)$ and let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. Split each (a_k, b_k) at the point $a + \eta$ if it contains it. Since f is increasing, the increment of f over (a_k, b_k) is nonnegative and equals the sum of its increments over the pieces; the pieces lying in $[a, a + \eta]$ are nonoverlapping, so their increments sum to at most $f(a + \eta) - f(a) < \epsilon/2$, while the pieces lying in $[a + \eta, b]$ have total length less than δ , so their increments sum to less than $M\delta = \epsilon/2$. Hence $\sum_{k=1}^n |f(b_k) - f(a_k)| < \epsilon$ and f is absolutely continuous. (This is Problem 37(iii), transplanted to $[a, b]$.) Thus $f \in \mathcal{F}_{AC} \setminus \mathcal{F}_{Lip}$.

To see the second inclusion is strict, let φ be the Cantor-Lebesgue function on $[0, 1]$ and define ψ on $[a, b]$ by

$$\psi(x) = \varphi\left(\frac{x-a}{b-a}\right).$$

Then ψ is increasing on $[a, b]$, and an increasing real-valued function is of bounded variation: for any partition $P = \{x_0, \dots, x_k\}$ of $[a, b]$ we have $V(\psi, P) = \sum_{i=1}^k [\psi(x_i) - \psi(x_{i-1})] = \psi(b) - \psi(a)$, so $TV(\psi) = \psi(b) - \psi(a) < \infty$. But ψ is not absolutely continuous. For suppose it were; the affine map $L(t) = a + (b-a)t$ carries $[0, 1]$ onto $[a, b]$, carries disjoint open subintervals of $(0, 1)$ to disjoint open subintervals of (a, b) , and multiplies lengths by $b-a$. Hence, given $\epsilon > 0$, if δ responds to the ϵ challenge for ψ on $[a, b]$, then $\delta/(b-a)$ responds to the ϵ challenge for $\varphi = \psi \circ L$ on $[0, 1]$, so φ would be absolutely continuous on $[0, 1]$. This contradicts the Example on page 120, where it is shown that there is no response to the $\epsilon = 1$ challenge for φ . Thus $\psi \in \mathcal{F}_{BV} \setminus \mathcal{F}_{AC}$.

Assertion 2: each collection is closed under linear combinations.

Let α, β be real numbers and f, g functions on $[a, b]$.

If f and g are Lipschitz with constants c_f and c_g , then for all $u, v \in [a, b]$,

$$|(\alpha f + \beta g)(u) - (\alpha f + \beta g)(v)| \leq |\alpha| |f(u) - f(v)| + |\beta| |g(u) - g(v)| \leq (|\alpha|c_f + |\beta|c_g)|u - v|,$$

so $\alpha f + \beta g$ is Lipschitz. Hence $\mathcal{F}_{Lip}$ is closed under linear combinations.

If f and g are absolutely continuous, let $\epsilon > 0$ and choose δ_f responding to the $\epsilon/[2(|\alpha| + 1)]$ challenge for f and δ_g responding to the $\epsilon/[2(|\beta| + 1)]$ challenge for g ; set $\delta = \min\{\delta_f, \delta_g\}$. For a disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$,

$$\sum_{k=1}^n |(\alpha f + \beta g)(b_k) - (\alpha f + \beta g)(a_k)| \leq |\alpha| \sum_{k=1}^n |f(b_k) - f(a_k)| + |\beta| \sum_{k=1}^n |g(b_k) - g(a_k)| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Hence $\mathcal{F}_{AC}$ is closed under linear combinations. (This is the assertion made on page 120 that linear combinations of absolutely continuous functions are absolutely continuous.)

If f and g are of bounded variation, then for every partition P of $[a, b]$, the same triangle-inequality estimate applied termwise gives

$$V(\alpha f + \beta g, P) \leq |\alpha|V(f, P) + |\beta|V(g, P) \leq |\alpha|TV(f) + |\beta|TV(g).$$

So the set of variations of $\alpha f + \beta g$ is bounded above and $TV(\alpha f + \beta g) \leq |\alpha|TV(f) + |\beta|TV(g) < \infty$. Hence $\mathcal{F}_{BV}$ is closed under linear combinations.

Assertion 3: the total variation function stays in the same collection.

For f of bounded variation on $[a, b]$ write $T_f(x) = TV(f_{[a, x]})$ for the total variation function of f . It is real-valued, since $TV(f_{[a, x]}) \leq TV(f) < \infty$, and it is increasing: by (21), $T_f(v) - T_f(u) = TV(f_{[u, v]}) \geq 0$ for $a \leq u < v \leq b$.

If $f \in \mathcal{F}_{BV}$, then T_f is real-valued and increasing, hence of bounded variation by the computation in Assertion 1 above; so $T_f \in \mathcal{F}_{BV}$.

If $f \in \mathcal{F}_{AC}$, then $f \in \mathcal{F}_{BV}$ by Theorem 8, so T_f is defined, and the last paragraph of the proof of Theorem 8 shows precisely that T_f is absolutely continuous: display (24) states that for each $\epsilon > 0$ there is a $\delta > 0$ such that for every disjoint collection $\{(c_k, d_k)\}_{k=1}^n$ of open subintervals of (a, b) ,

$$\sum_{k=1}^n |TV(f_{[a, d_k]}) - TV(f_{[a, c_k]})| < \epsilon \quad \text{if} \quad \sum_{k=1}^n [d_k - c_k] < \delta.$$

That is, $T_f \in \mathcal{F}_{AC}$.

If $f \in \mathcal{F}_{Lip}$ with Lipschitz constant c , then by the second Example of Section 6.3 (the one treating Lipschitz functions), applied to the restriction of f to a closed subinterval $[u, v]$ of $[a, b]$, which is Lipschitz there with the same constant c , we have $TV(f_{[u, v]}) \leq c \cdot [v - u]$; in particular $TV(f) \leq c(b - a) < \infty$, so $f \in \mathcal{F}_{BV}$ and T_f is defined. By (21), for $a \leq u < v \leq b$,

$$0 \leq T_f(v) - T_f(u) = TV(f_{[u, v]}) \leq c[v - u],$$

so $|T_f(v) - T_f(u)| \leq c|v - u|$ for all $u, v \in [a, b]$ and T_f is Lipschitz with the same constant c . Thus $T_f \in \mathcal{F}_{Lip}$.

Assertion 4: decomposition into increasing functions from the same collection.

Let $\mathcal{F}$ be any one of $\mathcal{F}_{Lip}$, $\mathcal{F}_{AC}$, $\mathcal{F}_{BV}$, and let $f \in \mathcal{F}$. By Assertion 1, f is of bounded variation, so Lemma 5 applies and (23) gives the explicit decomposition

$$f(x) = [f(x) + T_f(x)] - T_f(x) \quad \text{for all } x \in [a, b].$$

By Assertion 3, $T_f \in \mathcal{F}$; by Assertion 2 (closure under the linear combination $1 \cdot f + 1 \cdot T_f$), $f + T_f \in \mathcal{F}$. Both of these functions are increasing: T_f is increasing as noted above, and $f + T_f$ is increasing by (22), which states that $f(v) + TV(f_{[a,v]}) \geq f(u) + TV(f_{[a,u]})$ for $a \leq u < v \leq b$. Therefore f is the difference of two increasing functions belonging to $\mathcal{F}$, which is the final assertion of the remark. For $\mathcal{F} = \mathcal{F}_{AC}$ this recovers the first statement of Theorem 8.

Problem 6.47. Show that a function f is absolutely continuous on $[a, b]$ if and only if for each $\epsilon > 0$, there is a $\delta > 0$ such that for every finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) ,

$$\left| \sum_{k=1}^n [f(b_k) - f(a_k)] \right| < \epsilon \quad \text{if} \quad \sum_{k=1}^n [b_k - a_k] < \delta.$$

Solution. Call the displayed condition, in which the absolute value sits outside the sum, the weak criterion, and let the criterion for absolute continuity, in which the absolute values sit inside the sum, be the strong criterion. We must show the two are equivalent.

One implication is immediate. Suppose f is absolutely continuous on $[a, b]$, and let $\epsilon > 0$. Let $\delta > 0$ respond to the ϵ challenge regarding the criterion for the absolute continuity of f . If $\{(a_k, b_k)\}_{k=1}^n$ is a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$, then, by the triangle inequality,

$$\left| \sum_{k=1}^n [f(b_k) - f(a_k)] \right| \leq \sum_{k=1}^n |f(b_k) - f(a_k)| < \epsilon.$$

So the same δ responds to the ϵ challenge for the weak criterion.

Now suppose f satisfies the weak criterion; we show f is absolutely continuous. Let $\epsilon > 0$, and choose $\delta > 0$ to respond to the $\epsilon/2$ challenge regarding the weak criterion: for every finite disjoint collection $\{(c_j, d_j)\}_{j=1}^m$ of open intervals in (a, b) ,

$$\left| \sum_{j=1}^m [f(d_j) - f(c_j)] \right| < \epsilon/2 \quad \text{if} \quad \sum_{j=1}^m [d_j - c_j] < \delta.$$

We claim this δ responds to the ϵ challenge regarding the criterion for the absolute continuity of f . Indeed, let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. Sort the indices according to the sign of the increment of f : define

$$P = \{k : f(b_k) - f(a_k) \geq 0\}, \quad N = \{k : f(b_k) - f(a_k) < 0\},$$

so that $\{1, \dots, n\}$ is the disjoint union of P and N .

The subcollection $\{(a_k, b_k)\}_{k \in P}$ is itself a finite disjoint collection of open intervals in (a, b) , and

$$\sum_{k \in P} [b_k - a_k] \leq \sum_{k=1}^n [b_k - a_k] < \delta,$$

since all the terms are nonnegative. (Here and below, if the index set in question is empty, the corresponding sum is 0 and the estimate is trivially satisfied.) Hence, by the choice of δ for the weak criterion,

$$\sum_{k \in P} |f(b_k) - f(a_k)| = \sum_{k \in P} [f(b_k) - f(a_k)] = \left| \sum_{k \in P} [f(b_k) - f(a_k)] \right| < \epsilon/2,$$

the first equality because every term of the sum over P is nonnegative, and the second because a sum of nonnegative numbers equals its own absolute value.

The same reasoning applies to N : the subcollection $\{(a_k, b_k)\}_{k \in N}$ is a finite disjoint collection of open intervals in (a, b) whose lengths sum to less than δ , so by the same choice of δ ,

$$\sum_{k \in N} |f(b_k) - f(a_k)| = \sum_{k \in N} -[f(b_k) - f(a_k)] = \left| \sum_{k \in N} [f(b_k) - f(a_k)] \right| < \epsilon/2,$$

where now every term $f(b_k) - f(a_k)$ is negative, so the sum over N is negative and its absolute value is the sum of the absolute values of its terms.

Adding the two estimates,

$$\sum_{k=1}^n |f(b_k) - f(a_k)| = \sum_{k \in P} |f(b_k) - f(a_k)| + \sum_{k \in N} |f(b_k) - f(a_k)| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Thus δ responds to the ϵ challenge for absolute continuity, and f is absolutely continuous on $[a, b]$.

The point of the argument is that the two criteria differ only by the freedom to discard part of a disjoint collection: passing from a collection to a subcollection preserves both disjointness and the smallness of the total length, so the weak criterion may be applied separately to the intervals across which f increases and to those across which f decreases, and the two resulting estimates reassemble into the strong criterion.

Problem 6.48. The Cantor-Lebesgue function φ is continuous and increasing on $[0, 1]$. Conclude from Theorem 10 that φ is not absolutely continuous on $[0, 1]$. Compare this reasoning with that proposed in Problem 40.

Solution. Recall the construction of the Cantor set C : from $[0, 1]$ one deletes, at the n -th stage, 2^{n-1} open middle-third intervals, and C is what remains. The deleted intervals form a countable disjoint collection $\{I_j\}_{j=1}^{\infty}$ of open intervals with

$$m\left(\bigcup_{j=1}^{\infty} I_j\right) = m([0, 1] \setminus C) = 1 - m(C) = 1,$$

since $m(C) = 0$. The Cantor-Lebesgue function φ is, by its construction, constant on each I_j : on the j -th deleted interval it takes the constant dyadic value assigned at the stage at which that interval was removed.

Consequently φ is differentiable at every point of $\bigcup_j I_j$, with $\varphi' = 0$ there, because each such point has a neighbourhood (contained in the open interval I_j holding it) on which φ is constant. Since the complement of $\bigcup_j I_j$ in $[0, 1]$ is C , a set of measure zero, we conclude

$$\varphi'(x) = 0 \quad \text{for almost all } x \in (0, 1).$$

Now suppose, to argue by contradiction, that φ were absolutely continuous on $[0, 1]$. Theorem 10 asserts that if a function f is absolutely continuous on the closed, bounded interval $[a, b]$, then f is differentiable almost everywhere on (a, b) , its derivative f' is integrable over $[a, b]$, and

$$\int_a^b f' = f(b) - f(a).$$

Applying this to φ on $[0, 1]$, and using that φ' vanishes almost everywhere on $(0, 1)$ together with the fact that the integral of a function vanishing almost everywhere is zero,

$$\varphi(1) - \varphi(0) = \int_0^1 \varphi' = \int_0^1 0 = 0.$$

But the Cantor-Lebesgue function satisfies $\varphi(0) = 0$ and $\varphi(1) = 1$, so $\varphi(1) - \varphi(0) = 1$. This contradiction shows that φ is not absolutely continuous on $[0, 1]$.

Equivalently, in the language introduced just before these problems: φ is of bounded variation (being increasing) and its derivative vanishes almost everywhere, so φ is a singular function; and Theorem 10 tells us that an absolutely continuous function is singular if and only if it is constant. Since φ is not constant, it is not absolutely continuous.

Comparison with Problem 40. There one first shows (Problems 38 and 39) that an increasing absolutely continuous function on $[a, b]$ maps sets of measure zero to sets of measure zero. One then observes that $\psi(x) = x + \varphi(x)$ maps the Cantor set C , a set of measure zero, onto a set of measure 1 (page 52). If φ were absolutely continuous, then so would be ψ , being the sum of the absolutely continuous functions $x \mapsto x$ and φ ; and ψ is increasing, being the sum of an increasing and a strictly increasing function. So ψ would have to carry C to a set of measure zero, contradicting $m(\psi(C)) = 1$.

The two arguments turn on the same underlying fact, that φ accomplishes all of its increase on the null set C , but they extract the contradiction by different means. The Problem 40 argument is purely measure-theoretic: it uses only the definition of absolute continuity, through a covering estimate on outer measure, and never differentiates anything; on the other hand it needs the auxiliary function ψ and the nontrivial fact that $m(\psi(C)) = 1$. The present argument is shorter and more direct, requiring only the elementary observation that $\varphi' = 0$ off C , but it invokes the whole of the fundamental theorem of integral calculus for the Lebesgue integral, Theorem 10, which itself rests on Lebesgue's theorem on the differentiability of monotone functions, on Theorem 9, and on the Vitali Convergence Theorem. So the second argument buys brevity with much deeper machinery.

Problem 6.49. Let f be continuous on $[a, b]$ and differentiable almost everywhere on (a, b) . Show that

$$\int_a^b f' = f(b) - f(a)$$

if and only if

$$\int_a^b \left[\lim_{n \rightarrow \infty} \text{Diff}_{1/n} f \right] = \lim_{n \rightarrow \infty} \left[\int_a^b \text{Diff}_{1/n} f \right].$$

Solution. Throughout, f is extended to $[a, b + 1]$ by setting $f(x) = f(b)$ for $b < x \leq b + 1$, and for $0 < h \leq 1$,

$$\text{Diff}_h f(x) = \frac{f(x+h) - f(x)}{h}, \quad \text{Av}_h f(x) = \frac{1}{h} \int_x^{x+h} f \quad \text{for } x \in [a, b],$$

as on page 113. Since f is continuous on $[a, b]$ and the extension is the constant $f(b)$ on $[b, b + 1]$, the extended function is continuous on $[a, b + 1]$. Hence for each natural number n the function $\text{Diff}_{1/n} f$ is continuous, and therefore measurable and bounded, on $[a, b]$; in particular it is integrable over $[a, b]$ and the right-hand integral below is defined for every n .

The proof consists of two observations, after which the two displayed assertions are seen to be one and the same.

Step 1: for every continuous f on $[a, b]$,

$$\lim_{n \rightarrow \infty} \left[\int_a^b \text{Diff}_{1/n} f \right] = f(b) - f(a).$$

Take $u = a$ and $v = b$ in the change of variables formula (14) to obtain the discrete formulation of the fundamental theorem of integral calculus,

$$\int_a^b \text{Diff}_h f = \text{Av}_h f(b) - \text{Av}_h f(a) \quad \text{for } 0 < h \leq 1.$$

Now f is identically equal to $f(b)$ on $(b, b + 1]$, so for $0 < h \leq 1$,

$$\text{Av}_h f(b) = \frac{1}{h} \int_b^{b+h} f = \frac{1}{h} \int_b^{b+h} f(b) dt = f(b),$$

the value of f at the single point b being irrelevant to the integral. On the other hand, by the continuity of f at a ,

$$|\text{Av}_h f(a) - f(a)| = \left| \frac{1}{h} \int_a^{a+h} [f(t) - f(a)] dt \right| \leq \sup_{a \leq t \leq a+h} |f(t) - f(a)| \longrightarrow 0 \text{ as } h \rightarrow 0^+.$$

Taking $h = 1/n$ and letting $n \rightarrow \infty$ gives

$$\lim_{n \rightarrow \infty} \left[\int_a^b \text{Diff}_{1/n} f \right] = f(b) - \lim_{n \rightarrow \infty} \text{Av}_{1/n} f(a) = f(b) - f(a),$$

which is exactly (29) in the proof of Theorem 10. Note that this uses only the continuity of f ; no differentiability and no absolute continuity is involved.

Step 2: $\lim_{n \rightarrow \infty} \text{Diff}_{1/n} f = f'$ almost everywhere on $[a, b]$.

Let $x \in (a, b)$ be a point at which f is differentiable; by hypothesis almost every point of (a, b) is such a point. Choose N with $1/N < b - x$. For $n \geq N$ we have $x + 1/n \in (a, b)$, so the extension of f beyond b plays no role, and

$$\text{Diff}_{1/n} f(x) = \frac{f(x + 1/n) - f(x)}{1/n} \longrightarrow f'(x) \text{ as } n \rightarrow \infty,$$

since $1/n \rightarrow 0^+$ and f is differentiable at x . Thus the sequence $\{\text{Diff}_{1/n} f\}$ converges pointwise almost everywhere on $[a, b]$, and its limit function is f' almost everywhere. (In particular f' , being the almost-everywhere pointwise limit of a sequence of continuous, hence measurable, functions, is measurable on $[a, b]$.)

Conclusion.

By Step 2 the two functions $\lim_{n \rightarrow \infty} \text{Diff}_{1/n} f$ and f' are defined and equal at almost every point of $[a, b]$. Two measurable functions that agree almost everywhere on $[a, b]$ have the same integral over $[a, b]$, in the strong sense that one is integrable if and only if the other is, and then their integrals are equal. Hence

$$\int_a^b \left[\lim_{n \rightarrow \infty} \text{Diff}_{1/n} f \right] = \int_a^b f',$$

each side being defined precisely when the other is. By Step 1,

$$\lim_{n \rightarrow \infty} \left[\int_a^b \text{Diff}_{1/n} f \right] = f(b) - f(a),$$

this limit always existing.

Substituting these two identities into the second displayed assertion turns it, term by term, into the first: the assertion

$$\int_a^b \left[\lim_{n \rightarrow \infty} \text{Diff}_{1/n} f \right] = \lim_{n \rightarrow \infty} \left[\int_a^b \text{Diff}_{1/n} f \right]$$

says that $\int_a^b f'$ equals $f(b) - f(a)$, and conversely. Therefore each of the two assertions holds if and only if the other does. (Both presuppose the same thing, namely that f' is integrable over $[a, b]$, equivalently that $\lim_n \text{Diff}_{1/n} f$ is; the Remark on page 114 shows that this can fail, for instance for $f(x) = x^2 \sin(1/x^2)$ on $[0, 1]$ with $f(0) = 0$.)

The content of the exercise is thus the following reformulation of the fundamental theorem of integral calculus for a continuous, almost everywhere differentiable f : the equality $\int_a^b f' = f(b) - f(a)$ holds if and only if one may pass the limit under the integral sign for the sequence of divided difference functions $\{\text{Diff}_{1/n} f\}$. This is precisely how Theorem 10 is proved for absolutely continuous f : Theorem 9 tells us that $\{\text{Diff}_h f\}_{0 < h \leq 1}$ is then uniformly integrable over $[a, b]$, and the Vitali Convergence Theorem licenses the interchange, giving (30). Conversely the Cantor-Lebesgue function φ shows that the interchange genuinely can fail: there $\lim_n \text{Diff}_{1/n} \varphi = \varphi' = 0$ almost everywhere, so the left-hand side is 0, while the right-hand side equals $\varphi(1) - \varphi(0) = 1$.

6.8 Problems 6.50–6.56

Problem 6.50. Let f be continuous on $[a, b]$ and differentiable almost everywhere on (a, b) . Show that if $\{\text{Diff}_{1/n} f\}$ is uniformly integrable over $[a, b]$, then

$$\int_a^b f' = f(b) - f(a).$$

Solution. Throughout we use the conventions of Section 6.2: the function f is extended to $[a, b+1]$ by setting $f \equiv f(b)$ on $(b, b+1]$, and for $0 < h \leq 1$,

$$\text{Diff}_h f(x) = \frac{f(x+h) - f(x)}{h}, \quad \text{Av}_h f(x) = \frac{1}{h} \int_x^{x+h} f \quad \text{for all } x \in [a, b].$$

The extended function is continuous on $[a, b+1]$, since f is continuous on $[a, b]$ and the extension is constant, equal to $f(b)$, on $[b, b+1]$.

Step 1: the limit of the integrals of the divided differences. By the change of variables formula (14) of Section 6.2, taking $u = a$ and $v = b$,

$$\int_a^b \text{Diff}_h f = \text{Av}_h f(b) - \text{Av}_h f(a) \quad \text{for all } 0 < h \leq 1.$$

Fix $x \in \{a, b\}$. Since

$$|\text{Av}_h f(x) - f(x)| = \left| \frac{1}{h} \int_x^{x+h} [f(t) - f(x)] dt \right| \leq \sup_{x \leq t \leq x+h} |f(t) - f(x)|,$$

and f is continuous at x , we conclude that $\text{Av}_h f(x) \rightarrow f(x)$ as $h \rightarrow 0^+$. Therefore

$$\lim_{n \rightarrow \infty} \int_a^b \text{Diff}_{1/n} f = f(b) - f(a). \quad (*)$$

Step 2: passage to the limit under the integral sign. Each function $\text{Diff}_{1/n} f$ is continuous on $[a, b]$, since $x \mapsto f(x + 1/n)$ and $x \mapsto f(x)$ are continuous there; hence each $\text{Diff}_{1/n} f$ is measurable and bounded on $[a, b]$ and therefore integrable over $[a, b]$, a set of finite measure. Moreover, if $x \in (a, b)$ is a point at which f is differentiable, then

$$\lim_{n \rightarrow \infty} \text{Diff}_{1/n} f(x) = \lim_{n \rightarrow \infty} \frac{f(x + 1/n) - f(x)}{1/n} = f'(x),$$

so that $\{\text{Diff}_{1/n} f\}$ converges pointwise to f' almost everywhere on $[a, b]$; in particular f' , being the almost-everywhere pointwise limit of a sequence of measurable functions, is measurable.

By hypothesis the sequence $\{\text{Diff}_{1/n} f\}$ is uniformly integrable over $[a, b]$. Since $m([a, b]) < \infty$, the Vitali Convergence Theorem of Chapter 4 applies: f' is integrable over $[a, b]$ and

$$\lim_{n \rightarrow \infty} \int_a^b \text{Diff}_{1/n} f = \int_a^b \lim_{n \rightarrow \infty} \text{Diff}_{1/n} f = \int_a^b f'.$$

Step 3: conclusion. Comparing this with $(*)$, the two limits of the same sequence of numbers must agree, and therefore

$$\int_a^b f' = f(b) - f(a).$$

Problem 6.51. Let f be continuous on $[a, b]$ and differentiable almost everywhere on (a, b) . Suppose there is a nonnegative function g that is integrable over $[a, b]$ and

$$|\text{Diff}_{1/n} f| \leq g \quad \text{a.e. on } [a, b] \text{ for all } n.$$

Show that

$$\int_a^b f' = f(b) - f(a).$$

Solution. As in the preceding problem, f is extended to $[a, b+1]$ by $f \equiv f(b)$ on $(b, b+1]$; the extended function is continuous on $[a, b+1]$, and for $0 < h \leq 1$ the divided difference and average value functions on $[a, b]$ are

$$\text{Diff}_h f(x) = \frac{f(x+h) - f(x)}{h}, \quad \text{Av}_h f(x) = \frac{1}{h} \int_x^{x+h} f.$$

Step 1: the limit of the integrals. By the change of variables formula (14) of Section 6.2 with $u = a$, $v = b$,

$$\int_a^b \text{Diff}_h f = \text{Av}_h f(b) - \text{Av}_h f(a) \quad \text{for } 0 < h \leq 1.$$

For $x \in \{a, b\}$,

$$|\text{Av}_h f(x) - f(x)| = \left| \frac{1}{h} \int_x^{x+h} [f(t) - f(x)] dt \right| \leq \sup_{x \leq t \leq x+h} |f(t) - f(x)| \rightarrow 0 \quad \text{as } h \rightarrow 0^+,$$

by the continuity of f at x . Hence

$$\lim_{n \rightarrow \infty} \int_a^b \text{Diff}_{1/n} f = f(b) - f(a). \quad (*)$$

Step 2: pointwise convergence. Each $\text{Diff}_{1/n} f$ is continuous, hence measurable, on $[a, b]$. If $x \in (a, b)$ is a point of differentiability of f , then $\text{Diff}_{1/n} f(x) \rightarrow f'(x)$. Since f is differentiable almost everywhere on (a, b) , the sequence $\{\text{Diff}_{1/n} f\}$ converges pointwise almost everywhere on $[a, b]$ to f' , and therefore f' is measurable.

Step 3: domination. By hypothesis there is a nonnegative integrable g on $[a, b]$ with $|\text{Diff}_{1/n} f| \leq g$ almost everywhere on $[a, b]$, for every n . Discarding the countable union of the exceptional sets, which is a set of measure zero, we may assume $|\text{Diff}_{1/n} f| \leq g$ on $[a, b] \sim E_0$ with $m(E_0) = 0$, for all n simultaneously. Passing to the limit in this inequality gives $|f'| \leq g$ almost everywhere on $[a, b]$, so f' is integrable over $[a, b]$ by the integral comparison test.

The Lebesgue Dominated Convergence Theorem of Chapter 4 now applies to the sequence $\{\text{Diff}_{1/n} f\}$, which converges pointwise almost everywhere on $[a, b]$ to f' and is dominated there by the integrable function g . It yields

$$\lim_{n \rightarrow \infty} \int_a^b \text{Diff}_{1/n} f = \int_a^b f'.$$

(Alternatively, a sequence of measurable functions on a set of finite measure that is dominated by a single integrable function is uniformly integrable, by the absolute continuity of integration, Proposition 23 of Chapter 4; so the conclusion also follows immediately from the preceding problem.)

Step 4: conclusion. Comparing the last display with $(*)$,

$$\int_a^b f' = f(b) - f(a).$$

Problem 6.52. Let f and g be absolutely continuous on $[a, b]$. Show that

$$\int_a^b f \cdot g' = f(b)g(b) - f(a)g(a) - \int_a^b f' \cdot g.$$

Solution. Step 1: the product $f \cdot g$ is absolutely continuous on $[a, b]$. An absolutely continuous function is continuous, so both f and g are continuous on the closed, bounded interval $[a, b]$ and hence bounded there: choose $M > 0$ with $|f| \leq M$ and $|g| \leq M$ on $[a, b]$. Let $\epsilon > 0$. Choose $\delta_1 > 0$ responding to the challenge $\epsilon/(2M)$ in the criterion of absolute continuity for f , and $\delta_2 > 0$ responding to the same challenge for g ; put $\delta = \min\{\delta_1, \delta_2\}$. Let $\{(a_k, b_k)\}_{k=1}^n$ be a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$. Then, using the algebraic identity

$$f(b_k)g(b_k) - f(a_k)g(a_k) = f(b_k)[g(b_k) - g(a_k)] + g(a_k)[f(b_k) - f(a_k)],$$

we obtain

$$\sum_{k=1}^n |f(b_k)g(b_k) - f(a_k)g(a_k)| \leq M \sum_{k=1}^n |g(b_k) - g(a_k)| + M \sum_{k=1}^n |f(b_k) - f(a_k)| < M \cdot \frac{\epsilon}{2M} + M \cdot \frac{\epsilon}{2M} = \epsilon.$$

Thus $f \cdot g$ is absolutely continuous on $[a, b]$.

Step 2: the derivative of the product. By Theorem 10, each of f , g and $f \cdot g$ is differentiable almost everywhere on (a, b) , and each of f' , g' and $(f \cdot g)'$ is integrable over $[a, b]$. Let $x \in (a, b)$ be a point at which both f and g are differentiable; the set of such x has full measure in (a, b) , being the intersection of two sets of full measure. At such a point the usual product rule of elementary calculus is valid, since for $h \neq 0$ small,

$$\frac{f(x+h)g(x+h) - f(x)g(x)}{h} = f(x+h) \cdot \frac{g(x+h) - g(x)}{h} + g(x) \cdot \frac{f(x+h) - f(x)}{h},$$

and letting $h \rightarrow 0$, using the continuity of f at x , the right-hand side converges to $f(x)g'(x) + g(x)f'(x)$. Hence

$$(f \cdot g)' = f \cdot g' + f' \cdot g \quad \text{almost everywhere on } (a, b).$$

Step 3: integrability of each term. Since f and g are bounded by M and f' , g' are integrable over $[a, b]$, the comparison test gives that $f \cdot g'$ and $f' \cdot g$ are integrable over $[a, b]$, because $|f \cdot g'| \leq M|g'|$ and $|f' \cdot g| \leq M|f'|$ almost everywhere.

Step 4: conclusion. Apply Theorem 10 to the absolutely continuous function $f \cdot g$ and then use the linearity of integration, which is legitimate since both $f \cdot g'$ and $f' \cdot g$ are integrable:

$$f(b)g(b) - f(a)g(a) = \int_a^b (f \cdot g)' = \int_a^b [f \cdot g' + f' \cdot g] = \int_a^b f \cdot g' + \int_a^b f' \cdot g.$$

Rearranging,

$$\int_a^b f \cdot g' = f(b)g(b) - f(a)g(a) - \int_a^b f' \cdot g,$$

which is the integration by parts formula for absolutely continuous functions.

Problem 6.53. Let the function f be absolutely continuous on $[a, b]$. Show that f is Lipschitz on $[a, b]$ if and only if there is a $c > 0$ for which $|f'| \leq c$ a.e. on $[a, b]$.

Solution. Since f is absolutely continuous on $[a, b]$, Theorem 10 tells us that f is differentiable almost everywhere on (a, b) , that f' is integrable over $[a, b]$, and that f is the indefinite integral of f' ; indeed, by Theorem 11 (or by applying Theorem 10 to the restriction of f to a closed subinterval, which is

again absolutely continuous),

$$f(v) - f(u) = \int_u^v f' \quad \text{for all } a \leq u \leq v \leq b. \quad (\dagger)$$

Suppose first that f is Lipschitz on $[a, b]$, so there is a $c > 0$ with

$$|f(u) - f(v)| \leq c|u - v| \quad \text{for all } u, v \in [a, b].$$

Let $x \in (a, b)$ be a point at which f is differentiable. For $h \neq 0$ small enough that $x + h \in [a, b]$,

$$\left| \frac{f(x+h) - f(x)}{h} \right| \leq \frac{c|h|}{|h|} = c.$$

Letting $h \rightarrow 0$ and using the continuity of the absolute value, we get $|f'(x)| \leq c$. Since f is differentiable at almost all $x \in (a, b)$, we conclude that $|f'| \leq c$ almost everywhere on $[a, b]$. (Observe that this half of the equivalence requires no absolute continuity assumption; it holds for any Lipschitz function, which in any case is absolutely continuous.)

Conversely, suppose there is a $c > 0$ with $|f'| \leq c$ almost everywhere on $[a, b]$. Let $u, v \in [a, b]$ with $u < v$. By $(\dagger)$ and the monotonicity of integration together with the triangle inequality for integrals,

$$|f(v) - f(u)| = \left| \int_u^v f' \right| \leq \int_u^v |f'| \leq \int_u^v c = c(v - u).$$

Here the middle inequality is legitimate because f' is integrable over $[u, v]$, and the last inequality holds because $|f'| \leq c$ almost everywhere on $[u, v]$ and altering an integrand on a set of measure zero does not change its integral. Since the resulting estimate is symmetric in u and v and trivial when $u = v$, we have

$$|f(u) - f(v)| \leq c|u - v| \quad \text{for all } u, v \in [a, b],$$

that is, f is Lipschitz on $[a, b]$ with Lipschitz constant c .

Problem 6.54. (i) Let f be a singular increasing function on $[a, b]$. Use the Vitali Covering Lemma to show that f has the following property: Given $\epsilon > 0$, $\delta > 0$, there is a finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) for which

$$\sum_{k=1}^n [b_k - a_k] < \delta \quad \text{and} \quad \sum_{k=1}^n [f(b_k) - f(a_k)] > f(b) - f(a) - \epsilon.$$

(ii) Let f be an increasing function on $[a, b]$ with the property described in part (i). Show that f is singular.

(iii) Let $\{f_n\}$ be a sequence of singular increasing functions on $[a, b]$ for which the series $\sum_{n=1}^{\infty} f_n(x)$ converges to a finite value for each $x \in [a, b]$. Define

$$f(x) = \sum_{n=1}^{\infty} f_n(x) \quad \text{for } x \in [a, b].$$

Show that f is also singular.

Solution. Recall that a function of bounded variation is called singular provided its derivative vanishes almost everywhere. An increasing function on $[a, b]$ is of bounded variation, with $TV(f) = f(b) - f(a)$. Part (i). Let $\epsilon > 0$ and $\delta > 0$ be given. Set

$$\eta = \frac{\epsilon}{b-a} > 0,$$

and let E be the set of points $x \in (a, b)$ at which f is differentiable with $f'(x) = 0$. Since f is singular,

$$m(E) = b - a.$$

Let $\mathcal{F}$ be the collection of all closed, bounded, nondegenerate intervals $[c, d] \subseteq (a, b)$ for which

$$f(d) - f(c) < \eta(d - c).$$

We claim $\mathcal{F}$ covers E in the sense of Vitali. Indeed, let $x \in E$ and let $\ell > 0$. Since $f'(x) = 0$, there is an $h_0 > 0$ with $[x - h_0, x + h_0] \subseteq (a, b)$, $2h_0 < \ell$, and

$$|f(x + t) - f(x)| \leq \frac{\eta}{2} |t| \quad \text{for all } |t| \leq h_0.$$

Then for $0 < h \leq h_0$, the interval $[x - h, x + h]$ contains x , has length $2h < \ell$, and

$$f(x + h) - f(x - h) = [f(x + h) - f(x)] + [f(x) - f(x - h)] \leq \frac{\eta}{2}h + \frac{\eta}{2}h = \eta h < \eta \cdot (2h).$$

So $[x - h, x + h] \in \mathcal{F}$. Thus each point of E is contained in intervals of $\mathcal{F}$ of arbitrarily small length, which is precisely the Vitali covering condition.

Since $m^*(E) = b - a < \infty$, the Vitali Covering Lemma provides a finite disjoint subcollection $\{[c_k, d_k]\}_{k=1}^n$ of $\mathcal{F}$ for which

$$m^*\left(E \sim \bigcup_{k=1}^n [c_k, d_k]\right) < \delta.$$

Relabel so that $c_1 < d_1 < c_2 < d_2 < \cdots < c_n < d_n$; since these are disjoint closed intervals contained in (a, b) we also have $a < c_1$ and $d_n < b$. Put $d_0 = a$ and $c_{n+1} = b$, and consider the $n + 1$ complementary open intervals

$$(a_j, b_j) := (d_{j-1}, c_j), \quad j = 1, \dots, n + 1.$$

Each is a nonempty open interval contained in (a, b) , and they are pairwise disjoint.

Their total length is small. Indeed, $(a, b) \sim \bigcup_{k=1}^n [c_k, d_k]$ differs from $E \sim \bigcup_{k=1}^n [c_k, d_k]$ by a subset of $(a, b) \sim E$, a set of measure zero; therefore

$$\sum_{j=1}^{n+1} [b_j - a_j] = (b - a) - \sum_{k=1}^n [d_k - c_k] = m\left((a, b) \sim \bigcup_{k=1}^n [c_k, d_k]\right) = m^*\left(E \sim \bigcup_{k=1}^n [c_k, d_k]\right) < \delta.$$

Their total f -increase is large. Since the intervals $[c_k, d_k]$ and the gaps (d_{j-1}, c_j) together exhaust $[a, b]$ and abut consecutively, the increments telescope:

$$\sum_{j=1}^{n+1} [f(b_j) - f(a_j)] = [f(b) - f(a)] - \sum_{k=1}^n [f(d_k) - f(c_k)].$$

Because each $[c_k, d_k]$ belongs to $\mathcal{F}$ and the $[c_k, d_k]$ are disjoint subintervals of $[a, b]$,

$$\sum_{k=1}^n [f(d_k) - f(c_k)] < \eta \sum_{k=1}^n [d_k - c_k] \leq \eta(b - a) = \epsilon$$

(if $n = 0$ the left-hand sum is $0 < \epsilon$ as well). Therefore

$$\sum_{j=1}^{n+1} [f(b_j) - f(a_j)] > f(b) - f(a) - \epsilon,$$

and the collection $\{(a_j, b_j)\}_{j=1}^{n+1}$ has both required properties.

Part (ii). Let f be increasing on $[a, b]$ with the stated property. By Lebesgue's Theorem f is differentiable almost everywhere on (a, b) , $f' \geq 0$ almost everywhere, and by Corollary 4 the function f' is integrable over $[a, b]$. We show $\int_a^b f' = 0$; since $f' \geq 0$ almost everywhere, Proposition 9 of Chapter 4 then forces $f' = 0$ almost everywhere, that is, f is singular.

Let $\epsilon > 0$. Since f' is integrable over $[a, b]$, by the absolute continuity of integration (Proposition 23 of Chapter 4) there is a $\delta > 0$ such that

$$\int_A f' < \epsilon \quad \text{whenever } A \subseteq [a, b] \text{ is measurable with } m(A) < \delta.$$

For this ϵ and δ , the assumed property gives a finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) with

$$\sum_{k=1}^n [b_k - a_k] < \delta \quad \text{and} \quad \sum_{k=1}^n [f(b_k) - f(a_k)] > f(b) - f(a) - \epsilon.$$

Let $U = \bigcup_{k=1}^n (a_k, b_k)$, so that $m(U) < \delta$ and hence $\int_U f' < \epsilon$.

The complement $[a, b] \sim U$ is a finite disjoint union of closed intervals $[\alpha_j, \beta_j]$, $j = 1, \dots, p$, whose endpoints are exactly a, b and the points a_k, b_k (a degenerate one, occurring when $b_k = a_{k+1}$, is a single point and contributes nothing to any of the sums below; discard such j). Consecutive intervals of the two families abut, so the increments again telescope:

$$\sum_{j=1}^p [f(\beta_j) - f(\alpha_j)] = [f(b) - f(a)] - \sum_{k=1}^n [f(b_k) - f(a_k)] < \epsilon.$$

Applying Corollary 4 to the restriction of the increasing function f to each $[\alpha_j, \beta_j]$, and then using the additivity of integration over domains,

$$\int_{[a,b] \sim U} f' = \sum_{j=1}^p \int_{\alpha_j}^{\beta_j} f' \leq \sum_{j=1}^p [f(\beta_j) - f(\alpha_j)] < \epsilon.$$

(The finitely many endpoints form a set of measure zero and contribute nothing.) Hence

$$0 \leq \int_a^b f' = \int_U f' + \int_{[a,b] \sim U} f' < 2\epsilon.$$

As $\epsilon > 0$ was arbitrary, $\int_a^b f' = 0$, and f is singular.

Part (iii). Each f_n is increasing, so for $a \leq x < y \leq b$ we have $f(y) - f(x) = \sum_{n=1}^{\infty} [f_n(y) - f_n(x)] \geq 0$; here the series of nonnegative terms converges because both $\sum f_n(y)$ and $\sum f_n(x)$ converge. Thus f is a real-valued increasing function on $[a, b]$. We verify that f has the property of part (i); part (ii) will then show f is singular.

For $N \in \mathbb{N}$ set $s_N = \sum_{n=1}^N f_n$ and $r_N = f - s_N = \sum_{n>N} f_n$. Both are increasing on $[a, b]$, and s_N is singular, since a finite sum of functions differentiable at a point is differentiable there with derivative the sum of the derivatives, so $s'_N = \sum_{n=1}^N f'_n = 0$ almost everywhere on (a, b) .

Let $\epsilon > 0$ and $\delta > 0$ be given. Since $s_N(b) - s_N(a) = \sum_{n=1}^N [f_n(b) - f_n(a)]$ converges to $f(b) - f(a)$ as $N \rightarrow \infty$, we may fix N with

$$r_N(b) - r_N(a) = [f(b) - f(a)] - [s_N(b) - s_N(a)] < \frac{\epsilon}{2}.$$

Apply part (i) to the singular increasing function s_N , with the challenges $\epsilon/2$ and δ : there is a finite disjoint collection $\{(a_k, b_k)\}_{k=1}^n$ of open intervals in (a, b) with

$$\sum_{k=1}^n [b_k - a_k] < \delta \quad \text{and} \quad \sum_{k=1}^n [s_N(b_k) - s_N(a_k)] > s_N(b) - s_N(a) - \frac{\epsilon}{2}.$$

Since r_N is increasing, $f(b_k) - f(a_k) \geq s_N(b_k) - s_N(a_k)$ for each k . Therefore

$$\sum_{k=1}^n [f(b_k) - f(a_k)] \geq \sum_{k=1}^n [s_N(b_k) - s_N(a_k)] > s_N(b) - s_N(a) - \frac{\epsilon}{2} = [f(b) - f(a)] - [r_N(b) - r_N(a)] - \frac{\epsilon}{2} > f(b) - f(a) - \epsilon.$$

Thus f possesses the property of part (i), and by part (ii) the function f is singular.

Problem 6.55. Let f be of bounded variation on $[a, b]$, and define $v(x) = TV(f_{[a,x]})$ for all $x \in [a, b]$.

(i) Show that $|f'| \leq v'$ a.e. on $[a, b]$, and infer from this that

$$\int_a^b |f'| \leq TV(f).$$

(ii) Show that the above is an equality if and only if f is absolutely continuous on $[a, b]$.

(iii) Compare parts (i) and (ii) with Corollaries 4 and 12, respectively.

Solution. Part (i). By (21) of Section 6.3, for $a \leq u < w \leq b$,

$$v(w) - v(u) = TV(f_{[a,w]}) - TV(f_{[a,u]}) = TV(f_{[u,w]}) \geq 0,$$

so v is a real-valued increasing function on $[a, b]$ with $v(a) = 0$ and $v(b) = TV(f)$. Moreover, taking the crudest partition $\{u, w\}$ of $[u, w]$,

$$|f(w) - f(u)| \leq TV(f_{[u,w]}) = v(w) - v(u) \quad \text{for all } a \leq u < w \leq b. \quad (*)$$

By Lebesgue's Theorem the increasing function v is differentiable almost everywhere on (a, b) , and by Corollary 6 the function f , being of bounded variation, is differentiable almost everywhere on (a, b) with f' integrable over $[a, b]$. Let $x \in (a, b)$ be a point at which both f and v are differentiable; almost every point of (a, b) is such a point. For small $h > 0$, $(*)$ with $u = x$, $w = x + h$ gives

$$\frac{|f(x+h) - f(x)|}{h} \leq \frac{v(x+h) - v(x)}{h}.$$

Letting $h \rightarrow 0^+$ yields $|f'(x)| \leq v'(x)$. Hence $|f'| \leq v'$ almost everywhere on $[a, b]$.

Now v is increasing on $[a, b]$, so Corollary 4 tells us v' is integrable over $[a, b]$ and

$$\int_a^b v' \leq v(b) - v(a) = TV(f).$$

Since $0 \leq |f'| \leq v'$ almost everywhere and $|f'|$ is integrable (as f' is), the monotonicity of integration gives

$$\int_a^b |f'| \leq \int_a^b v' \leq TV(f). \quad (**)$$

Part (ii). Suppose first that f is absolutely continuous on $[a, b]$. By Theorem 11, f is the indefinite integral of f' , so for any partition $P = \{x_0, x_1, \dots, x_k\}$ of $[a, b]$,

$$V(f, P) = \sum_{i=1}^k |f(x_i) - f(x_{i-1})| = \sum_{i=1}^k \left| \int_{x_{i-1}}^{x_i} f' \right| \leq \sum_{i=1}^k \int_{x_{i-1}}^{x_i} |f'| = \int_a^b |f'|.$$

Taking the supremum over all partitions, $TV(f) \leq \int_a^b |f'|$. Together with $(**)$ this gives $\int_a^b |f'| = TV(f)$.

Conversely, suppose $\int_a^b |f'| = TV(f)$. Fix $x \in (a, b)$. The restriction of f to $[a, x]$ is of bounded variation with total variation function $u \mapsto v(u)$ on $[a, x]$, and its derivative agrees with f' on (a, x) ; similarly for the restriction to $[x, b]$, whose total variation is $TV(f_{[x,b]}) = v(b) - v(x)$ by (20). Applying the inequality of part (i) to each restriction,

$$\int_a^x |f'| \leq TV(f_{[a,x]}) = v(x) \quad \text{and} \quad \int_x^b |f'| \leq TV(f_{[x,b]}) = v(b) - v(x).$$

Adding these and using additivity over domains together with the assumed equality,

$$v(b) = TV(f) = \int_a^b |f'| = \int_a^x |f'| + \int_x^b |f'| \leq v(x) + [v(b) - v(x)] = v(b).$$

Hence both inequalities in the preceding display are equalities; in particular

$$v(x) = \int_a^x |f'| = v(a) + \int_a^x |f'| \quad \text{for all } x \in [a, b]$$

(the cases $x = a$ and $x = b$ being immediate). Thus v is the indefinite integral over $[a, b]$ of the integrable function $|f'|$, and therefore, by Theorem 11, v is absolutely continuous on $[a, b]$.

Finally, (*) transfers absolute continuity from v to f . Let $\epsilon > 0$ and choose $\delta > 0$ responding to the ϵ challenge in the criterion of absolute continuity for v . If $\{(a_k, b_k)\}_{k=1}^n$ is a disjoint collection of open intervals in (a, b) with $\sum_{k=1}^n [b_k - a_k] < \delta$, then by (*),

$$\sum_{k=1}^n |f(b_k) - f(a_k)| \leq \sum_{k=1}^n [v(b_k) - v(a_k)] = \sum_{k=1}^n |v(b_k) - v(a_k)| < \epsilon.$$

So f is absolutely continuous on $[a, b]$.

Part (iii). Suppose f is increasing on $[a, b]$. Then f is of bounded variation with $TV(f) = f(b) - f(a)$, and $f' \geq 0$ wherever it exists, so $|f'| = f'$ almost everywhere. With these identifications, the inequality of part (i) reads

$$\int_a^b f' \leq f(b) - f(a),$$

which is exactly Corollary 4; and the equivalence of part (ii) reads: f is absolutely continuous on $[a, b]$ if and only if $\int_a^b f' = f(b) - f(a)$, which is exactly Corollary 12. (For decreasing f the same reduction holds, since then $TV(f) = f(a) - f(b)$ and $|f'| = -f'$.) Thus parts (i) and (ii) are precisely the extensions of Corollaries 4 and 12 from monotone functions to functions of bounded variation, the increment $f(b) - f(a)$ being replaced by the total variation $TV(f)$ and the derivative f' by $|f'|$.

Problem 6.56. Let g be strictly increasing and absolutely continuous on $[a, b]$.

(i) Show that for any open subset $\mathcal{O}$ of (a, b) ,

$$m(g(\mathcal{O})) = \int_{\mathcal{O}} g'(x) dx.$$

(ii) Show that for any G_δ subset E of (a, b) ,

$$m(g(E)) = \int_E g'(x) dx.$$

(iii) Show that for any subset E of $[a, b]$ that has measure 0, its image $g(E)$ also has measure 0, so that

$$m(g(E)) = 0 = \int_E g'(x) dx.$$

(iv) Show that for any measurable subset A of $[a, b]$,

$$m(g(A)) = \int_A g'(x) dx.$$

(v) Let $c = g(a)$ and $d = g(b)$. Show that for any simple function φ on $[c, d]$,

$$\int_c^d \varphi(y) dy = \int_a^b \varphi(g(x)) g'(x) dx.$$

(vi) Show that for any nonnegative integrable function f over $[c, d]$,

$$\int_c^d f(y) dy = \int_a^b f(g(x)) g'(x) dx.$$

(vii) Show that part (i) follows from (vi) in the case that f is the characteristic function of $\mathcal{O}$ and the composition is defined.

Solution. Throughout, $c = g(a)$ and $d = g(b)$. Since g is absolutely continuous, it is continuous, and being strictly increasing it is a one-to-one continuous map of $[a, b]$ onto $[c, d]$ (onto by the Intermediate Value Theorem). By Theorem 10, g is differentiable almost everywhere on (a, b) and g' is integrable over $[a, b]$; since g is increasing, $g' \geq 0$ almost everywhere. Note also that g carries an open interval $(u, w) \subseteq (a, b)$ onto the open interval $(g(u), g(w))$, and that g , being one-to-one, carries disjoint sets to disjoint sets and satisfies $g(S \sim T) = g(S) \sim g(T)$ whenever $T \subseteq S \subseteq [a, b]$.

Part (i). Let $\mathcal{O}$ be an open subset of (a, b) . Write $\mathcal{O} = \bigcup_k (a_k, b_k)$ as the countable disjoint union of its component open intervals, each contained in (a, b) . Then

$$g(\mathcal{O}) = \bigcup_k g((a_k, b_k)) = \bigcup_k (g(a_k), g(b_k)),$$

a countable disjoint union of open intervals; in particular $g(\mathcal{O})$ is open, hence measurable, and by the countable additivity of Lebesgue measure

$$m(g(\mathcal{O})) = \sum_k [g(b_k) - g(a_k)].$$

The restriction of g to $[a_k, b_k]$ is absolutely continuous, so Theorem 10 gives $g(b_k) - g(a_k) = \int_{a_k}^{b_k} g'$. Since $g' \geq 0$ almost everywhere, the partial sums of $\sum_k g' \chi_{(a_k, b_k)}$ increase pointwise almost everywhere to $g' \chi_{\mathcal{O}}$, so the Monotone Convergence Theorem of Chapter 4, together with the finite additivity of integration over disjoint domains, gives $\sum_k \int_{a_k}^{b_k} g' = \int_{\mathcal{O}} g'$. Hence

$$m(g(\mathcal{O})) = \sum_k \int_{a_k}^{b_k} g' = \int_{\mathcal{O}} g'.$$

Part (ii). Let E be a G_δ subset of (a, b) , say $E = \bigcap_{n=1}^\infty \mathcal{U}_n$ with each $\mathcal{U}_n$ open. Replacing $\mathcal{U}_n$ by $\mathcal{O}_n = (a, b) \cap \bigcap_{j=1}^n \mathcal{U}_j$, we may assume the $\mathcal{O}_n$ are open subsets of (a, b) , descending, with $E = \bigcap_n \mathcal{O}_n$. Because g is one-to-one,

$$g(E) = g\left(\bigcap_n \mathcal{O}_n\right) = \bigcap_n g(\mathcal{O}_n),$$

so $g(E)$ is a G_δ set, in particular measurable. The sets $g(\mathcal{O}_n)$ are descending and contained in $g((a, b)) \subseteq [c, d]$, which has finite measure; by the continuity of measure,

$$m(g(E)) = \lim_{n \rightarrow \infty} m(g(\mathcal{O}_n)) = \lim_{n \rightarrow \infty} \int_{\mathcal{O}_n} g',$$

the last equality by part (i). On the other hand, $\chi_{\mathcal{O}_n} \rightarrow \chi_E$ pointwise on $[a, b]$ (the $\mathcal{O}_n$ descend to E), and $0 \leq g' \chi_{\mathcal{O}_n} \leq g'$ almost everywhere with g' integrable; the Lebesgue Dominated Convergence Theorem gives

$$\lim_{n \rightarrow \infty} \int_{\mathcal{O}_n} g' = \lim_{n \rightarrow \infty} \int_a^b g' \chi_{\mathcal{O}_n} = \int_a^b g' \chi_E = \int_E g'.$$

Therefore $m(g(E)) = \int_E g'$.

Part (iii). Let $E \subseteq [a, b]$ with $m(E) = 0$, and let $\epsilon > 0$. Since g' is integrable over $[a, b]$, the absolute continuity of integration (Proposition 23 of Chapter 4) provides a $\delta > 0$ such that $\int_A g' < \epsilon$ whenever $A \subseteq [a, b]$ is measurable with $m(A) < \delta$. As $m(E \cap (a, b)) = 0$, by the outer regularity of Lebesgue measure there is an open set $\mathcal{O}$ with $E \cap (a, b) \subseteq \mathcal{O} \subseteq (a, b)$ and $m(\mathcal{O}) < \delta$. By part (i) and the monotonicity of outer measure,

$$m^*(g(E \cap (a, b))) \leq m(g(\mathcal{O})) = \int_{\mathcal{O}} g' < \epsilon.$$

Since $\epsilon > 0$ was arbitrary, $m^*(g(E \cap (a, b))) = 0$. Finally $g(E) \sim g(E \cap (a, b)) \subseteq \{g(a), g(b)\}$ is finite, so $m^*(g(E)) = 0$ and $g(E)$ is measurable with $m(g(E)) = 0$. Also $\int_E g' = 0$ since $m(E) = 0$. Thus $m(g(E)) = 0 = \int_E g'$.

Part (iv). Let A be a measurable subset of $[a, b]$ and put $A_0 = A \cap (a, b)$. Then $A \sim A_0 \subseteq \{a, b\}$ has measure zero and $g(A) \sim g(A_0) \subseteq \{c, d\}$; since a set of measure zero may be added or removed without affecting either side of the asserted identity, it suffices to treat A_0 .

By the approximation properties of measurable sets (Theorem 11 of Chapter 2) there is a G_δ set G' with $A_0 \subseteq G'$ and $m(G' \sim A_0) = 0$. Set $G = G' \cap (a, b)$; since (a, b) is open, G is again a G_δ set, and $A_0 \subseteq G \subseteq (a, b)$ with $m(G \sim A_0) = 0$. Because g is one-to-one,

$$g(A_0) = g(G) \sim g(G \sim A_0).$$

By part (ii), $g(G)$ is measurable with $m(g(G)) = \int_G g'$; by part (iii), $g(G \sim A_0)$ is measurable with measure zero. Hence $g(A_0)$ is measurable and, by the excision property,

$$m(g(A_0)) = m(g(G)) - m(g(G \sim A_0)) = m(g(G)) = \int_G g' = \int_{A_0} g' + \int_{G \sim A_0} g' = \int_{A_0} g',$$

the last step because $m(G \sim A_0) = 0$. Therefore $m(g(A)) = \int_A g'$.

Part (v). We first record the key lemma, which also settles the measurability question implicit in the statement. Note that a strictly increasing absolutely continuous g need not carry measurable sets back to measurable sets under g^{-1} (the set $\{g' = 0\}$ can have positive measure), so the composition $\varphi \circ g$ need not be measurable; what is always measurable, up to a set of measure zero, is the product $(\varphi \circ g) \cdot g'$.

Lemma. Let $E \subseteq [c, d]$ be measurable. Then $x \mapsto \chi_E(g(x)) g'(x)$ agrees almost everywhere on $[a, b]$ with a measurable function, and

$$\int_a^b \chi_E(g(x)) g'(x) dx = m(E).$$

Proof of the Lemma. By the approximation properties of measurable sets there are Borel sets B and N with

$$B \subseteq E \subseteq B \cup N, \quad m(E \sim B) = 0, \quad m(N) = 0, \quad N \subseteq [c, d]$$

(take B an F_σ set contained in E with $m(E \sim B) = 0$, and N a G_δ set of measure zero containing $E \sim B$). Since g is continuous, the preimages $g^{-1}(B)$ and $g^{-1}(N)$ are Borel subsets of $[a, b]$, hence measurable, and

$$\chi_B \circ g = \chi_{g^{-1}(B)}, \quad \chi_N \circ g = \chi_{g^{-1}(N)}$$

are measurable functions. Because g maps $[a, b]$ one-to-one onto $[c, d]$, we have $g(g^{-1}(S)) = S$ for every $S \subseteq [c, d]$. Applying part (iv) to the measurable sets $g^{-1}(B)$ and $g^{-1}(N)$,

$$\int_{g^{-1}(B)} g' = m(B) = m(E), \quad \int_{g^{-1}(N)} g' = m(N) = 0.$$

As $g' \geq 0$ almost everywhere, the second identity forces $g' = 0$ almost everywhere on $g^{-1}(N)$. Since $g^{-1}(B) \subseteq g^{-1}(E) \subseteq g^{-1}(B) \cup g^{-1}(N)$,

$$0 \leq \chi_{g^{-1}(E)} - \chi_{g^{-1}(B)} \leq \chi_{g^{-1}(N)} \quad \text{on } [a, b],$$

and multiplying by $g' \geq 0$ we conclude that

$$\chi_E(g(x)) g'(x) = \chi_{g^{-1}(E)}(x) g'(x) = \chi_{g^{-1}(B)}(x) g'(x) \quad \text{for almost all } x \in [a, b].$$

The right-hand function is measurable, and its integral over $[a, b]$ equals $\int_{g^{-1}(B)} g' = m(E)$. The Lemma is proved.

Now let φ be simple on $[c, d]$, written as $\varphi = \sum_{i=1}^p \alpha_i \chi_{E_i}$ with the α_i real and the E_i measurable subsets of $[c, d]$. Then

$$\varphi(g(x)) g'(x) = \sum_{i=1}^p \alpha_i \chi_{E_i}(g(x)) g'(x) \quad \text{for all } x \text{ at which } g'(x) \text{ exists,}$$

which by the Lemma agrees almost everywhere with a measurable function; moreover $|\varphi(g)g'| \leq \max_i |\alpha_i| \cdot p \cdot g'$ almost everywhere, so it is integrable over $[a, b]$. By the linearity of integration and the Lemma,

$$\int_a^b \varphi(g(x)) g'(x) dx = \sum_{i=1}^p \alpha_i \int_a^b \chi_{E_i}(g(x)) g'(x) dx = \sum_{i=1}^p \alpha_i m(E_i) = \int_c^d \varphi(y) dy.$$

Part (vi). Let f be nonnegative and integrable over $[c, d]$. By the Simple Approximation Theorem of Chapter 3 there is an increasing sequence $\{\varphi_n\}$ of nonnegative simple functions on $[c, d]$ that converges pointwise on $[c, d]$ to f . By part (v), for each n the function $(\varphi_n \circ g) \cdot g'$ agrees almost everywhere on $[a, b]$ with a measurable function ψ_n , and

$$\int_a^b \psi_n = \int_c^d \varphi_n.$$

Discard the union of the countably many exceptional sets of measure zero, together with the set where g' fails to exist or is negative; off this single set E_0 of measure zero we have, for every n , $\psi_n = (\varphi_n \circ g) g' \geq 0$ and $\psi_n \leq \psi_{n+1}$, and

$$\lim_{n \rightarrow \infty} \psi_n(x) = \lim_{n \rightarrow \infty} \varphi_n(g(x)) g'(x) = f(g(x)) g'(x).$$

Hence $(f \circ g) \cdot g'$ agrees almost everywhere on $[a, b]$ with the measurable function $\lim_n \psi_n$, and the Monotone Convergence Theorem, applied on $[a, b] \sim E_0$, gives

$$\int_a^b f(g(x)) g'(x) dx = \lim_{n \rightarrow \infty} \int_a^b \psi_n = \lim_{n \rightarrow \infty} \int_c^d \varphi_n = \int_c^d f(y) dy,$$

the final equality by the Monotone Convergence Theorem on $[c, d]$. In particular $(f \circ g) \cdot g'$ is integrable over $[a, b]$, since f is integrable over $[c, d]$.

Part (vii). The proviso that the composition be defined is what fixes the meaning of the substitution: the function f in (vi) lives on $[c, d]$, whereas $\mathcal{O} \subseteq (a, b)$, so the characteristic function to be substituted is the one whose composition with g is $\chi_{\mathcal{O}}$, namely $\chi_{g(\mathcal{O})}$.

Let $\mathcal{O}$ be an open subset of (a, b) . As shown in part (i) the set $g(\mathcal{O})$ is open and bounded, hence measurable with finite measure, so $f = \chi_{g(\mathcal{O})}$ is a nonnegative integrable function on $[c, d]$. Because g is one-to-one, for $x \in [a, b]$ we have $g(x) \in g(\mathcal{O})$ if and only if $x \in \mathcal{O}$; that is, the composition is defined and

$$f(g(x)) = \chi_{g(\mathcal{O})}(g(x)) = \chi_{\mathcal{O}}(x) \quad \text{for all } x \in [a, b].$$

Applying part (vi) to this f ,

$$m(g(\mathcal{O})) = \int_c^d \chi_{g(\mathcal{O})}(y) dy = \int_a^b \chi_{g(\mathcal{O})}(g(x)) g'(x) dx = \int_a^b \chi_{\mathcal{O}}(x) g'(x) dx = \int_{\mathcal{O}} g'(x) dx,$$

which is exactly the assertion of part (i). (Of course the argument for part (i) given above is needed as an ingredient in the proof of part (vi), so this is a consistency check rather than an independent derivation.)

6.9 Problems 6.57–6.63

Problem 6.57. Is the change of variables formula in the last part of the preceding problem true if we just assume g is increasing, not necessarily strictly?

[Preceding problem, part (vi): for g strictly increasing and absolutely continuous on $[a, b]$, $c = g(a)$,

$d = g(b)$, and f a nonnegative integrable function over $[c, d]$,

$$\int_c^d f(y) dy = \int_a^b f(g(x))g'(x) dx.$$

]

Solution. Yes. The formula persists verbatim: if g is increasing (not necessarily strictly) and absolutely continuous on $[a, b]$, if $c = g(a)$, $d = g(b)$, and if f is a nonnegative integrable function over $[c, d]$, then

$$\int_c^d f(y) dy = \int_a^b f(g(x))g'(x) dx.$$

What must change is the proof: the route taken in the preceding problem passes through the identity $m(g(\mathcal{O})) = \int_{\mathcal{O}} g'$, whose proof uses that g carries disjoint intervals to disjoint intervals, i.e. that g is one-to-one. We argue instead by pushing Lebesgue measure back through g .

Since g is increasing and continuous, $g([a, b]) = [c, d]$. Since g is absolutely continuous, g' exists a.e. on (a, b) , is nonnegative a.e., is integrable, and, by Theorem 10, $\int_u^v g' = g(v) - g(u)$ for all $a \leq u \leq v \leq b$. Step 1: a set function. For a Borel subset E of $[c, d]$ define

$$\nu(E) = \int_a^b \chi_E(g(x)) g'(x) dx.$$

This makes sense: g is continuous, hence Borel measurable, so $\chi_E \circ g = \chi_{g^{-1}(E)}$ is a measurable function, and the integrand is nonnegative and measurable. Moreover ν is a measure on the Borel subsets of $[c, d]$: $\nu(\emptyset) = 0$, and if $\{E_k\}$ is a countable disjoint collection of Borel sets then $\chi_{\cup_k E_k} \circ g = \sum_k \chi_{E_k} \circ g$ pointwise, so countable additivity of the integral of nonnegative measurable functions (a consequence of the Monotone Convergence Theorem) gives $\nu(\cup_k E_k) = \sum_k \nu(E_k)$. Finally $\nu([c, d]) = \int_a^b g' = g(b) - g(a) = d - c < \infty$, so ν is finite.

Step 2: ν agrees with Lebesgue measure on intervals. Let $c \leq \alpha \leq \beta \leq d$. Put

$$u = \inf\{x \in [a, b] : g(x) \geq \alpha\}, \quad v = \sup\{x \in [a, b] : g(x) \leq \beta\}.$$

Both sets are nonempty ($g(b) = d \geq \alpha$ and $g(a) = c \leq \beta$), so $u, v \in [a, b]$. By continuity $g(u) \geq \alpha$; if $u > a$ then $g(x) < \alpha$ for $x < u$ and continuity forces $g(u) = \alpha$, while if $u = a$ then $g(u) = c \leq \alpha \leq g(u)$. In either case $g(u) = \alpha$, and symmetrically $g(v) = \beta$; since g is increasing, $u \leq v$. Furthermore $g^{-1}([\alpha, \beta]) = [u, v]$: if $u \leq x \leq v$ then $\alpha = g(u) \leq g(x) \leq g(v) = \beta$, while if $g(x) \in [\alpha, \beta]$ then x belongs to both defining sets, so $x \geq u$ and $x \leq v$. Therefore

$$\nu([\alpha, \beta]) = \int_a^b \chi_{[u, v]}(x) g'(x) dx = \int_u^v g' = g(v) - g(u) = \beta - \alpha = m([\alpha, \beta]).$$

The same computation applied to the degenerate interval $[\alpha, \alpha]$ gives $\nu(\{\alpha\}) = 0$, so ν and m agree on every subinterval of $[c, d]$, open, closed, or half-open.

Step 3: $\nu = m$ on the Borel sets. An open subset $\mathcal{O}$ of (c, d) is the union of a countable disjoint collection of open intervals, so countable additivity of ν and of m together with Step 2 give $\nu(\mathcal{O}) = m(\mathcal{O})$. If $G \subseteq (c, d)$ is a G_δ set, write $G = \bigcap_k \mathcal{O}_k$ with $\mathcal{O}_k$ open and, replacing $\mathcal{O}_k$ by $\mathcal{O}_1 \cap \cdots \cap \mathcal{O}_k$, decreasing; since ν and m are finite measures, continuity from above gives

$$\nu(G) = \lim_k \nu(\mathcal{O}_k) = \lim_k m(\mathcal{O}_k) = m(G).$$

Now let E be any Borel subset of $[c, d]$. The singletons $\{c\}$ and $\{d\}$ are m -null, and by the degenerate case of Step 2 they are ν -null as well, so replacing E by $E \cap (c, d)$ changes neither $m(E)$ nor $\nu(E)$; assume therefore $E \subseteq (c, d)$. By the outer approximation of measurable sets, Theorem 11 of Chapter 2, there is a G_δ set $G_0 \supseteq E$ with $m(G_0 \setminus E) = 0$; put $G = G_0 \cap (c, d)$, which is again a G_δ set, satisfies

$E \subseteq G \subseteq (c, d)$, and has $m(G \setminus E) = 0$. Choose likewise a G_δ set H with $G \setminus E \subseteq H \subseteq (c, d)$ and $m(H) = 0$. By the preceding paragraph $\nu(H) = m(H) = 0$, so $\nu(G \setminus E) \leq \nu(H) = 0$ and

$$\nu(E) = \nu(G) - \nu(G \setminus E) = m(G) = m(E).$$

Thus $\nu = m$ on Borel subsets of $[c, d]$.

Step 4: null sets and Lebesgue measurable sets. Let $N \subseteq [c, d]$ have $m(N) = 0$ and choose a Borel set $B \supseteq N$ with $m(B) = 0$. By Step 3, $\int_a^b \chi_B(g(x))g'(x) dx = \nu(B) = 0$, and the integrand is nonnegative, so by Proposition 9 of Chapter 4 it vanishes almost everywhere; that is,

$$g'(x) = 0 \text{ for almost all } x \in g^{-1}(B) \supseteq g^{-1}(N). \quad (*)$$

Consequently, if $E \subseteq [c, d]$ is Lebesgue measurable and B_0 is a Borel set with $m(E \Delta B_0) = 0$, then $\chi_E(g(x))g'(x) = \chi_{B_0}(g(x))g'(x)$ for almost all $x \in [a, b]$, by $(*)$ applied to the null set $E \Delta B_0$. Since Lebesgue measure is complete, $x \mapsto \chi_E(g(x))g'(x)$ is measurable and

$$\int_a^b \chi_E(g(x))g'(x) dx = \nu(B_0) = m(B_0) = m(E). \quad (**)$$

In particular $(*)$ shows that altering f on a set of measure zero alters $(f \circ g) \cdot g'$ only on a set of measure zero, so the right-hand side of the change of variables formula does not depend on the representative chosen for f .

Step 5: simple functions, then general f . Let $\varphi = \sum_{k=1}^n a_k \chi_{E_k}$ be a nonnegative simple function on $[c, d]$, with the E_k measurable and $a_k \geq 0$. By linearity of the integral and $(**)$,

$$\int_a^b \varphi(g(x))g'(x) dx = \sum_{k=1}^n a_k \int_a^b \chi_{E_k}(g(x))g'(x) dx = \sum_{k=1}^n a_k m(E_k) = \int_c^d \varphi.$$

Finally let f be nonnegative and integrable over $[c, d]$. By the Simple Approximation Theorem there is an increasing sequence $\{\varphi_n\}$ of nonnegative simple functions on $[c, d]$ with $\varphi_n \rightarrow f$ pointwise. For almost all x in (a, b) , $g'(x)$ exists and is nonnegative, and then $\varphi_n(g(x))g'(x)$ increases to $f(g(x))g'(x)$. Two applications of the Monotone Convergence Theorem give

$$\int_a^b f(g(x))g'(x) dx = \lim_{n \rightarrow \infty} \int_a^b \varphi_n(g(x))g'(x) dx = \lim_{n \rightarrow \infty} \int_c^d \varphi_n = \int_c^d f(y) dy.$$

Both sides are therefore equal, and in particular $(f \circ g) \cdot g'$ is integrable over $[a, b]$. This is the asserted formula, and strict monotonicity was nowhere used.

Remark. Geometrically, nothing goes wrong because a maximal interval on which a merely increasing absolutely continuous g is constant is collapsed by g to a single point, and by Theorem 10 the integral of g' over that interval is 0; such an interval therefore contributes nothing to either side. The only role strict monotonicity played in the preceding problem was to keep the images of disjoint intervals disjoint, and Steps 1 through 3 above replace that bookkeeping by the additivity of the measure ν .

Problem 6.58. Construct an absolutely continuous strictly increasing function f on $[0, 1]$ for which $f' = 0$ on a set of positive measure. (Hint: Let E be the relative complement in $[0, 1]$ of a generalized Cantor set of positive measure and f the indefinite integral of χ_E . See Problem 39 of Chapter 2 for the construction of such a Cantor set.)

Solution. The generalized Cantor set. Fix α with $0 < \alpha < 1$; we take $\alpha = 1/2$. Following Problem 39 of Chapter 2, construct a descending sequence $C_0 \supseteq C_1 \supseteq C_2 \supseteq \cdots$ of closed subsets of $[0, 1]$ as follows. Set $C_0 = [0, 1]$. Having obtained C_{n-1} as a disjoint union of 2^{n-1} closed intervals, delete from the interior of each of them the open middle interval of length $\alpha 3^{-n}$; the union of the 2^n remaining closed intervals is C_n . This is legitimate provided $\alpha 3^{-n}$ is smaller than the common length ℓ_{n-1} of the

intervals of C_{n-1} ; since

$$\ell_n = \frac{1}{2^n} \left(1 - \alpha \sum_{k=1}^n 2^{k-1} 3^{-k} \right) = \frac{1}{2^n} \left(1 - \alpha (1 - (2/3)^n) \right) \geq \frac{1 - \alpha}{2^n},$$

and $\alpha 3^{-n} < (1 - \alpha) 2^{-(n-1)}$ for $\alpha = 1/2$ and all $n \geq 1$, the construction proceeds. Put $C = \bigcap_{n \geq 0} C_n$. Then C is closed, being an intersection of closed sets. At stage n the total length deleted is $2^{n-1} \alpha 3^{-n}$, and the deleted open intervals are pairwise disjoint, so by countable additivity

$$m([0, 1] \setminus C) = \sum_{n=1}^{\infty} 2^{n-1} \alpha 3^{-n} = \frac{\alpha}{2} \sum_{n=1}^{\infty} \left(\frac{2}{3} \right)^n = \alpha,$$

whence $m(C) = 1 - \alpha = 1/2 > 0$. Finally C contains no open interval: $C \subseteq C_n$, and C_n is a union of intervals of length $\ell_n \leq 2^{-n}$, so any interval contained in C has length at most 2^{-n} for every n , hence length 0. Thus C is a closed set with empty interior, i.e. C is nowhere dense, and $m(C) = 1/2$.

The function. Let $E = [0, 1] \setminus C$, an open subset of $[0, 1]$ with $m(E) = 1/2$, and define

$$f(x) = \int_0^x \chi_E \quad \text{for } x \in [0, 1].$$

f is absolutely continuous. The function χ_E is nonnegative and bounded, hence integrable over $[0, 1]$, and f is by definition the indefinite integral of χ_E over $[0, 1]$ (with $f(0) = 0$). By Theorem 11, f is absolutely continuous on $[0, 1]$.

f is strictly increasing. Let $0 \leq x < y \leq 1$. By additivity over domains of integration,

$$f(y) - f(x) = \int_x^y \chi_E = m(E \cap (x, y)).$$

Since C has empty interior, the interval (x, y) is not contained in C , so $E \cap (x, y) = (x, y) \setminus C$ is nonempty, and it is open in $\mathbb{R}$ because C is closed. A nonempty open subset of $\mathbb{R}$ contains an open interval and therefore has positive measure. Hence $f(y) - f(x) = m(E \cap (x, y)) > 0$, so f is strictly increasing on $[0, 1]$.

$f' = 0$ on a set of positive measure. By Theorem 14,

$$f'(x) = \frac{d}{dx} \int_0^x \chi_E = \chi_E(x) \quad \text{for almost all } x \in (0, 1).$$

Let Z be the set of measure zero off which this holds. Then for every $x \in C \cap (0, 1) \setminus Z$ we have $\chi_E(x) = 0$ and hence $f'(x) = 0$. Since $m(Z) = 0$ and $m(C) = 1/2$,

$$m(\{x \in [0, 1] : f'(x) = 0\}) \geq m(C \cap (0, 1) \setminus Z) = m(C) = \frac{1}{2} > 0.$$

Thus f is absolutely continuous and strictly increasing on $[0, 1]$, yet f' vanishes on a set of measure $1/2$.

Remark. This shows that the converse of the obvious implication fails badly: an absolutely continuous strictly increasing function need not have $f' > 0$ anywhere in particular, and indeed $f' = 0$ on a set of measure as close to 1 as we please, by taking α close to 0 in the construction. Note also that, by part (iv) of Problem 56 applied to this strictly increasing absolutely continuous f , $m(f(C)) = \int_C f' = \int_C \chi_E = 0$; so f is a homeomorphism of $[0, 1]$ onto $[0, 1/2]$ carrying a set of measure $1/2$ onto a set of measure zero.

Problem 6.59. For a nonnegative integrable function f over $[c, d]$, and a strictly increasing absolutely continuous function g on $[a, b]$ such that $g([a, b]) \subseteq [c, d]$, is it possible to justify the change of variables

formula

$$\int_{g(a)}^{g(b)} f(y) dy = \int_a^b f(g(x))g'(x) dx$$

by showing that

$$\frac{d}{dx} \left[\int_{g(a)}^{g(x)} f(s) ds - \int_a^x f(g(t))g'(t) dt \right] = 0 \quad \text{for almost all } x \in (a, b)?$$

Solution. No, not as it stands. The displayed assertion is a **true** statement, but establishing it is not easier than the theorem, and by itself it does not deliver the theorem. There are two independent difficulties, and repairing either of them requires exactly the machinery of Problem 56 that already proves the formula outright.

Write $F(y) = \int_{g(a)}^y f(s) ds$ for $y \in [g(a), g(b)]$, $\Phi(x) = \int_a^x f(g(t))g'(t) dt$, and $H = F \circ g - \Phi$ on $[a, b]$, which is the bracketed expression.

First difficulty: a vanishing derivative does not force constancy. Even granting $H' = 0$ almost everywhere on (a, b) , one may not conclude that H is constant. The Cantor-Lebesgue function is continuous, increasing, and has derivative zero almost everywhere, yet is not constant. To pass from $H' = 0$ a.e. to $H \equiv H(a) = 0$ one needs H to be absolutely continuous, for it is only then that Theorem 10 gives $H(x) - H(a) = \int_a^x H' = 0$.

Now $F \circ g$ is indeed absolutely continuous: given $\epsilon > 0$ choose $\delta > 0$ responding to the ϵ challenge for the absolutely continuous F , and then $\eta > 0$ responding to the δ challenge for g ; if $\{(x_k, y_k)\}_{k=1}^n$ is a disjoint collection of intervals in (a, b) with $\sum_k (y_k - x_k) < \eta$, then, g being strictly increasing, $\{(g(x_k), g(y_k))\}_{k=1}^n$ is a disjoint collection of intervals in $(g(a), g(b))$ of total length $\sum_k [g(y_k) - g(x_k)] < \delta$, so $\sum_k |F(g(y_k)) - F(g(x_k))| < \epsilon$.

But Φ is a legitimate real-valued absolutely continuous function only if $(f \circ g) \cdot g'$ is **integrable** over $[a, b]$; a priori this product is merely a nonnegative measurable function (measurable after replacing f by a Borel representative, which changes $(f \circ g)g'$ only on a set of measure zero), and its integral could conceivably be $+\infty$, in which case $\Phi \equiv +\infty$ on $(a, b]$ and the bracketed difference is not even defined. The integrability of $(f \circ g) \cdot g'$ is not a technicality one may waive: it is half of the conclusion of the theorem. So the proposed scheme presupposes a substantial part of what it is meant to prove.

Second difficulty: the chain rule is unavailable on a set that can have positive measure. Suppose we grant integrability, so that H is absolutely continuous and H' exists a.e. The natural computation is

$$H'(x) = \frac{d}{dx} F(g(x)) - f(g(x))g'(x) = F'(g(x))g'(x) - f(g(x))g'(x) = 0,$$

using Theorem 14 in the form $F' = f$ and the chain rule. But Theorem 14 gives $F'(y) = f(y)$ only for y outside some set $N \subseteq [g(a), g(b)]$ with $m(N) = 0$, and at points of N the function F may fail to be differentiable altogether. The computation is therefore valid only for $x \notin g^{-1}(N)$, and $g^{-1}(N)$ **can have positive measure**.

Indeed, let g be the function of the preceding problem: $C \subseteq [0, 1]$ a closed nowhere dense set with $m(C) = 1/2$, $E = [0, 1] \setminus C$, and $g(x) = \int_0^x \chi_E$, which is strictly increasing and absolutely continuous on $[0, 1]$ with $g([0, 1]) = [0, 1/2]$. Then $N := g(C)$ satisfies $m(N) = \int_C g' = \int_C \chi_E = 0$ by part (iv) of Problem 56, while $g^{-1}(N) = C$ has measure $1/2$ because g , being strictly increasing, is one-to-one. Now take

$$f = 1 + \chi_N \quad \text{on } [0, 1/2],$$

a nonnegative integrable function. Since $m(N) = 0$ we have $F(y) = \int_0^y f = y$, so $F'(y) = 1$ for every y , whereas $f(y) = 2$ for $y \in N$. Thus F is differentiable everywhere, yet the identity $F' = f$ that Theorem 14 supplies fails at every point of N , and consequently the step $F'(g(x)) = f(g(x))$ in the computation above is false for every x in the set C of measure $1/2$. The naive chain-rule verification of $H' = 0$ is therefore unavailable on a set of positive measure. (In this example $H' = 0$ a.e. is nevertheless true, since $g' = \chi_E = 0$ on C ; but that is a fact about this g , established by an argument the proposed scheme does not contain.)

What is actually needed to repair the argument. On $A := g^{-1}(N)$ one must show separately that both terms of H' vanish almost everywhere.

For the second term: $m(g(A)) \leq m(N) = 0$, and by part (iv) of Problem 56, $\int_A g' = m(g(A)) = 0$; since $g' \geq 0$ a.e., Proposition 9 of Chapter 4 gives $g' = 0$ a.e. on A , hence $f(g(x))g'(x) = 0$ for almost all $x \in A$.

For the first term one needs the corresponding statement for the increasing absolutely continuous function $\psi := F \circ g$, namely $\int_A \psi' = m(\psi(A))$. Granting this, $\psi(A) = F(g(A)) \subseteq F(N)$, and an increasing absolutely continuous function maps sets of measure zero onto sets of measure zero, so $m(\psi(A)) = 0$ and therefore, ψ' being nonnegative a.e., $\psi' = 0$ a.e. on A . (The mapping property is proved directly: given $\epsilon > 0$ let $\delta > 0$ respond to the ϵ challenge for the absolute continuity of F ; choose an open set $\mathcal{O}$ with $N \subseteq \mathcal{O} \subseteq (g(a), g(b))$ and $m(\mathcal{O}) < \delta$, and write $\mathcal{O}$ as the union of a countable disjoint collection $\{(\alpha_k, \beta_k)\}$ of open intervals. Since F is increasing, $F(\mathcal{O}) \subseteq \bigcup_k [F(\alpha_k), F(\beta_k)]$, and for each n the disjoint collection $\{(\alpha_k, \beta_k)\}_{k=1}^n$ has total length less than δ , so $\sum_{k=1}^n [F(\beta_k) - F(\alpha_k)] < \epsilon$; letting $n \rightarrow \infty$, $m^*(F(N)) \leq m^*(F(\mathcal{O})) \leq \epsilon$. As $\epsilon > 0$ was arbitrary, $m(F(N)) = 0$.) Combining, $H' = 0$ a.e. on A , and off A the chain-rule computation applies; so indeed $H' = 0$ a.e. on (a, b) , and, H being absolutely continuous with $H(a) = 0$, we get $H \equiv 0$, which is the change of variables formula. Conclusion. The scheme can be pushed through, but only after (i) knowing in advance that $(f \circ g)g'$ is integrable and (ii) invoking the identity $m(h(A)) = \int_A h'$ for increasing absolutely continuous h and measurable A , i.e. precisely parts (i)-(iv) of Problem 56. Since those parts already yield the change of variables formula directly, through parts (v) and (vi), the proposed route is not an independent justification: as an argument standing on its own it is invalid, and as a corrected argument it is a detour through the proof it was meant to replace. The honest answer to the question posed is therefore no.

Problem 6.60. Let f be absolutely continuous and singular on $[a, b]$. Show that f is constant. Also show that the Lebesgue decomposition of a function of bounded variation is unique if the singular function is required to vanish at $x = a$.

Solution. Recall the definitions in force. A function of bounded variation on $[a, b]$ is **singular** provided its derivative vanishes almost everywhere on $[a, b]$; and a **Lebesgue decomposition** of a function f of bounded variation on $[a, b]$ is an expression $f = g + h$ on $[a, b]$ in which g is absolutely continuous and h is singular. Note that every function of bounded variation on $[a, b]$ is, by Jordan's Theorem together with Lebesgue's Theorem, differentiable almost everywhere on (a, b) with integrable derivative (Corollary 6), so the notion of singularity is meaningful; and every absolutely continuous function on $[a, b]$ is of bounded variation, so both summands in a Lebesgue decomposition are of bounded variation.

An absolutely continuous singular function is constant. Let f be absolutely continuous and singular on $[a, b]$, and let $x \in [a, b]$. The restriction of f to $[a, x]$ is absolutely continuous, so Theorem 10, applied on the interval $[a, x]$, tells us that f' is integrable over $[a, x]$ and

$$\int_a^x f' = f(x) - f(a).$$

Since f is singular, $f' = 0$ almost everywhere on $[a, b]$, hence almost everywhere on $[a, x]$, and therefore $\int_a^x f' = 0$. Thus $f(x) = f(a)$ for every $x \in [a, b]$, i.e. f is constant. (Conversely a constant function is trivially absolutely continuous and singular, so the absolutely continuous singular functions are precisely the constants.)

Uniqueness of the Lebesgue decomposition. Let f be of bounded variation on $[a, b]$ and suppose

$$f = g_1 + h_1 = g_2 + h_2 \quad \text{on } [a, b],$$

where g_1, g_2 are absolutely continuous, h_1, h_2 are singular, and $h_1(a) = h_2(a) = 0$. Define

$$u = g_1 - g_2 = h_2 - h_1 \quad \text{on } [a, b].$$

First, u is absolutely continuous: $u = g_1 - g_2$ and a difference of absolutely continuous functions on

$[a, b]$ is absolutely continuous, since for a disjoint collection $\{(x_k, y_k)\}_{k=1}^n$ of intervals in (a, b) ,

$$\sum_{k=1}^n |u(y_k) - u(x_k)| \leq \sum_{k=1}^n |g_1(y_k) - g_1(x_k)| + \sum_{k=1}^n |g_2(y_k) - g_2(x_k)|,$$

so that if δ_1, δ_2 respond to the challenge $\epsilon/2$ for g_1, g_2 respectively, then $\delta = \min\{\delta_1, \delta_2\}$ responds to the challenge ϵ for u .

Second, u is singular: $u = h_2 - h_1$ is of bounded variation, being a difference of functions of bounded variation, and h_1, h_2 are differentiable almost everywhere with $h'_1 = h'_2 = 0$ almost everywhere; at every point at which both derivatives exist, $u' = h'_2 - h'_1$, so $u' = 0$ almost everywhere on $[a, b]$.

By the first part of the problem, u is constant on $[a, b]$. Its value at a is

$$u(a) = h_2(a) - h_1(a) = 0 - 0 = 0.$$

Hence $u \equiv 0$, that is $g_1 = g_2$ and $h_1 = h_2$ on $[a, b]$. The Lebesgue decomposition is therefore unique under the normalization that the singular part vanish at a .

Remark on existence with this normalization. The decomposition exhibited in the text, namely

$$g(x) = \int_a^x f', \quad h(x) = f(x) - \int_a^x f' \quad \text{for } x \in [a, b],$$

has g absolutely continuous by Theorem 11 and h singular by Theorem 14, and it satisfies $h(a) = f(a)$ rather than 0. Replacing the pair (g, h) by $(g + f(a), h - f(a))$ leaves g absolutely continuous and h singular and normalizes $h(a) = 0$; so a normalized Lebesgue decomposition exists, and by the above it is unique. Without the normalization the decomposition is unique only up to the addition of a constant to one summand and its subtraction from the other, which is precisely the indeterminacy the constant u measures.

Problem 6.61. Show that a real-valued function φ on (a, b) is convex if and only if for points $x_1, \dots, x_n$ in (a, b) and nonnegative numbers $\lambda_1, \dots, \lambda_n$ such that $\sum_{k=1}^n \lambda_k = 1$,

$$\varphi\left(\sum_{k=1}^n \lambda_k x_k\right) \leq \sum_{k=1}^n \lambda_k \varphi(x_k).$$

Use this to directly prove Jensen's Inequality for f a simple function.

Solution. Preliminary observation. If $x_1, \dots, x_n$ belong to (a, b) and $\lambda_1, \dots, \lambda_n$ are nonnegative with $\sum_k \lambda_k = 1$, then the point $x = \sum_k \lambda_k x_k$ again belongs to (a, b) . Indeed, with $\mu = \min_k x_k$ and $M = \max_k x_k$ we have $\mu = \sum_k \lambda_k \mu \leq \sum_k \lambda_k x_k \leq \sum_k \lambda_k M = M$, and $\mu, M \in (a, b)$, so $x \in [\mu, M] \subseteq (a, b)$. Thus the left-hand side of the asserted inequality is defined.

The condition is sufficient. Suppose the inequality holds for all such finite systems. Taking $n = 2$, $\lambda_1 = \lambda$ and $\lambda_2 = 1 - \lambda$ for $0 \leq \lambda \leq 1$ and $x_1, x_2 \in (a, b)$ gives

$$\varphi(\lambda x_1 + (1 - \lambda)x_2) \leq \lambda \varphi(x_1) + (1 - \lambda)\varphi(x_2),$$

which is exactly (38). Hence φ is convex.

The condition is necessary. Let φ be convex on (a, b) . We argue by induction on n . For $n = 1$ the inequality reads $\varphi(x_1) \leq \varphi(x_1)$, and for $n = 2$ it is (38).

Assume the inequality holds for every system of $n - 1$ points, where $n \geq 3$, and let $x_1, \dots, x_n \in (a, b)$ and $\lambda_1, \dots, \lambda_n \geq 0$ with $\sum_{k=1}^n \lambda_k = 1$ be given. If $\lambda_n = 1$ then $\lambda_k = 0$ for $k < n$ and the inequality is the identity $\varphi(x_n) \leq \varphi(x_n)$. So suppose $\lambda_n < 1$ and set

$$\mu = \sum_{k=1}^{n-1} \lambda_k = 1 - \lambda_n > 0, \quad y = \sum_{k=1}^{n-1} \frac{\lambda_k}{\mu} x_k.$$

The numbers λ_k/μ , $1 \leq k \leq n-1$, are nonnegative and sum to 1, so by the preliminary observation $y \in (a, b)$, and by the induction hypothesis

$$\varphi(y) \leq \sum_{k=1}^{n-1} \frac{\lambda_k}{\mu} \varphi(x_k).$$

Moreover $\sum_{k=1}^n \lambda_k x_k = \mu y + (1-\mu)x_n$, so (38), applied with $\lambda = \mu \in (0, 1]$ to the points y and x_n of (a, b) , gives

$$\varphi\left(\sum_{k=1}^n \lambda_k x_k\right) = \varphi(\mu y + (1-\mu)x_n) \leq \mu \varphi(y) + (1-\mu)\varphi(x_n) \leq \mu \sum_{k=1}^{n-1} \frac{\lambda_k}{\mu} \varphi(x_k) + \lambda_n \varphi(x_n) = \sum_{k=1}^n \lambda_k \varphi(x_k),$$

where the second inequality used $\mu > 0$ and the monotonicity of multiplication by the positive number μ . This completes the induction.

Jensen's Inequality for a simple function. Let φ be convex on $(-\infty, \infty)$ and let f be a simple function on $[0, 1]$; being simple it is measurable and bounded, hence integrable over $[0, 1]$, and $\varphi \circ f$ is simple, hence also integrable over $[0, 1]$. Write f in canonical form,

$$f = \sum_{k=1}^n c_k \chi_{E_k} \quad \text{on } [0, 1],$$

where $c_1, \dots, c_n$ are the distinct values taken by f and $E_k = f^{-1}(c_k)$, so that $\{E_k\}_{k=1}^n$ is a disjoint collection of measurable sets whose union is $[0, 1]$. Set $\lambda_k = m(E_k)$. Then each $\lambda_k \geq 0$ and, by the finite additivity of Lebesgue measure,

$$\sum_{k=1}^n \lambda_k = m\left(\bigcup_{k=1}^n E_k\right) = m([0, 1]) = 1.$$

By the definition of the integral of a simple function,

$$\int_0^1 f = \sum_{k=1}^n c_k m(E_k) = \sum_{k=1}^n \lambda_k c_k.$$

On the other hand $\varphi \circ f$ takes the value $\varphi(c_k)$ precisely on E_k , so $\varphi \circ f = \sum_{k=1}^n \varphi(c_k) \chi_{E_k}$ and

$$\int_0^1 (\varphi \circ f) = \sum_{k=1}^n \varphi(c_k) m(E_k) = \sum_{k=1}^n \lambda_k \varphi(c_k).$$

Applying the inequality just proved, with the points $c_1, \dots, c_n$ of $(-\infty, \infty)$ and the weights $\lambda_1, \dots, \lambda_n$, we conclude

$$\varphi\left(\int_0^1 f\right) = \varphi\left(\sum_{k=1}^n \lambda_k c_k\right) \leq \sum_{k=1}^n \lambda_k \varphi(c_k) = \int_0^1 (\varphi \circ f),$$

which is (42) for f simple.

Problem 6.62. Show that a continuous function on (a, b) is convex if and only if

$$\varphi\left(\frac{x_1 + x_2}{2}\right) \leq \frac{\varphi(x_1) + \varphi(x_2)}{2} \quad \text{for all } x_1, x_2 \in (a, b).$$

Solution. Let φ be a continuous real-valued function on (a, b) . Call the displayed condition **midpoint convexity**.

Necessity. If φ is convex then (38) with $\lambda = 1/2$ is precisely midpoint convexity. (Continuity is not

needed for this direction.)

Sufficiency. Suppose φ is continuous and midpoint convex. Fix $x_1, x_2 \in (a, b)$; we must verify (38) for every $\lambda \in [0, 1]$. If $x_1 = x_2$ this is trivial, so assume $x_1 \neq x_2$. For $\lambda \in [0, 1]$ write

$$z(\lambda) = \lambda x_1 + (1 - \lambda)x_2,$$

a point of the closed interval with endpoints x_1, x_2 , which is contained in (a, b) ; the map $\lambda \mapsto z(\lambda)$ is continuous.

Step 1: dyadic λ . Let $D_n = \{k/2^n : k = 0, 1, \dots, 2^n\}$. We prove by induction on $n \geq 0$ that

$$\varphi(z(\lambda)) \leq \lambda\varphi(x_1) + (1 - \lambda)\varphi(x_2) \quad \text{for all } \lambda \in D_n. \quad (\dagger_n)$$

For $n = 0$ we have $\lambda \in \{0, 1\}$ and $(\dagger_0)$ is an identity. Assume $(\dagger_n)$ and let $\lambda = k/2^{n+1}$ with $0 \leq k \leq 2^{n+1}$. If k is even then $\lambda = (k/2)/2^n \in D_n$ and there is nothing to prove. If k is odd, then $1 \leq k \leq 2^{n+1} - 1$, and we set

$$\lambda' = \frac{k-1}{2^{n+1}}, \quad \lambda'' = \frac{k+1}{2^{n+1}}.$$

Both $k-1$ and $k+1$ are even and lie in $[0, 2^{n+1}]$, so $\lambda', \lambda'' \in D_n$, and $\lambda = \frac{1}{2}(\lambda' + \lambda'')$. Since z is an affine function of λ ,

$$z(\lambda) = \frac{z(\lambda') + z(\lambda'')}{2},$$

and $z(\lambda'), z(\lambda'') \in (a, b)$. Midpoint convexity and then $(\dagger_n)$ applied to λ' and to λ'' give

$$\begin{aligned} \varphi(z(\lambda)) &\leq \frac{\varphi(z(\lambda')) + \varphi(z(\lambda''))}{2} \\ &\leq \frac{1}{2} \left[\lambda' \varphi(x_1) + (1 - \lambda') \varphi(x_2) \right] + \frac{1}{2} \left[\lambda'' \varphi(x_1) + (1 - \lambda'') \varphi(x_2) \right] \\ &= \frac{\lambda' + \lambda''}{2} \varphi(x_1) + \left(1 - \frac{\lambda' + \lambda''}{2} \right) \varphi(x_2) \\ &= \lambda \varphi(x_1) + (1 - \lambda) \varphi(x_2). \end{aligned}$$

This establishes $(\dagger_{n+1})$ and completes the induction.

Step 2: arbitrary λ by continuity. Let $D = \bigcup_{n \geq 0} D_n$ be the set of dyadic rationals in $[0, 1]$; D is dense in $[0, 1]$, since the intervals $[k/2^n, (k+1)/2^n]$ have length $2^{-n} \rightarrow 0$. Given $\lambda \in [0, 1]$, choose a sequence $\{\lambda_j\}$ in D with $\lambda_j \rightarrow \lambda$. By Step 1,

$$\varphi(z(\lambda_j)) \leq \lambda_j \varphi(x_1) + (1 - \lambda_j) \varphi(x_2) \quad \text{for every } j.$$

Now $z(\lambda_j) \rightarrow z(\lambda)$, all these points lying in the closed interval with endpoints x_1, x_2 , a subset of (a, b) on which φ is continuous; hence $\varphi(z(\lambda_j)) \rightarrow \varphi(z(\lambda))$. The right-hand side converges to $\lambda \varphi(x_1) + (1 - \lambda) \varphi(x_2)$. Passing to the limit in the inequality,

$$\varphi(\lambda x_1 + (1 - \lambda)x_2) = \varphi(z(\lambda)) \leq \lambda \varphi(x_1) + (1 - \lambda) \varphi(x_2).$$

Since $x_1, x_2 \in (a, b)$ and $\lambda \in [0, 1]$ were arbitrary, φ satisfies (38) and is convex.

Remark. Continuity cannot be dropped. Regarding $\mathbb{R}$ as a vector space over the field $\mathbb{Q}$ and choosing a Hamel basis, one obtains additive functions $\varphi : \mathbb{R} \rightarrow \mathbb{R}$, satisfying $\varphi(s+t) = \varphi(s) + \varphi(t)$, that are not linear; such a φ satisfies $\varphi((x_1+x_2)/2) = (\varphi(x_1) + \varphi(x_2))/2$ with equality, hence is midpoint convex, yet it is unbounded on every interval and therefore is not convex, since by Corollary 17 a convex function on an open interval is continuous.

Problem 6.63. A function on a general interval I is said to be convex provided it is continuous on I and (38) holds for all $x_1, x_2 \in I$. Is a convex function on a closed, bounded interval $[a, b]$ necessarily Lipschitz on $[a, b]$?

Solution. No. Corollary 17 asserts that a convex function on an open interval (a, b) is Lipschitz on each closed, bounded subinterval $[c, d]$ of (a, b) , and the proof there uses the finiteness of the one-sided derivatives $\varphi'(c^+)$ and $\varphi'(d^-)$ at **interior** points c and d . At an endpoint of $[a, b]$ there is no room to the left (or right) to run this argument, and the conclusion genuinely fails.

Counterexample. Define

$$\varphi(x) = -\sqrt{x} \quad \text{for } x \in [0, 1].$$

φ is convex on $[0, 1]$ in the sense stated. It is continuous on $[0, 1]$, being the composition of the continuous functions $x \mapsto \sqrt{x}$ and $t \mapsto -t$. On the open interval $(0, 1)$ it is twice differentiable with

$$\varphi'(x) = -\frac{1}{2}x^{-1/2}, \quad \varphi''(x) = \frac{1}{4}x^{-3/2} > 0,$$

so φ' is increasing on $(0, 1)$ and Proposition 15 shows that φ is convex on $(0, 1)$; that is, (38) holds for all $x_1, x_2 \in (0, 1)$ and all $\lambda \in [0, 1]$.

It remains to extend (38) to pairs involving the endpoints. Let $x_1, x_2 \in [0, 1]$ and $\lambda \in [0, 1]$. Choose sequences $\{x_1^{(j)}\}$ and $\{x_2^{(j)}\}$ in $(0, 1)$ with $x_1^{(j)} \rightarrow x_1$ and $x_2^{(j)} \rightarrow x_2$ (possible since $(0, 1)$ is dense in $[0, 1]$). For each j ,

$$\varphi(\lambda x_1^{(j)} + (1 - \lambda)x_2^{(j)}) \leq \lambda\varphi(x_1^{(j)}) + (1 - \lambda)\varphi(x_2^{(j)}).$$

Since $\lambda x_1^{(j)} + (1 - \lambda)x_2^{(j)} \rightarrow \lambda x_1 + (1 - \lambda)x_2$, all these points lying in $[0, 1]$, and since φ is continuous on $[0, 1]$, both sides converge; passing to the limit gives (38) for x_1, x_2 . Hence φ is convex on the closed, bounded interval $[0, 1]$.

φ is not Lipschitz on $[0, 1]$. For $0 < x \leq 1$,

$$\left| \frac{\varphi(x) - \varphi(0)}{x - 0} \right| = \frac{\sqrt{x}}{x} = \frac{1}{\sqrt{x}}.$$

Given any $c > 0$, choose x with $0 < x < \min\{1, c^{-2}\}$; then $1/\sqrt{x} > c$, so $|\varphi(x) - \varphi(0)| > c|x - 0|$. Thus no constant c satisfies $|\varphi(u) - \varphi(v)| \leq c|u - v|$ for all $u, v \in [0, 1]$, and φ is not Lipschitz on $[0, 1]$.

What does survive. Two positive statements remain true, and they locate the failure precisely at the endpoints.

First, a convex function φ on $[a, b]$ is Lipschitz on every closed, bounded subinterval $[c, d]$ with $a < c \leq d < b$. Indeed the restriction of φ to (a, b) is convex there, so Corollary 17 applies. In the example above, $-\sqrt{x}$ is Lipschitz on $[c, 1]$ for each $c > 0$, with constant $1/(2\sqrt{c})$, but these constants blow up as $c \rightarrow 0^+$.

Second, a convex function on $[a, b]$ is bounded on $[a, b]$: it is continuous on a compact set. So the failure is not one of boundedness but purely one of the modulus of continuity near an endpoint.

Remark. The obstruction is exactly that a convex function on $[a, b]$ may have an infinite one-sided derivative at an endpoint: here $\varphi'(0^+) = \lim_{h \rightarrow 0^+} (-\sqrt{h})/h = -\infty$. Lemma 16 guarantees finite one-sided derivatives only at interior points, since its proof compares the slope at x with slopes of chords on both sides of x . Note that Lipschitzness is a strictly stronger demand than absolute continuity here: in this example $-\sqrt{x}$ is in fact absolutely continuous on $[0, 1]$, being the indefinite integral of the integrable function $-\frac{1}{2}x^{-1/2}$, and yet it is not Lipschitz. So the answer to the question is no even though the weaker conclusion of absolute continuity may still hold.

6.10 Problems 6.64–6.70

Problem 6.64. Let φ have a second derivative at each point in (a, b) . Show that φ is convex if and only if φ'' is nonnegative.

Solution. Throughout, (a, b) is an open interval and φ is real-valued on (a, b) with $\varphi''(x)$ existing (in particular φ' exists on all of (a, b) , since otherwise φ'' could not be formed) for every $x \in (a, b)$.

Suppose first that $\varphi'' \geq 0$ on (a, b) . This is exactly the hypothesis of the second assertion of Proposition 15: a function with a nonnegative second derivative on (a, b) is convex there. For completeness we recall why. Since $\varphi'' \geq 0$ on the interval (a, b) , the Mean Value Theorem applied to φ' shows that φ'

is increasing: for $u < v$ in (a, b) there is $c \in (u, v)$ with

$$\varphi'(v) - \varphi'(u) = \varphi''(c)(v - u) \geq 0.$$

Thus φ is differentiable on (a, b) with increasing derivative, and Proposition 15 tells us that φ is convex. Conversely, suppose φ is convex on (a, b) . Since φ is differentiable at every point of (a, b) by hypothesis, its one-sided derivatives coincide with φ' at each point, so the inequalities (40) of Lemma 16 read: for $u < v$ in (a, b) ,

$$\varphi'(u) = \varphi'(u^+) \leq \frac{\varphi(v) - \varphi(u)}{v - u} \leq \varphi'(v^-) = \varphi'(v).$$

Hence φ' is an increasing function on (a, b) . (This is also the content of Theorem 18, which asserts that the derivative of a convex function is increasing wherever it exists.)

Now fix $x \in (a, b)$. For all sufficiently small $h \neq 0$ the point $x + h$ lies in (a, b) , and since φ' is increasing the difference quotient

$$\frac{\varphi'(x + h) - \varphi'(x)}{h}$$

is nonnegative: if $h > 0$ then $x < x + h$ forces $\varphi'(x + h) - \varphi'(x) \geq 0$, while if $h < 0$ then $x + h < x$ forces $\varphi'(x + h) - \varphi'(x) \leq 0$, and in either case numerator and denominator have the same sign. By hypothesis the limit of this quotient as $h \rightarrow 0$ exists and equals $\varphi''(x)$. A limit of nonnegative numbers is nonnegative, so $\varphi''(x) \geq 0$.

Since $x \in (a, b)$ was arbitrary, $\varphi'' \geq 0$ on (a, b) . This completes both implications.

Problem 6.65. Suppose $a \geq 0$ and $b > 0$. Show that the function $\varphi(t) = (a + bt)^p$ is convex on $[0, \infty)$ for $1 \leq p < \infty$.

Solution. Since $[0, \infty)$ is not an open interval, convexity here is understood in the sense of Problem 63: φ is continuous on $[0, \infty)$ and the inequality (38),

$$\varphi(\lambda x_1 + (1 - \lambda)x_2) \leq \lambda\varphi(x_1) + (1 - \lambda)\varphi(x_2),$$

holds for all $x_1, x_2 \in [0, \infty)$ and all λ with $0 \leq \lambda \leq 1$.

Observe first that $a + bt > 0$ for every $t > 0$, since $a \geq 0$ and $b > 0$ give $a + bt \geq bt > 0$. Also $a + bt \geq 0$ for $t \geq 0$, so $(a + bt)^p$ is defined on all of $[0, \infty)$, and φ is continuous there, being the composition of the continuous function $t \mapsto a + bt$ with the function $s \mapsto s^p$, which is continuous on $[0, \infty)$ for $p \geq 1$. Convexity on the open interval $(0, \infty)$. For $t > 0$ we have $a + bt > 0$, so the chain rule gives

$$\varphi'(t) = pb(a + bt)^{p-1}, \quad \varphi''(t) = p(p-1)b^2(a + bt)^{p-2}.$$

(The exponents $p-1$ and $p-2$ may be negative, but this is harmless because the base $a + bt$ is strictly positive on $(0, \infty)$.) Since $p \geq 1$ we have $p(p-1) \geq 0$, and $b^2 > 0$, $(a + bt)^{p-2} > 0$; hence $\varphi''(t) \geq 0$ for all $t \in (0, \infty)$. By Proposition 15, φ is convex on the open interval $(0, \infty)$: for $x_1, x_2 \in (0, \infty)$ and $0 \leq \lambda \leq 1$,

$$\varphi(\lambda x_1 + (1 - \lambda)x_2) \leq \lambda\varphi(x_1) + (1 - \lambda)\varphi(x_2).$$

Call this the interior convexity inequality.

Extension to the endpoint 0. Let $x_1, x_2 \in [0, \infty)$ and $0 \leq \lambda \leq 1$ be arbitrary. If $\lambda = 0$ or $\lambda = 1$ the inequality is an identity, so assume $0 < \lambda < 1$. If both x_1 and x_2 are positive, the interior convexity inequality applies directly. If $x_1 = x_2 = 0$ the inequality is again an identity. There remains the case in which exactly one of the two points is 0; by symmetry (interchanging the roles of the points and replacing λ by $1 - \lambda$) we may assume $x_1 = 0$ and $x_2 > 0$.

For $0 < \varepsilon < x_2$ apply the interior convexity inequality to the points ε and x_2 of $(0, \infty)$:

$$\varphi(\lambda\varepsilon + (1 - \lambda)x_2) \leq \lambda\varphi(\varepsilon) + (1 - \lambda)\varphi(x_2).$$

Now let $\varepsilon \rightarrow 0^+$. Since φ is continuous on $[0, \infty)$ and $\lambda\varepsilon + (1 - \lambda)x_2 \rightarrow (1 - \lambda)x_2$, the left-hand side converges to $\varphi((1 - \lambda)x_2) = \varphi(\lambda \cdot 0 + (1 - \lambda)x_2)$, while the right-hand side converges to $\lambda\varphi(0) + (1 -$

$\lambda)\varphi(x_2)$. Passing to the limit in the inequality yields

$$\varphi(\lambda \cdot 0 + (1 - \lambda)x_2) \leq \lambda\varphi(0) + (1 - \lambda)\varphi(x_2),$$

which is the required inequality for the pair $(0, x_2)$.

Thus (38) holds for every pair of points of $[0, \infty)$ and every $\lambda \in [0, 1]$, and φ is continuous on $[0, \infty)$. Therefore $\varphi(t) = (a + bt)^p$ is convex on $[0, \infty)$ for $1 \leq p < \infty$.

Problem 6.66. For what functions φ is Jensen's Inequality always an equality?

Solution. Answer: precisely the affine functions, that is, the functions of the form $\varphi(t) = mt + c$ with m, c real constants.

Recall the statement of Jensen's Inequality: φ is convex on $(-\infty, \infty)$, f is integrable over $[0, 1]$, $\varphi \circ f$ is integrable over $[0, 1]$, and then

$$\varphi\left(\int_0^1 f(x) dx\right) \leq \int_0^1 (\varphi \circ f)(x) dx.$$

We ask for which convex φ equality holds for every such f .

Sufficiency. Suppose $\varphi(t) = mt + c$. Such a φ is convex, since it satisfies (38) with equality for every x_1, x_2 and λ . Let f be integrable over $[0, 1]$. Then $\varphi \circ f = mf + c$ is also integrable over $[0, 1]$, and by the linearity of the Lebesgue integral together with $\int_0^1 1 dx = 1$,

$$\int_0^1 (\varphi \circ f)(x) dx = m \int_0^1 f(x) dx + c = \varphi\left(\int_0^1 f(x) dx\right).$$

So Jensen's Inequality is an equality for every integrable f .

Necessity. Suppose now that φ is convex on $(-\infty, \infty)$ and that equality holds in Jensen's Inequality for every integrable f on $[0, 1]$ for which $\varphi \circ f$ is integrable. We show φ is affine.

Fix real numbers t_1, t_2 and λ with $0 \leq \lambda \leq 1$, and define the simple function

$$f = t_1 \cdot \chi_{[0, \lambda)} + t_2 \cdot \chi_{[\lambda, 1]}.$$

Then f is measurable and bounded on $[0, 1]$, hence integrable, and $\varphi \circ f = \varphi(t_1)\chi_{[0, \lambda)} + \varphi(t_2)\chi_{[\lambda, 1]}$ is likewise a bounded measurable, hence integrable, function. Since $m([0, \lambda)) = \lambda$ and $m([\lambda, 1]) = 1 - \lambda$, the additivity of the integral over the two pieces gives

$$\int_0^1 f = \lambda t_1 + (1 - \lambda)t_2, \quad \int_0^1 (\varphi \circ f) = \lambda\varphi(t_1) + (1 - \lambda)\varphi(t_2).$$

Equality in Jensen's Inequality for this f therefore reads

$$\varphi(\lambda t_1 + (1 - \lambda)t_2) = \lambda\varphi(t_1) + (1 - \lambda)\varphi(t_2)$$

for all real t_1, t_2 and all $\lambda \in [0, 1]$. Thus φ agrees on each interval with the chord over that interval. We now deduce that φ is affine. Put

$$m = \varphi(1) - \varphi(0), \quad c = \varphi(0), \quad \ell(t) = mt + c,$$

and let t be an arbitrary real number. There are three cases.

If $0 \leq t \leq 1$, write $t = (1 - t) \cdot 0 + t \cdot 1$ and apply the displayed equality with $t_1 = 0$, $t_2 = 1$, $\lambda = 1 - t$:

$$\varphi(t) = (1 - t)\varphi(0) + t\varphi(1) = \varphi(0) + t(\varphi(1) - \varphi(0)) = \ell(t).$$

If $t > 1$, then 1 lies between 0 and t : indeed $1 = \lambda \cdot 0 + (1 - \lambda)t$ with $1 - \lambda = 1/t \in (0, 1)$. The equality applied to the points 0 and t gives

$$\varphi(1) = \left(1 - \frac{1}{t}\right)\varphi(0) + \frac{1}{t}\varphi(t),$$

and solving for $\varphi(t)$,

$$\varphi(t) = t\varphi(1) - (t-1)\varphi(0) = \varphi(0) + t(\varphi(1) - \varphi(0)) = \ell(t).$$

If $t < 0$, then 0 lies between t and 1: with $\lambda = 1/(1-t) \in (0, 1)$ we have $1 - \lambda = -t/(1-t)$ and

$$\lambda t + (1 - \lambda) \cdot 1 = \frac{t}{1-t} - \frac{t}{1-t} = 0.$$

The equality applied to the points t and 1 gives

$$\varphi(0) = \frac{1}{1-t}\varphi(t) - \frac{t}{1-t}\varphi(1),$$

so that

$$\varphi(t) = (1-t)\varphi(0) + t\varphi(1) = \varphi(0) + t(\varphi(1) - \varphi(0)) = \ell(t).$$

In every case $\varphi(t) = mt + c$. Hence φ is affine, and the two implications together show that Jensen's Inequality is always an equality exactly for the affine functions.

Two remarks. First, the necessity argument used only simple functions f taking two values, so equality for all such f already forces φ to be affine. Second, this is consistent with the proof of Jensen's Inequality: there one integrates the supporting-line inequality $\varphi(t) \geq m(t - \alpha) + \varphi(\alpha)$, and equality in the integrated form forces $\varphi(f(x)) = m(f(x) - \alpha) + \varphi(\alpha)$ for almost all x ; demanding this for all f means φ coincides with a supporting line on all of $\mathbb{R}$, that is, φ is affine.

Problem 6.67. State and prove a version of Jensen's Inequality on a general closed, bounded interval $[a, b]$.

Solution. The interval $[0, 1]$ enters the statement of Jensen's Inequality through the single fact that it has measure 1: because of this, $\int_0^1 f$ is the average value of f , and dx restricted to $[0, 1]$ is a measure of total mass 1. On a general closed, bounded interval $[a, b]$ with $a < b$ one must therefore replace integrals by averages, dividing by $m([a, b]) = b - a$.

Jensen's Inequality on $[a, b]$. Let $a < b$, let φ be a convex function on $(-\infty, \infty)$, let f be integrable over $[a, b]$, and suppose $\varphi \circ f$ is also integrable over $[a, b]$. Then

$$\varphi\left(\frac{1}{b-a}\int_a^b f(x) dx\right) \leq \frac{1}{b-a}\int_a^b (\varphi \circ f)(x) dx.$$

As in the case $[a, b] = [0, 1]$, the integrability assumption on $\varphi \circ f$ may be dropped when $\varphi \circ f$ is nonnegative, since then the right-hand side is defined in $[0, \infty]$ and the inequality is trivial if it equals $+\infty$; note also that $\varphi \circ f$ is measurable, because φ , being convex on $(-\infty, \infty)$, is continuous there (Corollary 17) and the composition of a continuous function with a measurable function is measurable by Proposition 7 of Chapter 3.

Proof. Set

$$\alpha = \frac{1}{b-a}\int_a^b f(x) dx.$$

Since f is integrable over $[a, b]$, the integral $\int_a^b f$ is a finite real number and hence $\alpha \in \mathbb{R}$.

By Lemma 16 the convex function φ has left-hand and right-hand derivatives at the point α and $\varphi'(\alpha^-) \leq \varphi'(\alpha^+)$. Choose a real number m with $\varphi'(\alpha^-) \leq m \leq \varphi'(\alpha^+)$. As observed in the text following Theorem 18, the line $y = m(t - \alpha) + \varphi(\alpha)$ is then a supporting line for the graph of φ at α , that is,

$$\varphi(t) \geq m(t - \alpha) + \varphi(\alpha) \quad \text{for all } t \in \mathbb{R}.$$

(Explicitly: for $t > \alpha$, Lemma 16 gives $(\varphi(t) - \varphi(\alpha))/(t - \alpha) \geq \varphi'(\alpha^+) \geq m$, and multiplying by $t - \alpha > 0$ yields the inequality; for $t < \alpha$, Lemma 16 gives $(\varphi(\alpha) - \varphi(t))/(\alpha - t) \leq \varphi'(\alpha^-) \leq m$, and multiplying by $\alpha - t > 0$ and rearranging yields it again; for $t = \alpha$ it is an identity.)

Since f is integrable over $[a, b]$, it is finite almost everywhere on $[a, b]$. Substituting $t = f(x)$ in the supporting-line inequality we obtain

$$\varphi(f(x)) \geq m(f(x) - \alpha) + \varphi(\alpha) \quad \text{for almost all } x \in [a, b].$$

Both sides are integrable over $[a, b]$: the left-hand side by hypothesis, the right-hand side because f is integrable and constants are integrable over the bounded interval $[a, b]$. Hence, by the monotonicity and linearity of the Lebesgue integral,

$$\begin{aligned} \int_a^b \varphi(f(x)) \, dx &\geq \int_a^b [m(f(x) - \alpha) + \varphi(\alpha)] \, dx \\ &= m \left[\int_a^b f(x) \, dx - \alpha(b - a) \right] + \varphi(\alpha)(b - a) \\ &= m[\alpha(b - a) - \alpha(b - a)] + \varphi(\alpha)(b - a) \\ &= \varphi(\alpha)(b - a), \end{aligned}$$

where we used $\int_a^b f = \alpha(b - a)$ by the definition of α . Dividing by $b - a > 0$ gives

$$\frac{1}{b - a} \int_a^b (\varphi \circ f)(x) \, dx \geq \varphi(\alpha) = \varphi \left(\frac{1}{b - a} \int_a^b f(x) \, dx \right),$$

which is the asserted inequality.

Two comments. First, taking $[a, b] = [0, 1]$ recovers the inequality (42) exactly, since then $b - a = 1$. Second, the normalization by $1/(b - a)$ cannot be dispensed with: if $\varphi(t) = t^2$, $f \equiv 1$ and $[a, b] = [0, 2]$, then $\varphi(\int_0^2 f) = 4$ while $\int_0^2 \varphi \circ f = 2$, so the unnormalized inequality fails. What makes the averaged form work is that $\frac{1}{b-a} dx$ is a measure of total mass 1 on $[a, b]$, which is precisely what the last line of the computation exploited.

Problem 6.68. Let f be integrable over $[0, 1]$. Show that

$$\exp \left[\int_0^1 f(x) \, dx \right] \leq \int_0^1 \exp(f(x)) \, dx.$$

Solution. Let $\varphi(t) = e^t$ for $t \in \mathbb{R}$. Then φ has the second derivative $\varphi''(t) = e^t > 0$ at every t , so by Proposition 15 (or by Problem 64) φ is convex on $(-\infty, \infty)$. Moreover φ is continuous, so by Proposition 7 of Chapter 3 the composition $\varphi \circ f = e^f$ is measurable on $[0, 1]$; being nonnegative, its integral $\int_0^1 e^f$ is defined as an element of $[0, \infty]$.

Set

$$\alpha = \int_0^1 f(x) \, dx,$$

a finite real number because f is integrable over $[0, 1]$.

If $\int_0^1 e^{f(x)} \, dx = +\infty$ the asserted inequality is trivially true, since its left-hand side e^α is finite. So assume $\int_0^1 e^f < \infty$; then e^f , being nonnegative, measurable and of finite integral, is integrable over $[0, 1]$, and Jensen's Inequality applies directly to φ and f to give

$$\exp \left[\int_0^1 f(x) \, dx \right] = \varphi \left(\int_0^1 f \right) \leq \int_0^1 (\varphi \circ f) = \int_0^1 \exp(f(x)) \, dx,$$

as required.

For completeness we give the underlying supporting-line argument explicitly, since it also shows that the integrability of e^f need not be assumed. Since $\varphi(t) = e^t$ is differentiable everywhere, its unique supporting line at α is the tangent line there, of slope $\varphi'(\alpha) = e^\alpha$; thus

$$e^t \geq e^\alpha(t - \alpha) + e^\alpha \quad \text{for all } t \in \mathbb{R}.$$

(This is the familiar inequality $e^s \geq 1 + s$ with $s = t - \alpha$, multiplied by $e^\alpha > 0$; it follows from the convexity of φ exactly as in the proof of Jensen's Inequality, using Lemma 16.)

Since f is integrable it is finite almost everywhere on $[0, 1]$, so substituting $t = f(x)$ gives

$$e^{f(x)} \geq e^\alpha (f(x) - \alpha) + e^\alpha \quad \text{for almost all } x \in [0, 1].$$

The right-hand side is integrable over $[0, 1]$, being $e^\alpha f$ plus a constant, and the left-hand side is nonnegative and measurable. By the monotonicity of the Lebesgue integral (valid for the integral of a nonnegative measurable function even when it takes the value $+\infty$), and using $\int_0^1 1 \, dx = 1$,

$$\int_0^1 e^{f(x)} \, dx \geq e^\alpha \left[\int_0^1 f(x) \, dx - \alpha \right] + e^\alpha = e^\alpha \cdot 0 + e^\alpha = e^\alpha,$$

because $\int_0^1 f = \alpha$. That is,

$$\int_0^1 \exp(f(x)) \, dx \geq \exp \left[\int_0^1 f(x) \, dx \right],$$

which is the desired inequality, with no integrability assumption on $\exp \circ f$ needed.

Problem 6.69. Let $\{\alpha_n\}$ be a sequence of nonnegative numbers whose sum is 1 and $\{\zeta_n\}$ a sequence of positive numbers. Show that

$$\prod_{n=1}^{\infty} \zeta_n^{\alpha_n} \leq \sum_{n=1}^{\infty} \alpha_n \zeta_n.$$

Solution. This is the weighted arithmetic-geometric mean inequality for countably many terms; we deduce it from Problem 68. The infinite product is understood as $\lim_{N \rightarrow \infty} \prod_{n=1}^N \zeta_n^{\alpha_n}$, and $\zeta^0 = 1$.

Write

$$S = \sum_{n=1}^{\infty} \alpha_n \zeta_n \in (0, \infty].$$

The sum is positive: since $\sum_n \alpha_n = 1$, some $\alpha_{n_0} > 0$, and $\zeta_{n_0} > 0$, so $S \geq \alpha_{n_0} \zeta_{n_0} > 0$. If $S = +\infty$ the asserted inequality is trivial, so assume $S < \infty$.

Step 1: the left-hand side is well defined. Applying the inequality $e^s \geq 1 + s$ (valid for all real s , since e^s lies above its tangent line at $s = 0$, as noted in the solution of Problem 68) with $s = \log \zeta$ gives $\zeta \geq 1 + \log \zeta$, that is, the elementary inequality

$$\log \zeta \leq \zeta - 1 \quad \text{for all } \zeta > 0.$$

Hence $(\log \zeta_n)^+ \leq (\zeta_n - 1)^+ \leq \zeta_n$ for every n , and therefore

$$\sum_{n=1}^{\infty} \alpha_n (\log \zeta_n)^+ \leq \sum_{n=1}^{\infty} \alpha_n \zeta_n = S < \infty.$$

Consequently the series $\sum_n \alpha_n \log \zeta_n$ has convergent positive part, so it is well defined as an element of $[-\infty, \infty)$, namely as the difference $\sum_n \alpha_n (\log \zeta_n)^+ - \sum_n \alpha_n (\log \zeta_n)^-$ of a finite number and a number in $[0, \infty]$; and its partial sums converge to this value in the extended sense (they tend to $-\infty$ exactly when $\sum_n \alpha_n (\log \zeta_n)^- = \infty$). Since $\prod_{n=1}^N \zeta_n^{\alpha_n} = \exp \left(\sum_{n=1}^N \alpha_n \log \zeta_n \right)$ and $\exp$ is continuous with $\exp(s) \rightarrow 0$ as $s \rightarrow -\infty$, the partial products converge in $[0, \infty)$ to

$$\prod_{n=1}^{\infty} \zeta_n^{\alpha_n} = \exp \left(\sum_{n=1}^{\infty} \alpha_n \log \zeta_n \right),$$

with the convention $\exp(-\infty) = 0$.

If $\sum_n \alpha_n \log \zeta_n = -\infty$, the left-hand side is $0 < S$ and we are done. So assume from now on that $\sum_n \alpha_n \log \zeta_n$ converges to a real number, and note that in view of the bound on the positive part this

means

$$\sum_{n=1}^{\infty} \alpha_n |\log \zeta_n| < \infty.$$

Step 2: construction of a function on $[0, 1]$. Put $A_0 = 0$ and $A_N = \sum_{n=1}^N \alpha_n$ for $N \geq 1$; the A_N increase to 1. Set

$$E_n = [A_{n-1}, A_n), \quad n = 1, 2, \dots$$

These are pairwise disjoint intervals with $m(E_n) = \alpha_n$ (empty when $\alpha_n = 0$) whose union is $[0, 1]$, and $[0, 1]$ differs from $[0, 1)$ by a single point, a set of measure zero. Define g on $[0, 1)$ by

$$g(x) = \zeta_n \quad \text{for } x \in E_n,$$

and define $g(1) = 1$, say. Then g is measurable and positive, and $f := \log g$ is measurable, with $f = \log \zeta_n$ on E_n .

Step 3: computing the two integrals. Both $|f|$ and g are nonnegative and measurable on $[0, 1]$, so by the countable additivity of integration over the disjoint sets E_n (a consequence of the Monotone Convergence Theorem of Chapter 4, applied to the increasing sequence of partial sums $\sum_{n=1}^N h \cdot \chi_{E_n}$ for a nonnegative measurable h),

$$\int_0^1 |f| = \sum_{n=1}^{\infty} \alpha_n |\log \zeta_n| < \infty, \quad \int_0^1 e^f = \int_0^1 g = \sum_{n=1}^{\infty} \alpha_n \zeta_n = S.$$

The first of these shows that f is integrable over $[0, 1]$, and the same countable additivity, now applied to f^+ and f^- separately and subtracted (both integrals being finite), gives

$$\int_0^1 f = \sum_{n=1}^{\infty} \alpha_n \log \zeta_n.$$

Step 4: applying Problem 68. Since f is integrable over $[0, 1]$, Problem 68 gives

$$\exp \left[\int_0^1 f(x) dx \right] \leq \int_0^1 \exp(f(x)) dx.$$

Substituting the two computations of Step 3,

$$\exp \left(\sum_{n=1}^{\infty} \alpha_n \log \zeta_n \right) \leq S = \sum_{n=1}^{\infty} \alpha_n \zeta_n.$$

By Step 1 the left-hand side is exactly $\prod_{n=1}^{\infty} \zeta_n^{\alpha_n}$. Therefore

$$\prod_{n=1}^{\infty} \zeta_n^{\alpha_n} \leq \sum_{n=1}^{\infty} \alpha_n \zeta_n,$$

as was to be shown.

Remark. One can also argue without measure theory, using only the inequality $\log \zeta \leq \zeta - 1$: applying it to $\zeta = \zeta_n/S$ gives $\log \zeta_n \leq \log S + \zeta_n/S - 1$, and multiplying by $\alpha_n \geq 0$ and summing over $n \leq N$ yields

$$\sum_{n=1}^N \alpha_n \log \zeta_n \leq A_N \log S + \frac{1}{S} \sum_{n=1}^N \alpha_n \zeta_n - A_N.$$

Letting $N \rightarrow \infty$, the right-hand side tends to $\log S + 1 - 1 = \log S$, so $\sum_n \alpha_n \log \zeta_n \leq \log S$, which is the same conclusion.

Problem 6.70. Let g be a positive measurable function on $[0, 1]$. Show that $\log \left(\int_0^1 g(x) dx \right) \geq \int_0^1 \log(g(x)) dx$ whenever each side is defined.

Solution. Since g is nonnegative and measurable on $[0, 1]$, the integral $\int_0^1 g$ is defined as an element of $[0, \infty]$; in fact it is strictly positive. Indeed, since $g > 0$ everywhere on $[0, 1]$, the measurable sets $E_k = \{x \in [0, 1] : g(x) > 1/k\}$ increase to $[0, 1]$, so by the continuity of measure $m(E_k) \rightarrow 1$, and hence $m(E_{k_0}) > 0$ for some k_0 ; then by the monotonicity of the integral $\int_0^1 g \geq \int_{E_{k_0}} g \geq m(E_{k_0})/k_0 > 0$. Thus $\int_0^1 g \in (0, \infty]$ and the left-hand side is defined in $(-\infty, \infty]$. The function $\log \circ g$ is measurable: $\log$ is continuous on $(0, \infty)$ and g is measurable and positive, so Proposition 7 of Chapter 3 applies. Its integral is defined provided not both $\int_0^1 (\log g)^+$ and $\int_0^1 (\log g)^-$ are infinite. We show that under these standing conventions the inequality

$$\log \left(\int_0^1 g(x) dx \right) \geq \int_0^1 \log(g(x)) dx$$

always holds; in fact we show that whenever $\int_0^1 g < \infty$ the right-hand side is automatically defined in $[-\infty, \infty)$, so that the proviso is needed only to make sense of the case $\int_0^1 g = \infty$.

Case 1: $\int_0^1 g = +\infty$. (This includes the case in which g takes the value $+\infty$ on a set of positive measure, if g is allowed to be extended real-valued.) Then the left-hand side is $\log(+\infty) = +\infty$, which dominates any value the right-hand side may take. The inequality holds.

Case 2: $A := \int_0^1 g(x) dx$ is finite, so $0 < A < \infty$ and g is integrable over $[0, 1]$; in particular g is finite almost everywhere. Put $f = \log g$, a measurable function on $[0, 1]$ which is finite almost everywhere, and note that $e^f = g$ almost everywhere.

We first check that $\int_0^1 f$ is defined. By the inequality $\log \zeta \leq \zeta - 1$ for $\zeta > 0$ (see the solution of Problem 69, where it was derived from $e^s \geq 1 + s$), we have pointwise almost everywhere

$$f^+ = (\log g)^+ \leq (g - 1)^+ \leq g,$$

and hence, by the monotonicity of the integral for nonnegative measurable functions,

$$\int_0^1 f^+ \leq \int_0^1 g = A < \infty.$$

Thus the positive part of f is always integrable, and $\int_0^1 f$ is defined as an element of $[-\infty, \infty)$.

If $\int_0^1 f = -\infty$, the asserted inequality reads $\log A \geq -\infty$, which is true since $A > 0$. So assume $\int_0^1 f$ is finite; then f is integrable over $[0, 1]$, and Problem 68 applies to f :

$$\exp \left[\int_0^1 f(x) dx \right] \leq \int_0^1 \exp(f(x)) dx.$$

Now $\exp(f(x)) = g(x)$ for almost all $x \in [0, 1]$, so the right-hand side equals $\int_0^1 g = A$. Therefore

$$\exp \left[\int_0^1 \log(g(x)) dx \right] \leq A.$$

Since $A > 0$ and $\log$ is an increasing function on $(0, \infty)$, taking logarithms in this inequality preserves it and gives

$$\int_0^1 \log(g(x)) dx \leq \log A = \log \left(\int_0^1 g(x) dx \right),$$

which is exactly the asserted inequality.

In both cases the inequality holds, and the proof is complete.

Remark. The inequality is the integral form of the statement that the geometric mean of g does not exceed its arithmetic mean: writing $\exp(\int_0^1 \log g)$ for the geometric mean of g over $[0, 1]$, what has been proved is

$$\exp\left(\int_0^1 \log g\right) \leq \int_0^1 g.$$

Problem 69 is the special case in which g is the countably-valued step function taking the value ζ_n on a set of measure α_n . Equality holds precisely when g is constant almost everywhere; indeed, equality forces equality almost everywhere in the supporting-line inequality $e^t \geq e^\alpha(t - \alpha) + e^\alpha$ used to prove Problem 68, and since e^t is strictly convex this happens only for $t = \alpha$, that is, only when $\log g$ is almost everywhere equal to its average.

6.11 Problem 6.71

Problem 6.71. (Nemytskii) Let φ be a continuous function on $\mathbb{R}$. Show that if there are constants for which (45) holds, then $\varphi \circ f$ is integrable over $[0, 1]$ whenever f is. Then show that if $\varphi \circ f$ is integrable over $[0, 1]$ whenever f is, then there are constants c_1 and c_2 for which (45) holds.

[The reference to (45) is a misnumbering. The growth condition intended is the one displayed in the discussion following Jensen's Inequality, where it carries the number (43), namely

$$|\varphi(x)| \leq c_1 + c_2|x| \quad \text{for all } x \in \mathbb{R}.$$

The text there observes that in the absence of this growth assumption $\varphi \circ f$ may fail to be integrable over $[0, 1]$, and refers the reader to this problem.]

Solution. Throughout, integrability over $[0, 1]$ carries its meaning from Chapter 4: the function is measurable on $[0, 1]$ and its absolute value has finite integral there. The condition in question is

$$|\varphi(x)| \leq c_1 + c_2|x| \quad \text{for all } x \in \mathbb{R}.$$

We call this displayed inequality the growth condition.

Sufficiency of the growth condition. Assume there are constants c_1, c_2 for which the growth condition holds, and let f be integrable over $[0, 1]$. Then f is measurable on $[0, 1]$ and, by Proposition 15 of Chapter 4, finite almost everywhere on $[0, 1]$.

A preliminary reduction is needed because φ is defined only on $\mathbb{R}$, so that $\varphi \circ f$ is a priori defined only where f is finite. Set $Z = \{x \in [0, 1] : |f(x)| = \infty\}$, so $m(Z) = 0$, and define $\tilde{f} = f$ on $[0, 1] \setminus Z$ and $\tilde{f} = 0$ on Z . Then $\tilde{f}$ is real-valued and measurable on $[0, 1]$ and agrees with f except on a set of measure zero, so $\int_0^1 |\tilde{f}| = \int_0^1 |f| < \infty$ and $\tilde{f}$ is integrable over $[0, 1]$; moreover $\varphi \circ \tilde{f}$ agrees with $\varphi \circ f$ at every point at which the latter is defined, hence almost everywhere on $[0, 1]$. Since functions that agree almost everywhere have the same integral, it suffices to prove that $\varphi \circ \tilde{f}$ is integrable over $[0, 1]$. We therefore assume from the outset that f is real-valued on $[0, 1]$.

Since φ is continuous on all of $\mathbb{R}$ and f is a real-valued measurable function on $[0, 1]$, Proposition 7 of Chapter 3 tells us that the composition $\varphi \circ f$ is measurable on $[0, 1]$.

Define $g = c_1 + c_2|f|$ on $[0, 1]$. By the growth condition,

$$|(\varphi \circ f)(x)| = |\varphi(f(x))| \leq c_1 + c_2|f(x)| = g(x) \quad \text{for all } x \in [0, 1],$$

so in particular $g \geq 0$ on $[0, 1]$, since the left-hand side is nonnegative. Moreover $|f|$ is integrable over $[0, 1]$ because f is, and constant functions are integrable over the set $[0, 1]$, which has finite measure; hence, by Theorem 17 of Chapter 4 (Linearity and Monotonicity of Integration), g is integrable over $[0, 1]$ and

$$\int_0^1 g = c_1 + c_2 \int_0^1 |f| < \infty,$$

so g is a nonnegative integrable function on $[0, 1]$ that dominates $|\varphi \circ f|$. By Proposition 16 of Chapter 4 (the Integral Comparison Test), $\varphi \circ f$ is integrable over $[0, 1]$. This is exactly the assertion made in the text's remark following Jensen's Inequality.

Necessity of the growth condition. Now assume that $\varphi \circ f$ is integrable over $[0, 1]$ whenever f is, and suppose, to get a contradiction, that there is no pair of constants c_1, c_2 for which the growth condition holds. Then for each natural number n the particular choice $c_1 = c_2 = n$ fails, that is, there is a point $x_n \in \mathbb{R}$ for which

$$|\varphi(x_n)| > n + n|x_n| = n(1 + |x_n|).$$

Using this sequence $\{x_n\}$ we manufacture an integrable f on $[0, 1]$ whose composition with φ fails to be integrable. For each index n set

$$\alpha_n = \frac{1}{2n^2(1 + |x_n|)} > 0.$$

Since $1 + |x_n| \geq 1$ we have $0 < \alpha_n \leq 1/(2n^2)$, and therefore

$$\sum_{n=1}^{\infty} \alpha_n \leq \frac{1}{2} \sum_{n=1}^{\infty} \frac{1}{n^2} = \frac{\pi^2}{12} < 1.$$

Put $s_0 = 0$ and $s_n = \sum_{k=1}^n \alpha_k$ for $n \geq 1$; then $\{s_n\}$ is strictly increasing and $s_n < 1$ for every n . Define the pairwise disjoint intervals

$$E_n = [s_{n-1}, s_n) \subseteq [0, 1], \quad m(E_n) = \alpha_n,$$

and let $E_0 = [0, 1] \setminus \bigcup_{n=1}^{\infty} E_n$. Define f on $[0, 1]$ by

$$f = \sum_{n=1}^{\infty} x_n \chi_{E_n},$$

that is, $f(t) = x_n$ for $t \in E_n$ and $f(t) = 0$ for $t \in E_0$. Each partial sum $\sum_{n=1}^N x_n \chi_{E_n}$ is a simple function, and since the E_n are disjoint these partial sums converge to f pointwise on $[0, 1]$; hence f is measurable on $[0, 1]$, and it is real-valued.

Claim: f is integrable over $[0, 1]$. The functions $h_N = \sum_{n=1}^N |x_n| \chi_{E_n}$ form an increasing sequence of nonnegative measurable functions converging pointwise on $[0, 1]$ to $|f|$ (at a point of E_m we have $h_N = |x_m| = |f|$ once $N \geq m$, and at a point of E_0 every h_N vanishes, as does f). Each h_N is a nonnegative simple function whose integral is, by definition, $\sum_{n=1}^N |x_n| m(E_n) = \sum_{n=1}^N |x_n| \alpha_n$. Hence by the Monotone Convergence Theorem,

$$\int_0^1 |f| = \lim_{N \rightarrow \infty} \int_0^1 h_N = \lim_{N \rightarrow \infty} \sum_{n=1}^N |x_n| \alpha_n = \sum_{n=1}^{\infty} \frac{|x_n|}{2n^2(1 + |x_n|)}.$$

Since $|x_n| \leq 1 + |x_n|$, each term is at most $1/(2n^2)$, and therefore

$$\int_0^1 |f| \leq \frac{1}{2} \sum_{n=1}^{\infty} \frac{1}{n^2} < \infty.$$

Thus f is integrable over $[0, 1]$.

Claim: $\varphi \circ f$ is not integrable over $[0, 1]$. The function $\varphi \circ f$ is measurable on $[0, 1]$, by Proposition 7 of Chapter 3 again, and it takes the value $\varphi(x_n)$ on E_n and the value $\varphi(0)$ on E_0 . Being nonnegative and measurable, $|\varphi \circ f|$ has a well-defined integral over any measurable subset of $[0, 1]$, with value in $[0, \infty]$. Fix a natural number N and set $A_N = \bigcup_{n=1}^N E_n$, a measurable subset of $[0, 1]$. Applying Theorem 11 of Chapter 4 (Additivity Over Domains of Integration) to the disjoint decomposition $[0, 1] = A_N \cup ([0, 1] \setminus A_N)$, and then to the disjoint decomposition $A_N = E_1 \cup \cdots \cup E_N$, and using that $|\varphi \circ f|$ is the constant $|\varphi(x_n)|$ on E_n so that $\int_{E_n} |\varphi \circ f| = |\varphi(x_n)| m(E_n) = \alpha_n |\varphi(x_n)|$, we obtain

$$\int_0^1 |\varphi \circ f| \geq \int_{A_N} |\varphi \circ f| = \sum_{n=1}^N \alpha_n |\varphi(x_n)|.$$

By the choice of x_n and of α_n ,

$$\alpha_n |\varphi(x_n)| > \frac{1}{2n^2(1+|x_n|)} \cdot n(1+|x_n|) = \frac{1}{2n},$$

and hence

$$\int_0^1 |\varphi \circ f| \geq \sum_{n=1}^N \frac{1}{2n} \quad \text{for every } N.$$

The harmonic series diverges, so letting $N \rightarrow \infty$ gives $\int_0^1 |\varphi \circ f| = \infty$. Therefore $\varphi \circ f$ is not integrable over $[0, 1]$.

The f just constructed is integrable over $[0, 1]$ while $\varphi \circ f$ is not, contradicting the standing hypothesis that $\varphi \circ f$ is integrable over $[0, 1]$ whenever f is. The supposition that no pair of constants satisfies the growth condition is therefore untenable, and there do exist constants c_1 and c_2 for which $|\varphi(x)| \leq c_1 + c_2|x|$ for all $x \in \mathbb{R}$.

It is worth noting in passing that the sequence $\{x_n\}$ produced above is necessarily unbounded: were it contained in some closed, bounded interval, the continuity of φ would make $|\varphi|$ bounded on that interval, whereas $|\varphi(x_n)| > n(1+|x_n|) \geq n$ for every n . This is only a comment on the shape of a counterexample; no use of it was made in the proof, which is valid for any sequence with the stated property.

Remark. Combining the two halves: for a continuous φ on $\mathbb{R}$, the Nemytskii operator $f \mapsto \varphi \circ f$ carries every function integrable over $[0, 1]$ to a function integrable over $[0, 1]$ if and only if φ obeys the linear growth bound $|\varphi(x)| \leq c_1 + c_2|x|$ on $\mathbb{R}$. In particular, in the absence of that growth assumption the function $\varphi \circ f$ appearing in Jensen's Inequality may fail to be integrable, which is the assertion the text makes when it refers the reader here. A concrete instance is $\varphi(x) = x^2$: it is continuous and convex but obeys no bound of the form $c_1 + c_2|x|$, and the construction above (take x_n with $x_n^2 > n(1+|x_n|)$, for instance $x_n = 2n$) produces an f integrable over $[0, 1]$ for which $\varphi \circ f$ is not.

7.1 Problems 7.1–7.7

Problem 7.1. For f in $C[a, b]$, define

$$\|f\|_1 = \int_a^b |f|.$$

Show that this is a norm on $C[a, b]$. Also show that there is no number $c \geq 0$ for which

$$\|f\|_{\max} \leq c\|f\|_1 \quad \text{for all } f \text{ in } C[a, b],$$

but there is a $c \geq 0$ for which

$$\|f\|_1 \leq c\|f\|_{\max} \quad \text{for all } f \text{ in } C[a, b].$$

Solution. Throughout, $[a, b]$ is a nondegenerate closed, bounded interval, so $a < b$.

The functional is well defined and finite. If f is continuous on $[a, b]$, then f is measurable and, attaining a maximum value, bounded; hence $|f|$ is a bounded measurable function on a set of finite measure and $\int_a^b |f|$ is a finite real number.

The Triangle Inequality. Let f, g belong to $C[a, b]$. Then $|f + g| \leq |f| + |g|$ pointwise on $[a, b]$, so by the monotonicity and linearity of integration,

$$\|f + g\|_1 = \int_a^b |f + g| \leq \int_a^b [|f| + |g|] = \int_a^b |f| + \int_a^b |g| = \|f\|_1 + \|g\|_1.$$

Positive Homogeneity. For a real number α , $|\alpha f| = |\alpha| |f|$ pointwise, so by the linearity of integration

$$\|\alpha f\|_1 = \int_a^b |\alpha| |f| = |\alpha| \int_a^b |f| = |\alpha| \|f\|_1.$$

Nonnegativity. Since $|f| \geq 0$, monotonicity of integration gives $\|f\|_1 \geq 0$. Clearly $\|0\|_1 = 0$. Conversely, suppose $\|f\|_1 = 0$ and $f \neq 0$, say $|f(x_0)| = \epsilon > 0$ for some x_0 in $[a, b]$. Since $|f|$ is continuous at x_0 , there is a $\delta > 0$ such that $|f(x)| > \epsilon/2$ for all x in $(x_0 - \delta, x_0 + \delta) \cap [a, b]$. This intersection contains a closed interval $[c, d] \subseteq [a, b]$ with $d - c > 0$ (take a one-sided interval if x_0 is an endpoint). By monotonicity of integration,

$$\|f\|_1 = \int_a^b |f| \geq \int_c^d |f| \geq \frac{\epsilon}{2}(d - c) > 0,$$

a contradiction. Hence $\|f\|_1 = 0$ if and only if $f = 0$. Note that here, in contrast with $L^1[a, b]$, the conclusion is that f vanishes at **every** point, not merely almost everywhere: continuity upgrades “a.e.” to “everywhere”. Thus $\|\cdot\|_1$ is a norm on $C[a, b]$.

There is no $c \geq 0$ with $\|f\|_{\max} \leq c\|f\|_1$ for all f . Choose a natural number N with $1/N < b - a$. For each natural number $n \geq N$ define f_n in $C[a, b]$ by

$$f_n(x) = \begin{cases} n(1 - n(x - a)) & \text{if } a \leq x \leq a + 1/n, \\ 0 & \text{if } a + 1/n < x \leq b. \end{cases}$$

Each f_n is continuous (the two formulas agree, with value 0, at $x = a + 1/n$), nonnegative, and takes its maximum value n at $x = a$; thus $\|f_n\|_{\max} = n$. On the other hand f_n vanishes off $[a, a + 1/n]$ and its graph there is a triangle of base $1/n$ and height n , so

$$\|f_n\|_1 = \int_a^{a+1/n} n(1 - n(x - a)) dx = \frac{1}{2} \cdot \frac{1}{n} \cdot n = \frac{1}{2}.$$

Hence $\|f_n\|_{\max} = n = 2n \cdot \|f_n\|_1$. If there were a $c \geq 0$ with $\|f\|_{\max} \leq c\|f\|_1$ for all f in $C[a, b]$, then $n \leq c/2$ for every $n \geq N$, which is impossible. Therefore no such c exists.

There is a $c \geq 0$ with $\|f\|_1 \leq c\|f\|_{\max}$ for all f . Take $c = b - a$. Indeed, for f in $C[a, b]$ we have $|f(x)| \leq \|f\|_{\max}$ for all x in $[a, b]$, so by the monotonicity of integration,

$$\|f\|_1 = \int_a^b |f| \leq \int_a^b \|f\|_{\max} = (b - a) \|f\|_{\max}.$$

Thus the maximum norm dominates the L^1 norm on $C[a, b]$ up to the constant $b - a$, but the two norms are not equivalent: convergence in $\|\cdot\|_1$ does not imply uniform convergence.

Problem 7.2. Let X be the family of all polynomials with real coefficients defined on $\mathbb{R}$. Show that this is a linear space. For a polynomial p , define $\|p\|$ to be the sum of the absolute values of the coefficients of p . Is this a norm?

Solution. X is a linear space. Let $\mathcal{F}$ denote the linear space of all real-valued functions on $\mathbb{R}$, with the usual pointwise addition and scalar multiplication. Then $X \subseteq \mathcal{F}$, and it suffices to show that X is a linear subspace of $\mathcal{F}$, that is, that X is closed under addition and scalar multiplication and contains the zero function.

The zero function is the polynomial all of whose coefficients are 0, so 0 belongs to X . Let p, q belong to X and let α, β be real numbers. Write

$$p(x) = \sum_{k=0}^n a_k x^k, \quad q(x) = \sum_{k=0}^n b_k x^k,$$

where we have padded the shorter list of coefficients with zeros so that both sums run to the same index n . Then for every real x ,

$$(\alpha p + \beta q)(x) = \alpha p(x) + \beta q(x) = \sum_{k=0}^n (\alpha a_k + \beta b_k) x^k,$$

which is again a polynomial with real coefficients. Hence $\alpha p + \beta q$ belongs to X , and X is a linear space.

Well-definedness of $\|\cdot\|$. The proposed functional is defined in terms of the coefficients, while the elements of X are **functions**; so we must first check that a polynomial function determines its coefficients. Suppose $\sum_{k=0}^n a_k x^k = \sum_{k=0}^n c_k x^k$ for every real x . Then $r(x) = \sum_{k=0}^n (a_k - c_k) x^k$ vanishes identically on $\mathbb{R}$. If some coefficient $a_k - c_k$ were nonzero, r would be a nonzero polynomial of some degree $d \leq n$ and hence would have at most d real roots, contradicting the fact that every real number is a root. Therefore $a_k = c_k$ for all k . Consequently each p in X has a unique coefficient sequence $(a_0, a_1, \dots)$, all but finitely many of whose terms vanish, and

$$\|p\| = \sum_{k \geq 0} |a_k|$$

is an unambiguously defined finite nonnegative real number.

Yes, $\|\cdot\|$ is a norm. Let p and q have coefficient sequences (a_k) and (b_k) , each with only finitely many nonzero terms, and let α be a real number.

The Triangle Inequality: by the computation above, the coefficient sequence of $p + q$ is $(a_k + b_k)$, so using the triangle inequality for real numbers termwise,

$$\|p + q\| = \sum_{k \geq 0} |a_k + b_k| \leq \sum_{k \geq 0} [|a_k| + |b_k|] = \sum_{k \geq 0} |a_k| + \sum_{k \geq 0} |b_k| = \|p\| + \|q\|.$$

(All sums have only finitely many nonzero terms, so these manipulations are finite sums.)

Positive Homogeneity: the coefficient sequence of αp is (αa_k) , so

$$\|\alpha p\| = \sum_{k \geq 0} |\alpha a_k| = |\alpha| \sum_{k \geq 0} |a_k| = |\alpha| \|p\|.$$

Nonnegativity: $\|p\| \geq 0$ as a sum of nonnegative numbers, and $\|p\| = 0$ if and only if $|a_k| = 0$ for every k , that is, if and only if every coefficient of p vanishes, which by the uniqueness of coefficients just established holds if and only if p is the zero function.

Hence $\|\cdot\|$ is a norm on X , and X with this norm is a normed linear space.

Two remarks. First, the uniqueness of coefficients is essential: had we taken X to be the polynomial functions on a finite set, or on an interval-free domain such as a single point, distinct coefficient lists could give the same function and $\|\cdot\|$ would not even be well defined. Second, this norm is genuinely different from, say, $\|p\|_{\max}$ on a bounded interval; identifying X with the space of finitely supported real sequences, $\|\cdot\|$ is exactly the restriction of the ℓ^1 norm.

Problem 7.3. For f in $L^1[a, b]$, define $\|f\| = \int_a^b x^2 |f(x)| dx$. Show that this is a norm on $L^1[a, b]$.

Solution. Recall that $L^1[a, b]$ is the linear space of (equivalence classes of) integrable functions on $[a, b]$, two functions being identified when they agree almost everywhere.

The functional is well defined and finite. Set $M = \max\{a^2, b^2\}$, so that $0 \leq x^2 \leq M$ for all x in $[a, b]$. If f belongs to $L^1[a, b]$ then $x \mapsto x^2 |f(x)|$ is a nonnegative measurable function on $[a, b]$, and by the monotonicity and linearity of integration

$$0 \leq \int_a^b x^2 |f(x)| dx \leq M \int_a^b |f| = M \|f\|_1 < \infty.$$

So $\|f\|$ is a finite nonnegative real number. Moreover, if $f = g$ a.e. on $[a, b]$ then $x^2 |f(x)| = x^2 |g(x)|$ a.e. on $[a, b]$, so the two have the same integral; hence $\|\cdot\|$ is constant on equivalence classes and is a genuine functional on $L^1[a, b]$.

The Triangle Inequality. Let f, g belong to $L^1[a, b]$. Since f and g are integrable, they are finite a.e. on $[a, b]$, and at each point where both are finite the triangle inequality for real numbers gives $|f(x) + g(x)| \leq |f(x)| + |g(x)|$. Multiplying by the nonnegative number x^2 ,

$$x^2 |f(x) + g(x)| \leq x^2 |f(x)| + x^2 |g(x)| \quad \text{for almost all } x \text{ in } [a, b].$$

Hence, by the monotonicity and linearity of integration,

$$\|f + g\| = \int_a^b x^2 |f + g| \leq \int_a^b x^2 |f| + \int_a^b x^2 |g| = \|f\| + \|g\|.$$

Positive Homogeneity. For a real number α we have $x^2 |\alpha f(x)| = |\alpha| x^2 |f(x)|$ for all x , so by the linearity of integration

$$\|\alpha f\| = \int_a^b |\alpha| x^2 |f| = |\alpha| \int_a^b x^2 |f| = |\alpha| \|f\|.$$

Nonnegativity. We have already observed $\|f\| \geq 0$, and plainly $\|0\| = 0$. Conversely suppose $\|f\| = 0$. The function $h(x) = x^2 |f(x)|$ is nonnegative and integrable over $[a, b]$ with $\int_a^b h = 0$; therefore, by Proposition 9 of Chapter 4, $h = 0$ a.e. on $[a, b]$. Let $Z = \{x \in [a, b] : h(x) \neq 0\}$, so $m(Z) = 0$. If x belongs to $[a, b] \sim (Z \cup \{0\})$, then $x \neq 0$, so $x^2 > 0$, and $x^2 |f(x)| = 0$ forces $f(x) = 0$. Since $m(Z \cup \{0\}) \leq m(Z) + m(\{0\}) = 0$, we conclude that $f = 0$ a.e. on $[a, b]$, that is, f is the zero element of $L^1[a, b]$.

Note that this last step is where the choice of weight matters: the weight x^2 is allowed to vanish, but only on the single point $x = 0$, a set of measure zero, so no nonzero element of $L^1[a, b]$ is annihilated. (The same argument works for any measurable weight $w \geq 0$ that is bounded on $[a, b]$ and satisfies $m(\{x : w(x) = 0\}) = 0$.)

Therefore $\|\cdot\|$ satisfies the Triangle Inequality, Positive Homogeneity, and Nonnegativity, and so is a norm on $L^1[a, b]$.

Problem 7.4. For f in $L^\infty[a, b]$, show that

$$\|f\|_\infty = \min \left\{ M \mid m\{x \in [a, b] \mid |f(x)| > M\} = 0 \right\}$$

and if, furthermore, f is continuous on $[a, b]$, that

$$\|f\|_\infty = \|f\|_{\max}.$$

Solution. Recall the definitions. A function f is essentially bounded on E provided there is some $M \geq 0$, called an essential upper bound for f , for which $|f(x)| \leq M$ for almost all x in E ; and $\|f\|_\infty$ is defined to be the infimum of the essential upper bounds for f . As usual $a < b$.

Put

$$S = \left\{ M \in \mathbb{R} \mid m\{x \in [a, b] : |f(x)| > M\} = 0 \right\}.$$

Each set $\{x \in [a, b] : |f(x)| > M\}$ is measurable because f is measurable, so the condition makes sense. Step 1: S is exactly the set of essential upper bounds for f . Indeed, the statement “ $|f(x)| \leq M$ for almost all x in $[a, b]$ ” says precisely that the set of x in $[a, b]$ at which the inequality fails, namely $\{x \in [a, b] : |f(x)| > M\}$, has measure zero. Moreover every member of S is automatically nonnegative: if $M < 0$ then $\{x \in [a, b] : |f(x)| > M\} = [a, b]$, which has measure $b - a > 0$, so M is not in S . Hence S is the set of essential upper bounds for f , and by definition

$$\|f\|_\infty = \inf S.$$

Since f belongs to $L^\infty[a, b]$, S is nonempty; and S is bounded below by 0, so this infimum is a finite nonnegative number.

Step 2: the infimum is attained, that is, $\|f\|_\infty$ itself belongs to S . Let n be a natural number. Since $\|f\|_\infty = \inf S$ and $\|f\|_\infty + 1/n > \|f\|_\infty$, there is an M_n in S with $M_n < \|f\|_\infty + 1/n$. Define

$$E_n = \{x \in [a, b] : |f(x)| > M_n\},$$

so that $m(E_n) = 0$ and $|f(x)| \leq M_n \leq \|f\|_\infty + 1/n$ for all x in $[a, b] \setminus E_n$. Set $E_\infty = \bigcup_{n=1}^\infty E_n$. By the countable subadditivity of Lebesgue measure, $m(E_\infty) = 0$. If x belongs to $[a, b] \setminus E_\infty$, then for every natural number n we have $|f(x)| \leq \|f\|_\infty + 1/n$, and letting $n \rightarrow \infty$ gives $|f(x)| \leq \|f\|_\infty$. Therefore

$$\{x \in [a, b] : |f(x)| > \|f\|_\infty\} \subseteq E_\infty,$$

and by the monotonicity of measure this set has measure zero. Hence $\|f\|_\infty$ belongs to S . Being a lower bound for S that lies in S , it is the minimum of S :

$$\|f\|_\infty = \min S = \min \left\{ M \mid m\{x \in [a, b] : |f(x)| > M\} = 0 \right\}.$$

Equivalently: the essential supremum of f is itself an essential upper bound for f , that is, the smallest essential upper bound.

Step 3: if f is continuous on $[a, b]$, then $\|f\|_\infty = \|f\|_{\max}$. Here $\|f\|_{\max} = \max_{x \in [a, b]} |f(x)|$, which exists since $|f|$ is continuous on the closed, bounded interval $[a, b]$ and therefore attains a maximum value.

First, $|f(x)| \leq \|f\|_{\max}$ for **every** x in $[a, b]$, so a fortiori for almost every x ; thus $\|f\|_{\max}$ belongs to S , and since $\|f\|_\infty = \min S$,

$$\|f\|_\infty \leq \|f\|_{\max}.$$

For the reverse inequality, suppose to the contrary that $\|f\|_\infty < \|f\|_{\max}$ and set $\epsilon = \|f\|_{\max} - \|f\|_\infty > 0$. Choose x_0 in $[a, b]$ with $|f(x_0)| = \|f\|_{\max}$. Since $|f|$ is continuous at x_0 , there is a $\delta > 0$ such that

$$|f(x)| > |f(x_0)| - \frac{\epsilon}{2} = \|f\|_\infty + \frac{\epsilon}{2} > \|f\|_\infty \quad \text{for all } x \text{ in } (x_0 - \delta, x_0 + \delta) \cap [a, b].$$

Because $a < b$ and x_0 belongs to $[a, b]$, the set $(x_0 - \delta, x_0 + \delta) \cap [a, b]$ contains an interval of positive length and so has positive measure. But this set is contained in $\{x \in [a, b] : |f(x)| > \|f\|_\infty\}$, which by Step 2 has measure zero. This contradiction shows $\|f\|_{\max} \leq \|f\|_\infty$.

Combining the two inequalities, $\|f\|_\infty = \|f\|_{\max}$ for continuous f . (As the text observes, an element of $L^\infty[a, b]$ has at most one continuous representative, so this identifies the L^∞ norm with the maximum norm on the copy of $C[a, b]$ sitting inside $L^\infty[a, b]$.)

Problem 7.5. Show that ℓ^∞ and ℓ^1 are normed linear spaces.

Solution. Recall the definitions from the text: ℓ^∞ is the collection of bounded real sequences $a = (a_1, a_2, \dots)$ with

$$\|a\|_\infty = \sup_{1 \leq k < \infty} |a_k|,$$

and ℓ^1 is the collection of real sequences for which $\sum_{k=1}^\infty |a_k| < \infty$, with

$$\|a\|_1 = \sum_{k=1}^\infty |a_k|.$$

Both sit inside the linear space $\mathcal{S}$ of all real sequences, with coordinatewise addition and scalar multiplication, $(a+b)_k = a_k + b_k$ and $(\alpha a)_k = \alpha a_k$; so in each case it suffices to check that the collection is a linear subspace of $\mathcal{S}$ and that the proposed functional satisfies the three defining properties of a norm.

The space ℓ^∞ . Let a, b belong to ℓ^∞ and let α be a real number. For each index k ,

$$|a_k + b_k| \leq |a_k| + |b_k| \leq \|a\|_\infty + \|b\|_\infty,$$

so $a+b$ is a bounded sequence, and $\|a\|_\infty + \|b\|_\infty$ is an upper bound for the set $\{|a_k + b_k| : k \geq 1\}$. Since the supremum is the least upper bound,

$$\|a+b\|_\infty \leq \|a\|_\infty + \|b\|_\infty.$$

Also $|\alpha a_k| = |\alpha| |a_k| \leq |\alpha| \|a\|_\infty$ for each k , so αa is bounded. Thus ℓ^∞ is closed under linear combinations, and it contains the zero sequence, so it is a linear space.

For positive homogeneity, if $\alpha = 0$ then $\|\alpha a\|_\infty = 0 = |\alpha| \|a\|_\infty$. If $\alpha \neq 0$, then multiplication by the positive number $|\alpha|$ is an increasing bijection of $[0, \infty)$ onto itself, so

$$\|\alpha a\|_\infty = \sup_k |\alpha| |a_k| = |\alpha| \sup_k |a_k| = |\alpha| \|a\|_\infty.$$

(Concretely: $|\alpha| \|a\|_\infty$ is an upper bound for $\{|\alpha a_k|\}$; and if c is any upper bound for $\{|\alpha a_k|\}$, then $c/|\alpha|$ is an upper bound for $\{|a_k|\}$, so $c/|\alpha| \geq \|a\|_\infty$, that is, $c \geq |\alpha| \|a\|_\infty$.)

Finally $\|a\|_\infty \geq 0$ since it is a supremum of nonnegative numbers, and $\|a\|_\infty = 0$ if and only if $|a_k| \leq 0$ for every k , that is, if and only if $a_k = 0$ for every k , that is, if and only if a is the zero sequence. Hence ℓ^∞ is a normed linear space.

The space ℓ^1 . Let a, b belong to ℓ^1 and let α be a real number. For each natural number n , using the triangle inequality for real numbers termwise and then the fact that the full series have nonnegative terms,

$$\sum_{k=1}^n |a_k + b_k| \leq \sum_{k=1}^n |a_k| + \sum_{k=1}^n |b_k| \leq \|a\|_1 + \|b\|_1.$$

The partial sums of $\sum_{k=1}^\infty |a_k + b_k|$ form an increasing sequence bounded above by $\|a\|_1 + \|b\|_1$, hence converge to a finite limit that is at most this bound. Therefore $a+b$ belongs to ℓ^1 and

$$\|a+b\|_1 = \sum_{k=1}^\infty |a_k + b_k| \leq \|a\|_1 + \|b\|_1,$$

which is the Triangle Inequality. Likewise $\sum_{k=1}^n |\alpha a_k| = |\alpha| \sum_{k=1}^n |a_k| \leq |\alpha| \|a\|_1$ for every n , so αa belongs to ℓ^1 , and letting $n \rightarrow \infty$ in the identity $\sum_{k=1}^n |\alpha a_k| = |\alpha| \sum_{k=1}^n |a_k|$ gives

$$\|\alpha a\|_1 = |\alpha| \|a\|_1.$$

Since ℓ^1 contains the zero sequence and is closed under these two operations, it is a linear space.

For nonnegativity, $\|a\|_1$ is the limit of an increasing sequence of nonnegative partial sums, so $\|a\|_1 \geq 0$; and if $\|a\|_1 = 0$, then for each fixed k we have $|a_k| \leq \sum_{j=1}^\infty |a_j| = 0$, so $a_k = 0$. Thus $\|a\|_1 = 0$ if and only if a is the zero sequence. Hence ℓ^1 is a normed linear space.

Problem 7.6. Show that if Hölder's Inequality is true for normalized functions it is true in general.

Solution. Fix a measurable set E , a number p with $1 \leq p < \infty$, and let q be the conjugate of p . Hölder's Inequality (Theorem 1) asserts that if f belongs to $L^p(E)$ and g belongs to $L^q(E)$, then $f \cdot g$ is integrable over E and

$$\int_E |f \cdot g| \leq \|f\|_p \cdot \|g\|_q.$$

Recall that a function h in a normed linear space is called normalized, or a unit function, provided $\|h\| = 1$. So we assume the following.

Hypothesis. If f belongs to $L^p(E)$ with $\|f\|_p = 1$ and g belongs to $L^q(E)$ with $\|g\|_q = 1$, then $f \cdot g$ is integrable over E and $\int_E |f \cdot g| \leq 1$.

We must deduce the general inequality. Let f in $L^p(E)$ and g in $L^q(E)$ be arbitrary.

Two preliminary observations. First, $\|\cdot\|_p$ is positively homogeneous: for a real number α and h in $L^p(E)$, $|\alpha h|^p = |\alpha|^p |h|^p$, so by the linearity of integration

$$\|\alpha h\|_p = \left[\int_E |\alpha h|^p \right]^{1/p} = \left[|\alpha|^p \int_E |h|^p \right]^{1/p} = |\alpha| \left[\int_E |h|^p \right]^{1/p} = |\alpha| \|h\|_p,$$

and the same computation applies to $\|\cdot\|_q$ when $q < \infty$. (When the index is ∞ – which happens for q when $p = 1$ – positive homogeneity of $\|\cdot\|_\infty$ was verified in Section 7.1.) Second, for a finite index r , $\|h\|_r = 0$ if and only if $h = 0$ a.e. on E : this is Proposition 9 of Chapter 4 applied to the nonnegative integrable function $|h|^r$, whose integral vanishes exactly when $|h|^r = 0$ a.e. The same equivalence holds for the index ∞ : by the inequality (2) of Section 7.1, $|h| \leq \|h\|_\infty$ a.e. on E , so $\|h\|_\infty = 0$ forces $h = 0$ a.e.; and conversely if $h = 0$ a.e. then every $M \geq 0$ is an essential upper bound for h , so $\|h\|_\infty = 0$.

The degenerate cases. Suppose $\|f\|_p = 0$. Then $f = 0$ a.e. on E , hence $f \cdot g = 0$ a.e. on E ; so $f \cdot g$ is integrable over E with $\int_E |f \cdot g| = 0$, and the asserted inequality holds, indeed with equality, since $\|f\|_p \|g\|_q = 0$. The case $\|g\|_q = 0$ is identical. (Note $\|f\|_p$ and $\|g\|_q$ are finite, since f and g belong to $L^p(E)$ and $L^q(E)$ respectively.)

The general case. Assume now $\|f\|_p > 0$ and $\|g\|_q > 0$, and form the normalizations

$$f^\# = \frac{f}{\|f\|_p}, \quad g^\# = \frac{g}{\|g\|_q}.$$

These are scalar multiples of f and g , hence belong to $L^p(E)$ and $L^q(E)$ respectively, and by positive homogeneity

$$\|f^\#\|_p = \frac{1}{\|f\|_p} \|f\|_p = 1, \quad \|g^\#\|_q = \frac{1}{\|g\|_q} \|g\|_q = 1.$$

So $f^\#$ and $g^\#$ are normalized, and the Hypothesis applies to them: $f^\# \cdot g^\#$ is integrable over E and

$$\int_E |f^\# \cdot g^\#| \leq 1.$$

But pointwise on E ,

$$f \cdot g = (\|f\|_p f^\#) \cdot (\|g\|_q g^\#) = \|f\|_p \|g\|_q (f^\# \cdot g^\#),$$

a constant multiple of an integrable function. Hence $f \cdot g$ is integrable over E , and by the linearity of integration together with $|f \cdot g| = \|f\|_p \|g\|_q |f^\# \cdot g^\#|$,

$$\int_E |f \cdot g| = \|f\|_p \|g\|_q \int_E |f^\# \cdot g^\#| \leq \|f\|_p \cdot \|g\|_q.$$

This is exactly Hölder's Inequality for the arbitrary pair f, g . Therefore it suffices to prove the inequality for normalized functions, which is the reduction used in the text's proof of Theorem 1: one there assumes $\int_E |f|^p = 1$ and $\int_E |g|^q = 1$ and shows $\int_E |f \cdot g| \leq 1$.

Problem 7.7. Verify the assertions in the above two examples regarding the membership of the function f in $L^p(E)$.

[The two examples are: (i) for E of finite measure and $1 \leq p_1 < p_2 \leq \infty$, $L^{p_2}(E)$ is in general a proper subspace of $L^{p_1}(E)$ – for instance, let $E = (0, 1]$ and let f be defined by $f(x) = x^\alpha$ for $0 < x \leq 1$, where $-1/p_1 < \alpha < -1/p_2$; then f belongs to $L^{p_1}(E) \sim L^{p_2}(E)$. (ii) for E of infinite measure there are in general no inclusion relationships among the $L^p(E)$ spaces – for instance, for $E = (1, \infty)$ and f defined by

$$f(x) = \frac{x^{-1/2}}{1 + \ln x} \quad \text{for } x > 1,$$

f belongs to $L^p(E)$ if and only if $p = 2$.]

Solution. A computational lemma. For β a real number,

$$\int_{(0,1]} x^\beta dx = \begin{cases} \frac{1}{\beta+1} & \text{if } \beta > -1, \\ \infty & \text{if } \beta \leq -1, \end{cases} \quad \int_{(1,\infty)} x^\beta dx = \begin{cases} \frac{-1}{\beta+1} & \text{if } \beta < -1, \\ \infty & \text{if } \beta \geq -1. \end{cases}$$

To justify the first, let $g(x) = x^\beta$ on $(0, 1]$ and set $g_n = g \cdot \chi_{[1/n, 1]}$. Then $\{g_n\}$ is an increasing sequence of nonnegative measurable functions converging pointwise on $(0, 1]$ to g , so by the Monotone Convergence Theorem $\int_{(0,1]} g = \lim_n \int_{[1/n, 1]} g$. On $[1/n, 1]$ the function x^β is continuous, hence Riemann integrable, and by Theorem 3 of Chapter 4 its Riemann and Lebesgue integrals agree. For $\beta \neq -1$,

$$\int_{1/n}^1 x^\beta dx = \frac{1 - n^{-(\beta+1)}}{\beta+1},$$

which tends to $1/(\beta+1)$ if $\beta > -1$ (since then $n^{-(\beta+1)} \rightarrow 0$) and to ∞ if $\beta < -1$ (since then $n^{-(\beta+1)} \rightarrow \infty$ while $\beta+1 < 0$). For $\beta = -1$, $\int_{1/n}^1 x^{-1} dx = \ln n \rightarrow \infty$. The second formula is proved in the same way, with $g_n = g \cdot \chi_{(1, n]}$ and $\int_1^n x^\beta dx = (n^{\beta+1} - 1)/(\beta+1)$ for $\beta \neq -1$ and $\ln n$ for $\beta = -1$. Example (i). Let $E = (0, 1]$, let $1 \leq p_1 < p_2 \leq \infty$, and choose α with $-1/p_1 < \alpha < -1/p_2$, where $-1/p_2$ is read as 0 when $p_2 = \infty$. Such an α exists because $p_1 < p_2$ forces $-1/p_1 < -1/p_2$. Put $f(x) = x^\alpha$ for $0 < x \leq 1$; f is continuous and positive on E , hence measurable, and $\alpha < 0$.

f belongs to $L^{p_1}(E)$. Since $p_1 < \infty$, we must check $\int_E |f|^{p_1} < \infty$. Here $|f(x)|^{p_1} = x^{\alpha p_1}$, and $\alpha > -1/p_1$ gives $\alpha p_1 > -1$ (multiplying by the positive number p_1). By the lemma,

$$\int_{(0,1]} x^{\alpha p_1} dx = \frac{1}{\alpha p_1 + 1} < \infty.$$

f does not belong to $L^{p_2}(E)$. Suppose first $p_2 < \infty$. Then $\alpha < -1/p_2$ gives $\alpha p_2 < -1$, so by the lemma $\int_{(0,1]} |f|^{p_2} = \int_{(0,1]} x^{\alpha p_2} dx = \infty$, and f is not in $L^{p_2}(E)$. Now suppose $p_2 = \infty$, so that $\alpha < 0$. Let $M > 0$. Since $\alpha < 0$, $x^\alpha > M$ exactly when $x < M^{1/\alpha}$; hence

$$\{x \in (0, 1] : |f(x)| > M\} \supseteq (0, \min\{1, M^{1/\alpha}\}),$$

a set of positive measure. So no M is an essential upper bound for f , and f is not essentially bounded, that is, f is not in $L^\infty(E)$.

Thus f belongs to $L^{p_1}(E) \sim L^{p_2}(E)$, and the inclusion $L^{p_2}(E) \subseteq L^{p_1}(E)$ furnished by Corollary 3 is proper.

Example (ii). Let $E = (1, \infty)$ and $f(x) = x^{-1/2}/(1 + \ln x)$ for $x > 1$. On E we have $\ln x > 0$, so $1 + \ln x > 1$ and f is a well-defined, positive, continuous, hence measurable function, with

$$|f(x)|^p = \frac{x^{-p/2}}{(1 + \ln x)^p} \quad \text{for } 1 \leq p < \infty.$$

f belongs to $L^2(E)$. Here $|f(x)|^2 = 1/(x(1 + \ln x)^2)$. The function $F(x) = -1/(1 + \ln x)$ is continuously differentiable on $[1, n]$ with $F'(x) = 1/(x(1 + \ln x)^2)$, so by the Monotone Convergence Theorem (applied

to $|f|^2 \chi_{(1,n]}$ together with Theorem 3 of Chapter 4,

$$\int_{(1,\infty)} |f|^2 = \lim_{n \rightarrow \infty} \int_1^n \frac{dx}{x(1+\ln x)^2} = \lim_{n \rightarrow \infty} \left[1 - \frac{1}{1+\ln n} \right] = 1 < \infty.$$

f does not belong to $L^p(E)$ for $1 \leq p < 2$. Put $\delta = 1 - p/2 > 0$. Substituting $t = \ln x$,

$$\frac{x^\delta}{(1+\ln x)^p} = \frac{e^{\delta t}}{(1+t)^p} \rightarrow \infty \quad \text{as } t \rightarrow \infty,$$

since an exponential with positive exponent grows faster than any power. Hence there is an $X > 1$ with $x^\delta \geq (1+\ln x)^p$ for all $x \geq X$, and for such x ,

$$|f(x)|^p = \frac{x^{-p/2}}{(1+\ln x)^p} \geq \frac{x^{-p/2}}{x^\delta} = x^{-p/2-1+p/2} = \frac{1}{x}.$$

By the monotonicity of integration and the lemma, $\int_{(1,\infty)} |f|^p \geq \int_{(X,\infty)} x^{-1} dx = \infty$. So f is not in $L^p(E)$.

A correction to the printed assertion. The example as printed claims that f belongs to $L^p(E)$ if and only if $p = 2$; the “only if” half fails for $p > 2$. Indeed, let $2 < p < \infty$. Since $1 + \ln x > 1$ on E , we have $(1 + \ln x)^p > 1$, so $|f(x)|^p \leq x^{-p/2}$, and $-p/2 < -1$, so by the lemma

$$\int_{(1,\infty)} |f|^p \leq \int_{(1,\infty)} x^{-p/2} dx = \frac{1}{p/2 - 1} < \infty.$$

Moreover f is bounded on E : for $x > 1$, $x^{-1/2} < 1$ and $1 + \ln x > 1$, so $0 < f(x) < 1$, and f belongs to $L^\infty(E)$ with $\|f\|_\infty \leq 1$. Hence the correct statement is

$$f \in L^p((1, \infty)) \iff 2 \leq p \leq \infty.$$

This still serves the purpose of the example, since it exhibits a function in $L^2(E) \sim L^1(E)$ and so shows that $L^{p_1}(E) \supseteq L^{p_2}(E)$ can fail for $p_1 < p_2$ when $m(E) = \infty$.

The repaired example. To get membership exactly at $p = 2$, take $E = (0, \infty)$ and

$$h(x) = \frac{x^{-1/2}}{1 + |\ln x|} \quad \text{for } x > 0,$$

which is continuous and positive on $(0, \infty)$, hence measurable. On $(1, \infty)$ we have $|\ln x| = \ln x$, so h agrees there with the f above and, by what we proved, $\int_{(1,\infty)} |h|^p < \infty$ if and only if $p \geq 2$ (and h is bounded on $(1, \infty)$). On $(0, 1)$ we have $|\ln x| = -\ln x$, so $|h|^2 = 1/(x(1 - \ln x)^2)$ has antiderivative $1/(1 - \ln x)$, and $\int_{1/n}^1 |h|^2 = 1 - 1/(1 + \ln n) \rightarrow 1$, so $\int_{(0,1)} |h|^2 < \infty$; while for $p > 2$, writing $\delta = p/2 - 1 > 0$ we have $x^{-\delta} \geq (1 - \ln x)^p$ for all sufficiently small $x > 0$ (again exponential beats power, via $t = -\ln x \rightarrow \infty$), whence $|h(x)|^p \geq x^{-p/2} x^\delta = 1/x$ there, and $\int_{(0,1)} x^{-1} dx = \infty$. Finally h is not in $L^\infty((0, \infty))$: for $0 < x < 1$, $h(x) = x^{-1/2}/(1 - \ln x)$ and, with $t = -\ln x$, this equals $e^{t/2}/(1+t) \rightarrow \infty$ as $t \rightarrow \infty$, so h exceeds any given M on a set of positive measure. Thus

$$h \in L^p((0, \infty)) \iff p = 2,$$

because failure at $p < 2$ comes from the tail at ∞ and failure at $p > 2$ from the singularity at 0. The same construction works at any exponent: for $1 \leq r < \infty$ set

$$h_r(x) = \frac{x^{-1/r}}{(1 + |\ln x|)^{2/r}} \quad \text{for } x > 0,$$

so that $|h_r(x)|^r = x^{-1}(1 + |\ln x|)^{-2}$, whose integral over $(0, \infty)$ equals $2 \int_0^\infty (1+t)^{-2} dt = 2$ after the substitutions $t = \ln x$ on $(1, \infty)$ and $t = -\ln x$ on $(0, 1)$; while for $p < r$ the integral of $|h_r|^p = x^{-p/r}(1 + |\ln x|)^{-2p/r}$ diverges at ∞ (compare with $1/x$ exactly as above, using $p/r < 1$), and for $p > r$ it diverges at 0; and h_r is unbounded near 0, so it is not in L^∞ . Thus h_r belongs to $L^p((0, \infty))$ precisely when $p = r$. Finally, the constant function 1 belongs to $L^\infty((0, \infty))$ but to no $L^p((0, \infty))$ with $p < \infty$. Hence for any $p_1 \neq p_2$ in $[1, \infty]$ there is a function in $L^{p_1}((0, \infty)) \sim L^{p_2}((0, \infty))$: on a set of infinite measure there are indeed no inclusion relationships among the L^p spaces.

7.2 Problems 7.8–7.14

Problem 7.8. Let f and g belong to $L^2(E)$. From the linearity of integration show that for any number λ ,

$$\lambda^2 \int_E f^2 + 2\lambda \int_E f \cdot g + \int_E g^2 = \int_E (\lambda f + g)^2 \geq 0.$$

From this and the quadratic formula directly derive the Cauchy-Schwarz Inequality.

Solution. Recall that f belongs to $L^2(E)$ means that f is measurable on E and f^2 is integrable over E .

Step 1: the product $f \cdot g$ is integrable. Since the nonnegative functions f^2 and g^2 are integrable over E , Proposition 13 of Chapter 4 tells us that f^2 and g^2 , and hence f and g , are finite a.e. on E . All the pointwise identities below are therefore valid a.e. on E , and that suffices, since by the excision property of integration a set of measure zero affects no integral. Moreover $f \cdot g$ is measurable, by Theorem 6 of Chapter 3. For a.e. x in E ,

$$|f(x)g(x)| \leq \frac{1}{2}(f^2(x) + g^2(x)),$$

since $0 \leq (|f(x)| - |g(x)|)^2$. The right-hand side is integrable over E , being one half of the sum of two integrable functions, so by the integral comparison test $f \cdot g$ is integrable over E . In particular all three numbers

$$A = \int_E f^2, \quad B = \int_E f \cdot g, \quad C = \int_E g^2$$

are finite, and $A \geq 0$, $C \geq 0$.

Step 2: the identity. Fix a real number λ . At a.e. point of E (namely wherever f and g are finite),

$$(\lambda f + g)^2 = \lambda^2 f^2 + 2\lambda f \cdot g + g^2.$$

Each of the three functions on the right is integrable over E , so their linear combination is integrable and, by the linearity of integration,

$$\int_E (\lambda f + g)^2 = \lambda^2 \int_E f^2 + 2\lambda \int_E f \cdot g + \int_E g^2 = A\lambda^2 + 2B\lambda + C.$$

Moreover $(\lambda f + g)^2 \geq 0$ on E , so by the monotonicity of integration $\int_E (\lambda f + g)^2 \geq 0$. Therefore

$$p(\lambda) := A\lambda^2 + 2B\lambda + C \geq 0 \quad \text{for every real } \lambda.$$

Step 3: the quadratic formula. Suppose first $A > 0$. Then p is a genuine quadratic with real coefficients whose roots are, by the quadratic formula,

$$\lambda_{\pm} = \frac{-2B \pm \sqrt{4B^2 - 4AC}}{2A}.$$

If $B^2 - AC > 0$ these are two distinct real numbers, and since $A > 0$ the parabola p is strictly negative at every λ strictly between them, contradicting $p \geq 0$. Hence

$$B^2 \leq AC, \quad \text{that is} \quad \left| \int_E f \cdot g \right| \leq \sqrt{\int_E f^2} \cdot \sqrt{\int_E g^2}. \quad (*)$$

If $A = 0$, then f^2 is a nonnegative function with zero integral, so by Proposition 9 of Chapter 4, $f^2 = 0$ a.e. on E ; thus $f = 0$ a.e. on E , hence $f \cdot g = 0$ a.e. on E and $B = 0$. Thus $(*)$ holds trivially in this case as well. The same argument covers $C = 0$. Therefore $(*)$ holds for all f, g in $L^2(E)$.

Step 4: the Cauchy-Schwarz Inequality. The functions $|f|$ and $|g|$ are measurable and $|f|^2 = f^2$, $|g|^2 = g^2$ are integrable, so $|f|$ and $|g|$ also belong to $L^2(E)$. Applying $(*)$ to the pair $|f|, |g|$ and noting $\int_E |f| \cdot |g| = \int_E |f \cdot g|$ because the integrand is nonnegative, we obtain

$$\int_E |f \cdot g| \leq \sqrt{\int_E f^2} \cdot \sqrt{\int_E g^2},$$

which is the Cauchy-Schwarz Inequality. (Step 1 already showed that $f \cdot g$ is integrable over E , which is the other assertion of that theorem.)

Problem 7.9. Show that in Young's Inequality there is equality if and only if $a = b = 1$.

Solution. Throughout, $1 < p < \infty$, $q = p/(p-1)$ is the conjugate of p , and a, b are positive numbers. Young's Inequality asserts

$$ab \leq \frac{a^p}{p} + \frac{b^q}{q}.$$

We first determine exactly when equality holds, then comment on the assertion as printed.

Sharpening the proof of Young's Inequality. Let $g(x) = \frac{1}{p}x^p + \frac{1}{q} - x$ for $x > 0$, the function used in the book's proof. Then

$$g'(x) = x^{p-1} - 1,$$

which is negative for $0 < x < 1$ and positive for $x > 1$, since $p-1 > 0$ so $x \mapsto x^{p-1}$ is strictly increasing on $(0, \infty)$ and takes the value 1 at $x = 1$. Hence g is strictly decreasing on $(0, 1]$ and strictly increasing on $[1, \infty)$, so g attains its minimum on $(0, \infty)$ at the single point $x = 1$. Since $g(1) = \frac{1}{p} + \frac{1}{q} - 1 = 0$, we conclude

$$x \leq \frac{1}{p}x^p + \frac{1}{q} \quad \text{for all } x > 0, \quad \text{with equality if and only if } x = 1. \quad (6)$$

Transfer to Young's Inequality. Because $p(q-1) = q$, we have $b^{p(q-1)} = b^q$. Dividing each side of Young's Inequality by the positive number b^q and putting

$$x_0 = \frac{a}{b^{q-1}} > 0$$

gives the equivalent statement

$$\frac{ab}{b^q} = \frac{a}{b^{q-1}} = x_0 \leq \frac{a^p}{p b^{p(q-1)}} + \frac{b^q}{q b^q} = \frac{x_0^p}{p} + \frac{1}{q},$$

which is exactly (6) evaluated at x_0 . Since dividing by the positive number b^q preserves equality as well as inequality, we conclude from (6):

$$ab = \frac{a^p}{p} + \frac{b^q}{q} \iff x_0 = 1 \iff a = b^{q-1} \iff a^p = b^{p(q-1)} = b^q.$$

Thus equality holds in Young's Inequality if and only if

$$a^p = b^q.$$

Relation to the printed assertion. If $a = b = 1$ then $a^p = 1 = b^q$, so equality does indeed hold; this is the easy half of the printed claim, and it is correct. The converse as printed is a misprint: the correct condition is $a^p = b^q$, which does not force $a = b = 1$. For example, when $p = q = 2$ Young's Inequality reads $ab \leq (a^2 + b^2)/2$, and there is equality for every pair with $a = b$, say $a = b = 3$. More generally, for any p and any $a > 0$ the number $b = a^{p/q}$ produces equality.

The printed statement becomes true if one asks for equality for all conjugate pairs at once. Suppose $a, b > 0$ and $a^p = b^q$ holds for every $p \in (1, \infty)$ with $q = p/(p-1)$. Letting $p \rightarrow \infty$, we have $q \rightarrow 1$, so $b^q \rightarrow b$, a finite positive number. If $a > 1$ then $a^p \rightarrow \infty$, and if $a < 1$ then $a^p \rightarrow 0$; neither limit can equal the positive finite number b . Hence $a = 1$, and then $b^q = a^p = 1$ forces $b = 1$. So $a = b = 1$ is precisely the condition for equality to hold in Young's Inequality simultaneously for all $1 < p < \infty$.

Problem 7.10. Show that in Holder's Inequality there is equality if and only if there are constants

α and β , not both zero, for which

$$\alpha|f|^p = \beta|g|^q \quad \text{a.e. on } E.$$

Solution. Here $1 < p < \infty$, q is the conjugate of p , f belongs to $L^p(E)$ and g belongs to $L^q(E)$; Holder's Inequality is

$$\int_E |f \cdot g| \leq \|f\|_p \|g\|_q. \quad (3)$$

(The exponents p and q appearing in the asserted relation presuppose $1 < p < \infty$, and that is the case we treat.)

A preliminary remark on Young's Inequality. Young's Inequality was stated for positive numbers, but it extends to all $a, b \geq 0$, together with its equality case from Problem 9: if $a, b \geq 0$ then

$$ab \leq \frac{a^p}{p} + \frac{b^q}{q}, \quad \text{with equality if and only if } a^p = b^q. \quad (7)$$

Indeed, for $a, b > 0$ this is Problem 9. If $a = 0$ and $b > 0$, then $ab = 0 < b^q/q$, so the inequality is strict, and correspondingly $a^p = 0 \neq b^q$; symmetrically if $b = 0 < a$. If $a = b = 0$ both sides vanish and $a^p = 0 = b^q$.

Sufficiency. Suppose $\alpha|f|^p = \beta|g|^q$ a.e. on E with α, β not both zero.

If $\alpha = 0$, then $\beta \neq 0$ and $\beta|g|^q = 0$ a.e., so $g = 0$ a.e. on E ; then $f \cdot g = 0$ a.e. and $\|g\|_q = 0$, so both sides of (3) are zero. Symmetrically if $\beta = 0$ then $f = 0$ a.e. and both sides of (3) are zero. If α and β are nonzero and of opposite sign, then $\alpha|f|^p = \beta|g|^q$ forces both sides to be simultaneously ≥ 0 and ≤ 0 , hence $|f|^p = 0$ and $|g|^q = 0$ a.e., and again both sides of (3) vanish.

So assume α, β are nonzero of the same sign; replacing the pair (α, β) by $(-\alpha, -\beta)$ if necessary, we may assume $\alpha > 0$ and $\beta > 0$. Put $c = \alpha/\beta > 0$, so that

$$|g|^q = c|f|^p \quad \text{a.e. on } E.$$

If $f = 0$ a.e. then $g = 0$ a.e. and (3) is an equality $0 = 0$. Otherwise $\|f\|_p > 0$. Since $\frac{1}{p} + \frac{1}{q} = 1$ gives $1 + \frac{p}{q} = p$, we have a.e. on E

$$|f \cdot g| = |f| \cdot (c|f|^p)^{1/q} = c^{1/q}|f|^{1+p/q} = c^{1/q}|f|^p,$$

so, integrating, $\int_E |f \cdot g| = c^{1/q}\|f\|_p^p$. On the other hand $\|g\|_q^q = \int_E |g|^q = c\|f\|_p^p$, whence

$$\|f\|_p \|g\|_q = \|f\|_p (c\|f\|_p^p)^{1/q} = c^{1/q}\|f\|_p^{1+p/q} = c^{1/q}\|f\|_p^p.$$

The two sides agree, so there is equality in (3).

Necessity. Suppose there is equality in (3). If $f = 0$ a.e. on E , take $\alpha = 1, \beta = 0$: then $\alpha|f|^p = 0 = \beta|g|^q$ a.e. Similarly if $g = 0$ a.e., take $\alpha = 0, \beta = 1$. So assume neither, and set

$$A = \|f\|_p > 0, \quad B = \|g\|_q > 0$$

(these are positive because, by Proposition 9 of Chapter 4, $\int_E |f|^p = 0$ would force $f = 0$ a.e.). Define the normalizations

$$F = \frac{|f|}{A}, \quad G = \frac{|g|}{B},$$

so that $\int_E F^p = 1$, $\int_E G^q = 1$, and, by the assumed equality in (3),

$$\int_E F \cdot G = \frac{1}{AB} \int_E |f \cdot g| = \frac{\|f\|_p \|g\|_q}{AB} = 1.$$

By (7) applied pointwise to the nonnegative numbers $F(x), G(x)$ (both are finite a.e. on E , since F^p and G^q are integrable),

$$h := \frac{F^p}{p} + \frac{G^q}{q} - F \cdot G \geq 0 \quad \text{a.e. on } E.$$

The function h is integrable, being a linear combination of integrable functions, and by the linearity of integration

$$\int_E h = \frac{1}{p} \int_E F^p + \frac{1}{q} \int_E G^q - \int_E F \cdot G = \frac{1}{p} + \frac{1}{q} - 1 = 0.$$

A nonnegative integrable function with zero integral vanishes a.e. (Proposition 9 of Chapter 4), so $h = 0$ a.e. on E . By the equality case in (7), this means

$$F^p = G^q \quad \text{a.e. on } E, \quad \text{that is} \quad \frac{|f|^p}{A^p} = \frac{|g|^q}{B^q} \quad \text{a.e. on } E.$$

Therefore

$$\alpha|f|^p = \beta|g|^q \quad \text{a.e. on } E, \quad \alpha = B^q > 0, \quad \beta = A^p > 0,$$

and in particular α, β are not both zero. This completes the proof.

Problem 7.11. For a point $x = (x_1, x_2, \dots, x_n)$ in $\mathbb{R}^n$, define T_x to be the step function on the interval $[1, n+1)$ that takes the value x_k on the interval $[k, k+1)$, for $1 \leq k \leq n$. For $p \geq 1$, define $\|x\|_p = \|T_x\|_p$, the norm of the function T_x in $L^p[1, n+1)$. Show that this defines a norm on $\mathbb{R}^n$. State and prove the Holder and Minkowski Inequalities for this norm.

Solution. Write $I = [1, n+1)$ and $I_k = [k, k+1)$ for $1 \leq k \leq n$, so that I is the disjoint union of the I_k and $m(I_k) = 1$ for each k . Thus

$$T_x = \sum_{k=1}^n x_k \chi_{I_k}$$

is a simple function on I ; it is measurable and bounded on a set of finite measure, so it belongs to $L^p(I)$ for every p with $1 \leq p \leq \infty$, and $\|x\|_p$ is a well-defined finite number.

An explicit formula. For $1 \leq p < \infty$, the function $|T_x|^p = \sum_{k=1}^n |x_k|^p \chi_{I_k}$ is simple, so by the additivity of integration over the disjoint sets I_k ,

$$\|x\|_p^p = \int_I |T_x|^p = \sum_{k=1}^n |x_k|^p m(I_k) = \sum_{k=1}^n |x_k|^p, \quad \text{so} \quad \|x\|_p = \left[\sum_{k=1}^n |x_k|^p \right]^{1/p}.$$

For $p = \infty$: $|T_x| \leq \max_{1 \leq k \leq n} |x_k|$ everywhere on I , and for each k the set where $|T_x| = |x_k|$ has measure $1 > 0$; hence the essential supremum of $|T_x|$ is $\max_{1 \leq k \leq n} |x_k|$ and $\|x\|_\infty = \max_{1 \leq k \leq n} |x_k|$.

The map T is linear and one-to-one. For x, y in $\mathbb{R}^n$ and λ in $\mathbb{R}$, evaluating on each I_k shows

$$T_{x+y} = T_x + T_y \quad \text{and} \quad T_{\lambda x} = \lambda T_x \quad \text{everywhere on } I.$$

Moreover, if $T_x = 0$ a.e. on I , then for each k the constant value x_k of T_x on I_k must be 0, since $m(I_k) = 1 > 0$; hence $x = 0$. So T is one-to-one even after identifying functions that agree a.e.

$\|\cdot\|_p$ is a norm on $\mathbb{R}^n$. Fix p with $1 \leq p \leq \infty$.

(i) Finiteness and nonnegativity are clear from the formulas above.

(ii) If $\|x\|_p = 0$, then $\|T_x\|_p = 0$, so $T_x = 0$ a.e. on I (for $1 \leq p < \infty$ this is Proposition 9 of Chapter 4 applied to the nonnegative function $|T_x|^p$; for $p = \infty$ it is immediate from the definition of the essential supremum). By the injectivity just proved, $x = 0$. Conversely $\|0\|_p = 0$.

(iii) Positive homogeneity: $\|\lambda x\|_p = \|T_{\lambda x}\|_p = \|\lambda T_x\|_p = |\lambda| \|T_x\|_p = |\lambda| \|x\|_p$, using the positive homogeneity of the L^p norm.

(iv) Triangle inequality: by linearity of T and Minkowski's Inequality in $L^p(I)$ (valid for $1 \leq p \leq \infty$),

$$\|x + y\|_p = \|T_{x+y}\|_p = \|T_x + T_y\|_p \leq \|T_x\|_p + \|T_y\|_p = \|x\|_p + \|y\|_p.$$

Hence $\|\cdot\|_p$ is a norm on $\mathbb{R}^n$.

Holder's Inequality in $\mathbb{R}^n$. Let $1 \leq p \leq \infty$ and let q be the conjugate of p . Then for all x, y in $\mathbb{R}^n$,

$$\sum_{k=1}^n |x_k y_k| \leq \|x\|_p \|y\|_q,$$

that is, for $1 < p < \infty$,

$$\sum_{k=1}^n |x_k y_k| \leq \left[\sum_{k=1}^n |x_k|^p \right]^{1/p} \left[\sum_{k=1}^n |y_k|^q \right]^{1/q},$$

while for $p = 1$, $q = \infty$ it reads $\sum_{k=1}^n |x_k y_k| \leq (\sum_{k=1}^n |x_k|) \max_{1 \leq k \leq n} |y_k|$.

Proof. The pointwise product $T_x \cdot T_y$ is the step function on I taking the value $x_k y_k$ on I_k , that is, $T_x \cdot T_y = T_z$ where $z = (x_1 y_1, \dots, x_n y_n)$. Hence, as computed above with $p = 1$,

$$\int_I |T_x \cdot T_y| = \sum_{k=1}^n |x_k y_k|.$$

Since T_x belongs to $L^p(I)$ and T_y belongs to $L^q(I)$, Theorem 1 (Holder's Inequality) gives

$$\sum_{k=1}^n |x_k y_k| = \int_I |T_x \cdot T_y| \leq \|T_x\|_p \|T_y\|_q = \|x\|_p \|y\|_q.$$

Theorem 1 is stated for $1 \leq p < \infty$; the remaining case $p = \infty$, $q = 1$ is obtained by applying Theorem 1 to the pair T_y (in $L^1(I)$) and T_x (in $L^\infty(I)$), since $\int_I |T_y \cdot T_x| = \int_I |T_x \cdot T_y|$.

Minkowski's Inequality in $\mathbb{R}^n$. For $1 \leq p \leq \infty$ and all x, y in $\mathbb{R}^n$,

$$\left[\sum_{k=1}^n |x_k + y_k|^p \right]^{1/p} \leq \left[\sum_{k=1}^n |x_k|^p \right]^{1/p} + \left[\sum_{k=1}^n |y_k|^p \right]^{1/p} \quad (1 \leq p < \infty),$$

and $\max_k |x_k + y_k| \leq \max_k |x_k| + \max_k |y_k|$ for $p = \infty$.

Proof. This is exactly step (iv) above: $T_{x+y} = T_x + T_y$, so Minkowski's Inequality in $L^p(I)$ yields $\|x + y\|_p \leq \|x\|_p + \|y\|_p$, which is the displayed inequality once the explicit formulas for $\|\cdot\|_p$ are inserted.

Problem 7.12. For $1 \leq p < \infty$ and a sequence $a = (a_1, a_2, \dots)$ in ℓ^p , define T_a to be the function on the interval $[1, \infty)$ that takes the value a_k on $[k, k+1)$, for $k = 1, 2, \dots$. Show that T_a belongs to $L^p[1, \infty)$ and that $\|a\|_p = \|T_a\|_p$. Use this to state and prove the Holder and Minkowski Inequalities in ℓ^p .

Solution. Write $I = [1, \infty)$ and $I_k = [k, k+1)$ for $k = 1, 2, \dots$, so that I is the disjoint union of the I_k and $m(I_k) = 1$ for every k . Recall that ℓ^p consists of those real sequences $a = (a_k)$ for which $\sum_{k=1}^\infty |a_k|^p < \infty$, normed by $\|a\|_p = [\sum_{k=1}^\infty |a_k|^p]^{1/p}$.

T_a is measurable. For any real number c ,

$$\{x \in I : T_a(x) > c\} = \bigcup \{I_k : a_k > c\},$$

a countable union of intervals and therefore measurable. Hence T_a is a measurable function on I . The same computation applies to $|T_a|^p$, which is the function taking the value $|a_k|^p$ on I_k .

T_a belongs to $L^p(I)$ and $\|T_a\|_p = \|a\|_p$. For each n set

$$\varphi_n = \sum_{k=1}^n |a_k|^p \chi_{I_k},$$

a nonnegative simple function; $\{\varphi_n\}$ is an increasing sequence which converges pointwise on I to $|T_a|^p$. By the Monotone Convergence Theorem and the additivity of integration over the disjoint sets $I_1, \dots, I_n$,

$$\int_I |T_a|^p = \lim_{n \rightarrow \infty} \int_I \varphi_n = \lim_{n \rightarrow \infty} \sum_{k=1}^n |a_k|^p m(I_k) = \sum_{k=1}^\infty |a_k|^p < \infty.$$

Thus $|T_a|^p$ is integrable over I , so T_a belongs to $L^p(I)$, and taking p -th roots,

$$\|T_a\|_p = \left[\int_I |T_a|^p \right]^{1/p} = \left[\sum_{k=1}^{\infty} |a_k|^p \right]^{1/p} = \|a\|_p. \quad (8)$$

Observe also that the map $a \mapsto T_a$ is linear: evaluating on each I_k gives $T_{a+b} = T_a + T_b$ and $T_{\lambda a} = \lambda T_a$ on all of I . Note that (8) with $p = 1$ says: for any sequence (c_k) of nonnegative numbers, $\int_I T_c = \sum_{k=1}^{\infty} c_k$, a fact we use below (the computation above is valid for any nonnegative sequence, the value $+\infty$ being allowed on both sides).

Holder's Inequality in ℓ^p . Let $1 < p < \infty$ and let q be the conjugate of p . If $a = (a_k)$ belongs to ℓ^p and $b = (b_k)$ belongs to ℓ^q , then the sequence $(a_k b_k)$ belongs to ℓ^1 and

$$\sum_{k=1}^{\infty} |a_k b_k| \leq \left[\sum_{k=1}^{\infty} |a_k|^p \right]^{1/p} \left[\sum_{k=1}^{\infty} |b_k|^q \right]^{1/q} = \|a\|_p \|b\|_q.$$

Proof. The pointwise product $T_a \cdot T_b$ takes the value $a_k b_k$ on I_k , that is, $T_a \cdot T_b = T_c$ where $c = (a_k b_k)$. By (8), T_a belongs to $L^p(I)$ and T_b belongs to $L^q(I)$, so Theorem 1 tells us that $T_a \cdot T_b$ is integrable over I and

$$\int_I |T_a \cdot T_b| \leq \|T_a\|_p \|T_b\|_q = \|a\|_p \|b\|_q.$$

By the remark following (8), applied to the nonnegative sequence $(|a_k b_k|)$,

$$\sum_{k=1}^{\infty} |a_k b_k| = \int_I |T_a \cdot T_b| \leq \|a\|_p \|b\|_q < \infty.$$

In particular the series converges, so $(a_k b_k)$ belongs to ℓ^1 , and the asserted inequality holds.

The case $p = 1$, $q = \infty$ is the same argument once one checks that T_b belongs to $L^\infty(I)$ with $\|T_b\|_\infty = \sup_k |b_k|$ when b belongs to ℓ^∞ : indeed $|T_b| \leq \sup_k |b_k|$ everywhere on I , so that number is an essential upper bound; and if M is an essential upper bound then, since $|T_b| = |b_k|$ on the set I_k of measure $1 > 0$, necessarily $|b_k| \leq M$ for every k , so $\sup_k |b_k| \leq M$. Holder's Inequality in $L^1(I)$ then gives $\sum_k |a_k b_k| = \int_I |T_a \cdot T_b| \leq \|T_a\|_1 \|T_b\|_\infty = \|a\|_1 \sup_k |b_k|$.

Minkowski's Inequality in ℓ^p . Let $1 \leq p < \infty$. If a and b belong to ℓ^p , then so does $a + b = (a_k + b_k)$, and

$$\left[\sum_{k=1}^{\infty} |a_k + b_k|^p \right]^{1/p} \leq \left[\sum_{k=1}^{\infty} |a_k|^p \right]^{1/p} + \left[\sum_{k=1}^{\infty} |b_k|^p \right]^{1/p},$$

that is, $\|a + b\|_p \leq \|a\|_p + \|b\|_p$.

Proof. By (8), T_a and T_b belong to $L^p(I)$, so by Minkowski's Inequality in $L^p(I)$ their sum $T_a + T_b = T_{a+b}$ belongs to $L^p(I)$ and

$$\|T_{a+b}\|_p \leq \|T_a\|_p + \|T_b\|_p.$$

Now $\int_I |T_{a+b}|^p = \sum_{k=1}^{\infty} |a_k + b_k|^p$ by the computation leading to (8) (valid for an arbitrary sequence, with $+\infty$ permitted), and the left-hand side is finite; hence $a + b$ belongs to ℓ^p and $\|a + b\|_p = \|T_{a+b}\|_p$. Substituting the three identities of (8) into the last display gives $\|a + b\|_p \leq \|a\|_p + \|b\|_p$.

Together with the evident positive homogeneity $\|\lambda a\|_p = |\lambda| \|a\|_p$ and the fact that $\|a\|_p = 0$ forces every $a_k = 0$, this shows that ℓ^p is a normed linear space for $1 \leq p < \infty$.

Problem 7.13. Show that if f is a bounded function on E that belongs to $L^{p_1}(E)$, then it belongs to $L^{p_2}(E)$ for any $p_2 > p_1$.

Solution. Let $1 \leq p_1 < \infty$, let f belong to $L^{p_1}(E)$, and suppose f is bounded on E : there is a number $M \geq 0$ for which

$$|f(x)| \leq M \quad \text{for all } x \text{ in } E.$$

(Only an essential bound is needed; the argument below is unchanged if $|f| \leq M$ merely a.e. on E ,

that is, if f belongs to $L^\infty(E)$ and $M = \|f\|_\infty$.) Let $p_2 > p_1$.

The case $p_2 = \infty$. Since f is measurable and $|f| \leq M$ on E , the number M is an essential upper bound for f , so f belongs to $L^\infty(E)$ with $\|f\|_\infty \leq M$.

The case $p_2 < \infty$. If $M = 0$ then $f \equiv 0$ on E and there is nothing to prove, so assume $M > 0$. The function f is measurable, hence so is $|f|^{p_2}$. Since $p_2 - p_1 > 0$ and $0 \leq |f(x)| \leq M$ for all x in E , monotonicity of $t \mapsto t^{p_2-p_1}$ on $[0, \infty)$ gives $|f(x)|^{p_2-p_1} \leq M^{p_2-p_1}$, and therefore

$$|f(x)|^{p_2} = |f(x)|^{p_1} \cdot |f(x)|^{p_2-p_1} \leq M^{p_2-p_1} |f(x)|^{p_1} \quad \text{for all } x \text{ in } E.$$

The function on the right is integrable over E , being a constant multiple of the integrable function $|f|^{p_1}$. By the integral comparison test, the nonnegative measurable function $|f|^{p_2}$ is integrable over E , and by the monotonicity and linearity of integration

$$\int_E |f|^{p_2} \leq M^{p_2-p_1} \int_E |f|^{p_1} < \infty.$$

Hence f belongs to $L^{p_2}(E)$; indeed, taking p_2 -th roots,

$$\|f\|_{p_2} \leq M^{1-p_1/p_2} \|f\|_{p_1}^{p_1/p_2}.$$

Remark. No assumption on $m(E)$ is needed here. This complements Corollary 3, which for $m(E) < \infty$ gives the opposite inclusion $L^{p_2}(E) \subseteq L^{p_1}(E)$ for $p_1 < p_2$; boundedness of f is what buys the inclusion in the direction of larger exponents, on a set of arbitrary measure.

Problem 7.14. Show that if $f(x) = \ln(1/x)$ for $x \in (0, 1]$, then f belongs to $L^p(0, 1]$ for all $1 \leq p < \infty$ but does not belong to $L^\infty(0, 1]$.

Solution. The function $f(x) = \ln(1/x)$ is continuous on $(0, 1]$, hence measurable, and $f \geq 0$ there since $1/x \geq 1$.

f does not belong to $L^\infty(0, 1]$. Let $M > 0$ be any number. Then

$$\{x \in (0, 1] : |f(x)| > M\} = \{x \in (0, 1] : \ln(1/x) > M\} = (0, e^{-M}),$$

a set of measure $e^{-M} > 0$. So no number M is an essential upper bound for f , and therefore f does not belong to $L^\infty(0, 1]$. (Equivalently, in the notation of Problem 4, the set of M for which $m\{x : |f(x)| > M\} = 0$ is empty, so $\|f\|_\infty = \infty$.)

A logarithmic estimate. We use the elementary inequality

$$\ln v \leq v - 1 \leq v \quad \text{for all } v > 0,$$

which follows from the fact that $v \mapsto v - 1 - \ln v$ has derivative $1 - 1/v$, negative on $(0, 1)$ and positive on $(1, \infty)$, hence attains its minimum value 0 at $v = 1$. Now fix p with $1 \leq p < \infty$ and put $\alpha = 1/(2p) > 0$. Applying the inequality with $v = u^\alpha$, where $u > 0$, gives $\alpha \ln u = \ln u^\alpha \leq u^\alpha$, that is,

$$\ln u \leq \frac{u^\alpha}{\alpha} = 2p u^{1/(2p)} \quad \text{for all } u > 0.$$

Taking $u = 1/x$ for x in $(0, 1]$ we obtain

$$0 \leq f(x) = \ln(1/x) \leq 2p x^{-1/(2p)},$$

and raising to the p -th power (both sides are nonnegative),

$$|f(x)|^p \leq (2p)^p x^{-1/2} \quad \text{for all } x \text{ in } (0, 1]. \quad (9)$$

The majorant is integrable. Let $g(x) = x^{-1/2}$ on $(0, 1]$ and let $g_n = g \cdot \chi_{[1/n, 1]}$ for $n \geq 2$. Each g_n is nonnegative and measurable, $\{g_n\}$ increases pointwise on $(0, 1]$ to g , and g_n vanishes off $[1/n, 1]$ and

is continuous, hence Riemann integrable, on $[1/n, 1]$. So by Theorem 3 of Chapter 4 together with the additivity of integration over domains,

$$\int_{(0,1]} g_n = \int_{[1/n,1]} x^{-1/2} = \int_{1/n}^1 x^{-1/2} dx = \left[2\sqrt{x} \right]_{1/n}^1 = 2 - \frac{2}{\sqrt{n}} \leq 2,$$

the last integral being a Riemann integral evaluated by the Fundamental Theorem of Calculus. By the Monotone Convergence Theorem,

$$\int_{(0,1]} x^{-1/2} dx = \lim_{n \rightarrow \infty} \left(2 - \frac{2}{\sqrt{n}} \right) = 2 < \infty,$$

so g is integrable over $(0, 1]$.

Conclusion. By (9), the nonnegative measurable function $|f|^p$ is dominated on $(0, 1]$ by the integrable function $(2p)^p g$. By the integral comparison test, $|f|^p$ is integrable over $(0, 1]$, and

$$\int_{(0,1]} |f|^p \leq (2p)^p \int_{(0,1]} x^{-1/2} dx = 2 (2p)^p < \infty.$$

Hence f belongs to $L^p(0, 1]$, with $\|f\|_p \leq 2^{1/p} (2p)$, for every p with $1 \leq p < \infty$, while f does not belong to $L^\infty(0, 1]$.

Remark. Since $m((0, 1]) = 1 < \infty$, Corollary 3 shows that the containments $L^{p_2}(0, 1] \subseteq L^{p_1}(0, 1]$ hold for $p_1 < p_2$; this f shows that the intersection of all the $L^p(0, 1]$ with $p < \infty$ is strictly larger than $L^\infty(0, 1]$.

7.3 Problems 7.15–7.21

Problem 7.15. Formulate and prove an extension of Holder's Inequality for the product of three functions.

Solution. Formulation. Let E be a measurable set and let p, q, r belong to $[1, \infty]$ satisfy

$$\frac{1}{p} + \frac{1}{q} + \frac{1}{r} = 1,$$

with the usual convention $1/\infty = 0$. If $f \in L^p(E)$, $g \in L^q(E)$ and $h \in L^r(E)$, then the product $f \cdot g \cdot h$ is integrable over E and

$$\int_E |f \cdot g \cdot h| \leq \|f\|_p \cdot \|g\|_q \cdot \|h\|_r.$$

Proof. We first dispose of the cases in which one of the exponents is infinite. Suppose $r = \infty$. Then $1/p + 1/q = 1$, so p and q are conjugate. Since $|h| \leq \|h\|_\infty$ a.e. on E (the essential supremum is itself an essential upper bound, by observation (2) of Section 7.1), monotonicity of integration and Holder's Inequality, Theorem 1 of Chapter 7, applied to f and g give

$$\int_E |f \cdot g \cdot h| \leq \|h\|_\infty \int_E |f \cdot g| \leq \|f\|_p \|g\|_q \|h\|_\infty,$$

and in particular $f \cdot g \cdot h$ is integrable. The cases $p = \infty$ and $q = \infty$ are identical after relabeling. Observe also that if two of the exponents were infinite the third would have to satisfy $1/p = 1$, that is $p = 1$, and the same argument applies. Finally, if one of the exponents equals 1, say $p = 1$, then $1/q + 1/r = 0$ forces $q = r = \infty$, a case already treated.

So assume $1 < p, q, r < \infty$. Define s by

$$\frac{1}{s} = \frac{1}{q} + \frac{1}{r} = 1 - \frac{1}{p}.$$

Then s is the conjugate of p , and since $1/s > 1/q$ and $1/s > 1/r$ we have $1 < s < q$ and $s < r$.

Step 1: $g \cdot h$ belongs to $L^s(E)$ and $\|g \cdot h\|_s \leq \|g\|_q \|h\|_r$. Put

$$\alpha = \frac{q}{s}, \quad \beta = \frac{r}{s}.$$

Both exceed 1, and

$$\frac{1}{\alpha} + \frac{1}{\beta} = \frac{s}{q} + \frac{s}{r} = s \left(\frac{1}{q} + \frac{1}{r} \right) = s \cdot \frac{1}{s} = 1,$$

so α and β are conjugate. The function $|g|^s$ belongs to $L^\alpha(E)$, since $\int_E (|g|^s)^\alpha = \int_E |g|^q < \infty$, and likewise $|h|^s$ belongs to $L^\beta(E)$. By Holder's Inequality applied to this pair of functions and this pair of conjugate exponents, the product $|g|^s |h|^s$ is integrable over E and

$$\int_E |g|^s |h|^s \leq \left[\int_E |g|^{s\alpha} \right]^{1/\alpha} \cdot \left[\int_E |h|^{s\beta} \right]^{1/\beta} = \left[\int_E |g|^q \right]^{s/q} \cdot \left[\int_E |h|^r \right]^{s/r} = \|g\|_q^s \cdot \|h\|_r^s.$$

Since $|g \cdot h|^s = |g|^s |h|^s$, the product $g \cdot h$ is measurable with $|g \cdot h|^s$ integrable, so $g \cdot h \in L^s(E)$, and taking s -th roots in the displayed inequality yields $\|g \cdot h\|_s \leq \|g\|_q \|h\|_r$.

Step 2: apply Holder to f and $g \cdot h$. Since p and s are conjugate, $f \in L^p(E)$ and $g \cdot h \in L^s(E)$, Holder's Inequality tells us that $f \cdot (g \cdot h)$ is integrable over E and

$$\int_E |f \cdot g \cdot h| \leq \|f\|_p \cdot \|g \cdot h\|_s \leq \|f\|_p \cdot \|g\|_q \cdot \|h\|_r.$$

This is the asserted inequality, and the proof is complete. ■

Remark. An entirely parallel argument, by induction on n , gives the n -function version: if $1/p_1 + \cdots + 1/p_n = 1$ with each $p_k \in [1, \infty]$ and $f_k \in L^{p_k}(E)$, then $f_1 \cdots f_n$ is integrable over E and $\int_E |f_1 \cdots f_n| \leq \prod_{k=1}^n \|f_k\|_{p_k}$.

Alternative proof of the three-function case, all three exponents finite. Suppose now $1 < p, q, r < \infty$ (the cases in which some exponent is infinite were disposed of above, and there is no analogue of the term $|h|^r/r$ below when $r = \infty$). One may argue directly, as the book does for two functions in the proof of Theorem 1 of Chapter 7, by first normalizing. It suffices to prove the inequality when $\|f\|_p = \|g\|_q = \|h\|_r = 1$ (if one of the three norms vanishes then the corresponding function is zero a.e., the product is zero a.e., and the inequality is trivial; otherwise replace f, g, h by $f/\|f\|_p, g/\|g\|_q, h/\|h\|_r$ and use the positive homogeneity of both sides). Under this normalization we claim

$$|f| \cdot |g| \cdot |h| \leq \frac{|f|^p}{p} + \frac{|g|^q}{q} + \frac{|h|^r}{r} \quad \text{a.e. on } E.$$

Indeed, since $|f|^p, |g|^q, |h|^r$ are integrable, the three functions are finite a.e. on E . At a point where all three values $a = |f|, b = |g|, c = |h|$ are positive and finite, the concavity of the logarithm together with the weights $1/p, 1/q, 1/r$, which are positive and sum to 1, gives

$$\ln \left(\frac{a^p}{p} + \frac{b^q}{q} + \frac{c^r}{r} \right) \geq \frac{1}{p} \ln a^p + \frac{1}{q} \ln b^q + \frac{1}{r} \ln c^r = \ln(abc),$$

and exponentiating yields the claim; if one of a, b, c is zero the claim is trivial. Integrating the claim over E and using the linearity of integration and the integral comparison test, $f \cdot g \cdot h$ is integrable over E and

$$\int_E |f \cdot g \cdot h| \leq \frac{1}{p} \int_E |f|^p + \frac{1}{q} \int_E |g|^q + \frac{1}{r} \int_E |h|^r = \frac{1}{p} + \frac{1}{q} + \frac{1}{r} = 1 = \|f\|_p \|g\|_q \|h\|_r. \quad \blacksquare$$

Problem 7.16. Suppose that $\{f_n\}$ is bounded in $L^1[0, 1]$. Is $\{f_n\}$ uniformly integrable over $[0, 1]$?

Solution. No. Boundedness in L^1 does not imply uniform integrability. Corollary 2 of Chapter 7, which asserts that a family bounded in $L^p(E)$ is uniformly integrable, is stated for $1 < p < \infty$, and that

restriction is essential: the conclusion fails for $p = 1$.

Counterexample. For each natural number n define f_n on $[0, 1]$ by

$$f_n = n \cdot \chi_{[0, 1/n]}, \quad \text{that is,} \quad f_n(x) = \begin{cases} n, & 0 \leq x \leq 1/n, \\ 0, & 1/n < x \leq 1. \end{cases}$$

Each f_n is a nonnegative simple function, hence measurable, and

$$\|f_n\|_1 = \int_0^1 |f_n| = n \cdot m([0, 1/n]) = n \cdot \frac{1}{n} = 1.$$

Thus $\{f_n\}$ belongs to $L^1[0, 1]$ and is bounded there, with $\|f_n\|_1 = 1 \leq 1$ for all n .

We claim $\{f_n\}$ is not uniformly integrable over $[0, 1]$. Recall the definition: the family is uniformly integrable over $[0, 1]$ provided that for each $\epsilon > 0$ there is a $\delta > 0$ such that

$$\int_A |f_n| < \epsilon \quad \text{for all } n \text{ and all measurable } A \subseteq [0, 1] \text{ with } m(A) < \delta.$$

Take the challenge $\epsilon = 1/2$ and let $\delta > 0$ be arbitrary. Choose a natural number n with $1/n < \delta$ and set $A = [0, 1/n]$. Then A is a measurable subset of $[0, 1]$ with $m(A) = 1/n < \delta$, while

$$\int_A |f_n| = \int_0^{1/n} n = n \cdot \frac{1}{n} = 1 > \frac{1}{2} = \epsilon.$$

Hence no δ responds to the challenge $\epsilon = 1/2$, and the family fails to be uniformly integrable.

Why the argument for $p > 1$ breaks down at $p = 1$. In the proof of Corollary 2 one estimates, for measurable $A \subseteq E$,

$$\int_A |f| \leq \|f\|_p \cdot [m(A)]^{1/q},$$

where q is the conjugate of p . This is what forces the integral over a small set to be small uniformly. When $p = 1$ the conjugate exponent is $q = \infty$, the factor $[m(A)]^{1/q}$ degenerates to $[m(A)]^0 = 1$, and the estimate reduces to the vacuous $\int_A |f| \leq \|f\|_1$. The example above shows that no substitute estimate is available: the mass 1 carried by f_n can be concentrated on a set of arbitrarily small measure.

Remark. What is true is that a single integrable function is uniformly integrable in this sense, by Proposition 23 of Chapter 4, and more generally that any finite family of integrable functions is, by Proposition 24 of Chapter 4; the failure above is a failure of uniformity across an infinite family. Note also that $\{f_n\}$ converges to 0 pointwise on $(0, 1]$ while $\int_0^1 f_n = 1$ for all n , which is exactly the failure of passage to the limit under the integral sign that uniform integrability is designed to preclude.

Problem 7.17. For $1 < p < \infty$, suppose that $\{f_n\}$ is bounded in $L^p(\mathbb{R})$. Is $\{f_n\}$ tight?

Solution. No. Recall the definition from Section 5.1: a family $\mathcal{F}$ of measurable functions on E is tight over E provided that for each $\epsilon > 0$ there is a subset E_0 of E of finite measure for which

$$\int_{E \setminus E_0} |f| < \epsilon \quad \text{for all } f \in \mathcal{F}.$$

Boundedness in $L^p(\mathbb{R})$ for $1 < p < \infty$ does not imply this. Thus while Corollary 2 of Chapter 7 upgrades L^p -boundedness to uniform integrability for $p > 1$, no analogous upgrade to tightness holds on a set of infinite measure. We give two counterexamples: the first shows the failure already for a single function, the second shows that the failure persists even for a sequence of integrable functions of constant L^1 -norm.

Counterexample 1 (a one-element family). Fix $1 < p < \infty$ and define

$$f(x) = \frac{1}{1 + |x|} \quad \text{for } x \in \mathbb{R},$$

and set $f_n = f$ for all n . This f is continuous, hence measurable, and

$$\int_{\mathbb{R}} |f|^p = 2 \int_0^\infty \frac{dx}{(1+x)^p} = \frac{2}{p-1} < \infty,$$

so $f \in L^p(\mathbb{R})$ and $\{f_n\}$ is bounded in $L^p(\mathbb{R})$. On the other hand

$$\int_{\mathbb{R}} |f| = 2 \int_0^\infty \frac{dx}{1+x} = \infty,$$

so f is not integrable over $\mathbb{R}$. Now let $E_0 \subseteq \mathbb{R}$ be measurable with finite measure. Since $0 \leq f \leq 1$ on $\mathbb{R}$, monotonicity gives $\int_{E_0} f \leq m(E_0) < \infty$. Because f is nonnegative and measurable, additivity of integration over domains holds in the extended sense:

$$\int_{\mathbb{R}} f = \int_{E_0} f + \int_{\mathbb{R} \sim E_0} f \quad \text{in } [0, \infty].$$

Were $\int_{\mathbb{R} \sim E_0} f$ finite, the right-hand side would be finite and f would be integrable over $\mathbb{R}$, which it is not. Hence $\int_{\mathbb{R} \sim E_0} f = \infty$. Hence no set of finite measure responds to the challenge $\epsilon = 1$, and $\{f_n\}$ is not tight over $\mathbb{R}$. (This is consistent with the observation recorded after the definition of tightness: a family that is both uniformly integrable and tight consists of integrable functions, and here f is not integrable.)

Counterexample 2 (integrable functions, escaping mass). One might object that the first example fails only because its single member is not integrable. Tightness can fail even for a sequence of integrable functions of constant norm. Define

$$f_n = \chi_{[n, n+1]} \quad \text{for } n = 1, 2, \dots$$

Each f_n is measurable, and for every r with $1 \leq r < \infty$,

$$\|f_n\|_r = \left[\int_{\mathbb{R}} \chi_{[n, n+1]} \right]^{1/r} = 1,$$

so $\{f_n\}$ is bounded in $L^p(\mathbb{R})$ (indeed in every $L^r(\mathbb{R})$, and each f_n is integrable with $\int_{\mathbb{R}} |f_n| = 1$).

We claim $\{f_n\}$ is not tight over $\mathbb{R}$. Let $E_0 \subseteq \mathbb{R}$ be measurable with $m(E_0) < \infty$. The sets $E_0 \cap [n, n+1]$, for $n = 1, 2, \dots$, are disjoint measurable subsets of E_0 , so by the countable additivity and monotonicity of Lebesgue measure,

$$\sum_{n=1}^{\infty} m(E_0 \cap [n, n+1]) = m(E_0 \cap [1, \infty)) \leq m(E_0) < \infty.$$

A convergent series has terms tending to 0, so $m(E_0 \cap [n, n+1]) \rightarrow 0$, and since $m(E_0 \cap [n, n+1]) = m(E_0 \cap [n, n+1])$ (the single point $n+1$ has measure zero), we may choose N with $m(E_0 \cap [N, N+1]) < 1/2$. For this N ,

$$\int_{\mathbb{R} \sim E_0} |f_N| = m([N, N+1] \sim E_0) = 1 - m(E_0 \cap [N, N+1]) > \frac{1}{2}.$$

Thus no set of finite measure responds to the challenge $\epsilon = 1/2$, and $\{f_n\}$ is not tight over $\mathbb{R}$.

Conclusion. The answer is no: for $1 < p < \infty$, boundedness in $L^p(\mathbb{R})$ implies uniform integrability over $\mathbb{R}$, by Corollary 2 of Chapter 7, but it does not imply tightness. Tightness controls the escape of mass to infinity, a phenomenon invisible to the L^p norm, which is invariant under translation.

Problem 7.18. Assume $m(E) < \infty$. For $f \in L^\infty(E)$, show that $\lim_{p \rightarrow \infty} \|f\|_p = \|f\|_\infty$.

Solution. Throughout, write $M = \|f\|_\infty$, the essential supremum of f on E , that is, the infimum of the essential upper bounds for f . As established in Section 7.1 (observation (2) there), this infimum is attained: M is itself an essential upper bound, so that

$$|f| \leq M \quad \text{a.e. on } E. \quad (*)$$

The norms $\|f\|_p$ are finite. Since $m(E) < \infty$ and $f \in L^\infty(E)$, Corollary 3 of Chapter 7 (with $p_1 = p$ and $p_2 = \infty$) gives $L^\infty(E) \subseteq L^p(E)$ for every p with $1 \leq p < \infty$, so $\|f\|_p$ is a finite nonnegative number for each such p . Directly: by $(*)$ and the monotonicity of integration, $\int_E |f|^p \leq M^p m(E) < \infty$.

The degenerate case $m(E) = 0$. If $m(E) = 0$ then every nonnegative number is an essential upper bound for f , so $M = 0$; and $\int_E |f|^p = 0$ for every p , so $\|f\|_p = 0$. Thus the limit relation holds trivially. Assume henceforth that $m(E) > 0$, so $0 < m(E) < \infty$.

Step 1: $\limsup_{p \rightarrow \infty} \|f\|_p \leq M$. By $(*)$ and the monotonicity of integration, for each p with $1 \leq p < \infty$,

$$\int_E |f|^p \leq \int_E M^p = M^p \cdot m(E),$$

and taking p -th roots,

$$\|f\|_p \leq M \cdot [m(E)]^{1/p}.$$

Since $0 < m(E) < \infty$, we have $[m(E)]^{1/p} = \exp\left(\frac{1}{p} \ln m(E)\right) \rightarrow \exp(0) = 1$ as $p \rightarrow \infty$. Therefore

$$\limsup_{p \rightarrow \infty} \|f\|_p \leq M \cdot \lim_{p \rightarrow \infty} [m(E)]^{1/p} = M.$$

Step 2: $\liminf_{p \rightarrow \infty} \|f\|_p \geq M$. If $M = 0$ this is immediate, since $\|f\|_p \geq 0$ for all p . So assume $M > 0$ and let ϵ satisfy $0 < \epsilon < M$. Define

$$E_\epsilon = \{x \in E : |f(x)| > M - \epsilon\},$$

a measurable subset of E since f is measurable. We claim $m(E_\epsilon) > 0$. Indeed, if $m(E_\epsilon) = 0$, then $|f| \leq M - \epsilon$ a.e. on E , so $M - \epsilon$ would be an essential upper bound for f ; this contradicts the fact that M is the infimum of the essential upper bounds, since $M - \epsilon < M$. Hence $m(E_\epsilon) > 0$, and of course $m(E_\epsilon) \leq m(E) < \infty$.

Now, by the monotonicity of integration and the additivity of integration over domains, for each p with $1 \leq p < \infty$,

$$\int_E |f|^p \geq \int_{E_\epsilon} |f|^p \geq \int_{E_\epsilon} (M - \epsilon)^p = (M - \epsilon)^p \cdot m(E_\epsilon),$$

the middle inequality because $|f| > M - \epsilon > 0$ on E_ϵ and $t \mapsto t^p$ is increasing on $[0, \infty)$. Taking p -th roots,

$$\|f\|_p \geq (M - \epsilon) \cdot [m(E_\epsilon)]^{1/p}.$$

Since $0 < m(E_\epsilon) < \infty$, again $[m(E_\epsilon)]^{1/p} \rightarrow 1$ as $p \rightarrow \infty$, and therefore

$$\liminf_{p \rightarrow \infty} \|f\|_p \geq (M - \epsilon) \cdot \lim_{p \rightarrow \infty} [m(E_\epsilon)]^{1/p} = M - \epsilon.$$

As $\epsilon \in (0, M)$ was arbitrary, letting $\epsilon \rightarrow 0^+$ gives $\liminf_{p \rightarrow \infty} \|f\|_p \geq M$.

Conclusion. Combining the two steps,

$$M \leq \liminf_{p \rightarrow \infty} \|f\|_p \leq \limsup_{p \rightarrow \infty} \|f\|_p \leq M,$$

so the limit exists and

$$\lim_{p \rightarrow \infty} \|f\|_p = M = \|f\|_\infty. \quad \blacksquare$$

Remark. The hypothesis $m(E) < \infty$ is needed for Step 1 (and to guarantee $f \in L^p(E)$ at all). For instance, with $E = \mathbb{R}$ and $f \equiv 1$ we have $\|f\|_\infty = 1$ while $\|f\|_p = \infty$ for every $p < \infty$. Step 2, by contrast, is valid on any measurable set $E \subseteq \mathbb{R}$: one still has $\liminf_{p \rightarrow \infty} \|f\|_p \geq \|f\|_\infty$, where $\|f\|_p$ is read as ∞ when $|f|^p$ fails to be integrable. Indeed, if $m(E_\epsilon) = \infty$, then by the continuity of measure $m(E_\epsilon \cap [-n, n]) \rightarrow m(E_\epsilon)$, so for n large this intersection has finite positive measure and may be used in place of E_ϵ in the argument.

Problem 7.19. For $1 \leq p < \infty$, q the conjugate of p , and $f \in L^p(E)$, show that

$$\|f\|_p = \max_{g \in L^q(E), \|g\|_q \leq 1} \int_E f \cdot g.$$

Solution. Two things must be shown: that $\int_E f \cdot g \leq \|f\|_p$ for every $g \in L^q(E)$ with $\|g\|_q \leq 1$, so that $\|f\|_p$ is an upper bound for the set of such numbers; and that this upper bound is attained by some particular such g , so that the supremum is a maximum.

Observe first that the expression $\int_E f \cdot g$ makes sense: for $f \in L^p(E)$ and $g \in L^q(E)$ with p and q conjugate, Holder's Inequality, Theorem 1 of Chapter 7, asserts precisely that $f \cdot g$ is integrable over E , so $\int_E f \cdot g$ is a real number.

Step 1: $\|f\|_p$ is an upper bound. Let $g \in L^q(E)$ with $\|g\|_q \leq 1$. By the monotonicity of integration and Holder's Inequality,

$$\int_E f \cdot g \leq \int_E |f \cdot g| \leq \|f\|_p \cdot \|g\|_q \leq \|f\|_p \cdot 1 = \|f\|_p.$$

Hence

$$\sup \left\{ \int_E f \cdot g : g \in L^q(E), \|g\|_q \leq 1 \right\} \leq \|f\|_p.$$

Step 2: the bound is attained.

Case $f = 0$ in $L^p(E)$, that is, $f = 0$ a.e. on E . Then $\|f\|_p = 0$. Take $g = 0$, which belongs to $L^q(E)$ and has $\|g\|_q = 0 \leq 1$. Then $\int_E f \cdot g = 0 = \|f\|_p$, so the supremum is attained. (By Step 1 the supremum is ≤ 0 , and this g realizes the value 0.)

Case $f \neq 0$. Then $\|f\|_p > 0$, and in particular $m(E) > 0$. Consider the conjugate function of f introduced in Section 7.2,

$$f^* = \|f\|_p^{1-p} \cdot \operatorname{sgn}(f) \cdot |f|^{p-1},$$

where $\operatorname{sgn}(f)$ takes the value 1 where $f \geq 0$ and -1 where $f < 0$. As part of the statement of Holder's Inequality, Theorem 1 of Chapter 7, the book records that f^* belongs to $L^q(E)$ and that

$$\int_E f \cdot f^* = \|f\|_p \quad \text{and} \quad \|f^*\|_q = 1.$$

For completeness we recall the verification. Since $\operatorname{sgn}(f) \cdot f = |f|$ a.e. on E (f being finite a.e., as $|f|^p$ is integrable), we have

$$f \cdot f^* = \|f\|_p^{1-p} \cdot |f|^{p-1} \cdot \operatorname{sgn}(f) \cdot f = \|f\|_p^{1-p} \cdot |f|^p \quad \text{a.e. on } E,$$

so by the linearity of integration

$$\int_E f \cdot f^* = \|f\|_p^{1-p} \int_E |f|^p = \|f\|_p^{1-p} \cdot \|f\|_p^p = \|f\|_p.$$

As for the norm of f^* : when $p > 1$, q is finite and $q(p-1) = p$, so

$$\int_E |f^*|^q = \|f\|_p^{q(1-p)} \int_E |f|^{q(p-1)} = \|f\|_p^{-p} \int_E |f|^p = 1,$$

whence $f^* \in L^q(E)$ and $\|f^*\|_q = 1$; when $p = 1$ we have $\|f\|_p^{1-p} = 1$ and $|f|^{p-1} = 1$, so $f^* = \operatorname{sgn}(f)$, which belongs to $L^\infty(E)$ with $\|f^*\|_\infty = 1$: indeed $|f^*| = 1$ everywhere on E , so 1 is an essential upper bound for f^* , while no $c < 1$ is one, since $m(E) > 0$.

Thus $g = f^*$ is admissible in the competition, since $f^* \in L^q(E)$ and $\|f^*\|_q = 1 \leq 1$, and it achieves the value

$$\int_E f \cdot f^* = \|f\|_p.$$

Conclusion. By Step 1 no admissible g gives a value exceeding $\|f\|_p$, and by Step 2 some admissible g gives exactly $\|f\|_p$. Therefore the supremum is attained and

$$\|f\|_p = \max_{g \in L^q(E), \|g\|_q \leq 1} \int_E f \cdot g. \quad \blacksquare$$

Remark. The hypothesis $p < \infty$ matters. For $p = \infty$ the conjugate exponent is $q = 1$ and the analogous identity $\|f\|_\infty = \sup\{\int_E f \cdot g : \|g\|_1 \leq 1\}$ does hold when $m(E) > 0$, but the supremum need not be attained: for $E = [0, 1]$ and $f(x) = x$ one has $\|f\|_\infty = 1$, while $\int_0^1 x g(x) dx < 1$ for every $g \in L^1[0, 1]$ with $\|g\|_1 \leq 1$.

Problem 7.20. For $1 \leq p < \infty$, q the conjugate of p , and $f \in L^p(E)$, show that $f = 0$ if and only if

$$\int_E f \cdot g = 0 \quad \text{for all } g \in L^q(E).$$

Solution. Here, as always for the L^p spaces, the equation $f = 0$ means that f is the zero element of $L^p(E)$, that is, $f = 0$ a.e. on E . Note first that for every $g \in L^q(E)$ the product $f \cdot g$ is integrable over E , by Holder's Inequality, Theorem 1 of Chapter 7, so each of the integrals in question is a well-defined real number.

Necessity. Suppose $f = 0$ a.e. on E . Let $g \in L^q(E)$. Then $f \cdot g = 0$ a.e. on E , and a function that vanishes a.e. on E has $\int_E f \cdot g = 0$. Thus the stated condition holds.

Sufficiency. Suppose $\int_E f \cdot g = 0$ for all $g \in L^q(E)$. We argue by contradiction: assume $f \neq 0$ in $L^p(E)$, that is, $\|f\|_p > 0$. Consider the conjugate function of f from Section 7.2,

$$f^* = \|f\|_p^{1-p} \cdot \operatorname{sgn}(f) \cdot |f|^{p-1},$$

where $\operatorname{sgn}(f)$ equals 1 where $f \geq 0$ and -1 where $f < 0$. As recorded in the statement of Holder's Inequality, Theorem 1 of Chapter 7, f^* belongs to $L^q(E)$, with $\|f^*\|_q = 1$ and

$$\int_E f \cdot f^* = \|f\|_p.$$

Let us verify this last identity again. Since $|f|^p$ is integrable, f is finite a.e. on E , so $\operatorname{sgn}(f) \cdot f = |f|$ a.e. on E and therefore

$$f \cdot f^* = \|f\|_p^{1-p} \cdot |f|^{p-1} \cdot \operatorname{sgn}(f) \cdot f = \|f\|_p^{1-p} \cdot |f|^p \quad \text{a.e. on } E.$$

By the linearity of integration,

$$\int_E f \cdot f^* = \|f\|_p^{1-p} \int_E |f|^p = \|f\|_p^{1-p} \cdot \|f\|_p^p = \|f\|_p > 0.$$

That $f^* \in L^q(E)$ is immediate: for $p > 1$ the exponent q is finite and $q(p-1) = p$, so $\int_E |f^*|^q = \|f\|_p^{-p} \int_E |f|^p = 1$; for $p = 1$ we have $f^* = \operatorname{sgn}(f)$, a measurable function bounded in absolute value by 1, hence a member of $L^\infty(E)$.

So $g = f^*$ is a member of $L^q(E)$ with $\int_E f \cdot g = \|f\|_p > 0$, contradicting the hypothesis that this integral vanishes for every g in $L^q(E)$. Therefore $\|f\|_p = 0$. But $\int_E |f|^p = 0$ with $|f|^p$ nonnegative and measurable forces $|f|^p = 0$ a.e. on E , by Proposition 9 of Chapter 4; this is exactly the observation made in Section 7.1 that $\|f\|_p = 0$ if and only if f vanishes a.e. on E . We conclude $f = 0$ a.e. on E . $\blacksquare$

Alternative derivation of sufficiency. Granting the preceding problem, the implication is immediate: if $\int_E f \cdot g = 0$ for every $g \in L^q(E)$, then in particular this holds for every $g \in L^q(E)$ with $\|g\|_q \leq 1$, so

$$\|f\|_p = \max_{g \in L^q(E), \|g\|_q \leq 1} \int_E f \cdot g = 0,$$

and hence $f = 0$ a.e. on E .

Remark. The proof shows more: it is enough to test f against the single function $g = f^*$, or indeed to know only that $\sup\{\int_E f \cdot g : g \in L^q(E), \|g\|_q \leq 1\} = 0$. The hypothesis $p < \infty$ is used to know that the conjugate function f^* lies in $L^q(E)$; for $p = \infty$ and $q = 1$ the corresponding statement is still true when E is of σ -finite measure, but the witness must be built by exhaustion rather than taken directly as f^* , since $\text{sgn}(f) \cdot \chi_E$ need not be integrable.

Problem 7.21. For $1 \leq p \leq \infty$, find the values of the parameter λ for which

$$\lim_{\epsilon \rightarrow 0^+} \frac{1}{\epsilon^\lambda} \int_0^\epsilon f = 0 \quad \text{for all } f \in L^p[0, 1].$$

Solution. Answer. Let q be the conjugate of p . The property holds for all $f \in L^p[0, 1]$ precisely when

$$\lambda \leq \frac{1}{q} = 1 - \frac{1}{p} \quad \text{if } 1 \leq p < \infty, \quad \text{and} \quad \lambda < 1 \quad \text{if } p = \infty.$$

Thus for $p = 1$ the admissible λ are those with $\lambda \leq 0$; for $1 < p < \infty$ they are those with $\lambda \leq 1 - 1/p$; and for $p = \infty$ they are those with $\lambda < 1$, the endpoint $\lambda = 1$ now being excluded.

Throughout we take $0 < \epsilon \leq 1$, and we note that each $f \in L^p[0, 1]$ is integrable over $[0, 1]$: for $p = \infty$ this is because $m([0, 1]) < \infty$ and f is essentially bounded, and for $1 \leq p < \infty$ it is Corollary 3 of Chapter 7 with $p_1 = 1 \leq p_2 = p$. So $\int_0^\epsilon f$ is a well-defined real number for every ϵ .

Sufficiency, the case $1 \leq p < \infty$ and $\lambda \leq 1/q$. Let $f \in L^p[0, 1]$ and $0 < \epsilon \leq 1$. Both $u = f \cdot \chi_{[0, \epsilon]}$ and $v = \chi_{[0, \epsilon]}$ are measurable on $[0, 1]$, with $u \in L^p[0, 1]$ (since $|u| \leq |f|$) and $v \in L^q[0, 1]$. Since $|u \cdot v| = |f| \cdot \chi_{[0, \epsilon]}$, Holder's Inequality, Theorem 1 of Chapter 7, applied to u and v gives

$$\left| \int_0^\epsilon f \right| \leq \int_0^\epsilon |f| = \int_0^1 |u \cdot v| \leq \|u\|_p \cdot \|v\|_q = \|f \cdot \chi_{[0, \epsilon]}\|_p \cdot \epsilon^{1/q},$$

where $\|v\|_q = [\int_0^1 \chi_{[0, \epsilon]}^q]^{1/q} = \epsilon^{1/q}$ for $q < \infty$, while for $p = 1$, so that $q = \infty$, one reads $\|v\|_\infty = 1 = \epsilon^0 = \epsilon^{1/q}$. Consequently

$$\left| \frac{1}{\epsilon^\lambda} \int_0^\epsilon f \right| \leq \epsilon^{1/q - \lambda} \cdot \|f \cdot \chi_{[0, \epsilon]}\|_p.$$

Since $\lambda \leq 1/q$ and $0 < \epsilon \leq 1$, we have $\epsilon^{1/q - \lambda} \leq 1$. It remains to observe that

$$\|f \cdot \chi_{[0, \epsilon]}\|_p = \left[\int_0^\epsilon |f|^p \right]^{1/p} \longrightarrow 0 \quad \text{as } \epsilon \rightarrow 0^+.$$

This is Proposition 23 of Chapter 4 applied to the integrable function $|f|^p$: given $\eta > 0$ there is $\delta > 0$ such that $\int_A |f|^p < \eta^p$ whenever $A \subseteq [0, 1]$ is measurable with $m(A) < \delta$; taking $A = [0, \epsilon]$ with $\epsilon < \delta$ gives $\|f \cdot \chi_{[0, \epsilon]}\|_p < \eta$. Therefore the right-hand side of the displayed estimate tends to 0, and so does the left. This proves the assertion for all $\lambda \leq 1/q$.

Sufficiency, the case $p = \infty$ and $\lambda < 1$. Let $f \in L^\infty[0, 1]$. Since $|f| \leq \|f\|_\infty$ a.e. on $[0, 1]$, monotonicity of integration gives, for $0 < \epsilon \leq 1$,

$$\left| \frac{1}{\epsilon^\lambda} \int_0^\epsilon f \right| \leq \frac{1}{\epsilon^\lambda} \int_0^\epsilon |f| \leq \frac{1}{\epsilon^\lambda} \cdot \|f\|_\infty \cdot \epsilon = \|f\|_\infty \cdot \epsilon^{1-\lambda}.$$

Because $1 - \lambda > 0$, we have $\epsilon^{1-\lambda} \rightarrow 0$ as $\epsilon \rightarrow 0^+$, and the limit is 0.

Necessity. We show that for every remaining λ there is a single $f \in L^p[0, 1]$ for which the limit is not 0. The remaining values are: $\lambda > 1 - 1/p$ when $1 \leq p < \infty$, and $\lambda \geq 1$ when $p = \infty$. In every such case $\lambda > 0$; indeed for $p < \infty$ we have $\lambda > 1 - 1/p \geq 0$, and for $p = \infty$ we have $\lambda \geq 1$.

Define

$$f(x) = x^{\lambda-1} \text{ for } 0 < x \leq 1, \quad f(0) = 0.$$

This f is continuous on $(0, 1]$, hence measurable on $[0, 1]$.

We check $f \in L^p[0, 1]$ for the λ under consideration.

First suppose $1 \leq p < \infty$. Then $|f|^p = x^{(\lambda-1)p}$ on $(0, 1]$. Since $\lambda > 1 - 1/p$, we have $(\lambda - 1)p > -1$, so $(\lambda - 1)p + 1 > 0$. The functions $x^{(\lambda-1)p} \cdot \chi_{[1/n, 1]}$ are nonnegative and measurable and increase pointwise on $(0, 1]$ to $|f|^p$, and on each $[1/n, 1]$ the integrand is continuous, so its Lebesgue integral agrees with its Riemann integral, which the Fundamental Theorem of Calculus evaluates. Hence, by the Monotone Convergence Theorem,

$$\int_0^1 |f|^p = \lim_{n \rightarrow \infty} \int_{1/n}^1 x^{(\lambda-1)p} dx = \lim_{n \rightarrow \infty} \frac{1 - (1/n)^{(\lambda-1)p+1}}{(\lambda-1)p+1} = \frac{1}{(\lambda-1)p+1} < \infty,$$

the last equality because $(\lambda - 1)p + 1 > 0$. Hence $f \in L^p[0, 1]$. If instead $p = \infty$, then $\lambda \geq 1$, so $\lambda - 1 \geq 0$ and $0 \leq f(x) = x^{\lambda-1} \leq 1$ for $x \in (0, 1]$; thus f is bounded and $f \in L^\infty[0, 1]$.

Now compute, for $0 < \epsilon \leq 1$, again by the Monotone Convergence Theorem and the Fundamental Theorem of Calculus, using $\lambda > 0$,

$$\int_0^\epsilon f = \lim_{n \rightarrow \infty} \int_{1/n}^\epsilon x^{\lambda-1} dx = \lim_{n \rightarrow \infty} \frac{\epsilon^\lambda - (1/n)^\lambda}{\lambda} = \frac{\epsilon^\lambda}{\lambda},$$

where the sequence of integrals is taken over n with $1/n < \epsilon$. Therefore

$$\frac{1}{\epsilon^\lambda} \int_0^\epsilon f = \frac{1}{\lambda} \quad \text{for every } \epsilon \in (0, 1],$$

so that

$$\lim_{\epsilon \rightarrow 0^+} \frac{1}{\epsilon^\lambda} \int_0^\epsilon f = \frac{1}{\lambda} \neq 0.$$

Hence such a λ does not have the required property.

Conclusion. Combining sufficiency and necessity, the set of admissible parameters is exactly

$$\{\lambda : \lambda \leq 1/q\} = \{\lambda : \lambda \leq 1 - 1/p\} \quad \text{for } 1 \leq p < \infty, \quad \{\lambda : \lambda < 1\} \quad \text{for } p = \infty. \quad \blacksquare$$

Remark on the endpoint. The asymmetry at $p = \infty$ is worth noting. For $p < \infty$ the critical exponent $\lambda = 1/q$ is admissible because the quantity $\|f \cdot \chi_{[0, \epsilon]}\|_p$ carries an extra, though non-quantitative, decay to 0 as $\epsilon \rightarrow 0^+$; this is exactly the continuity of the integral expressed by Proposition 23 of Chapter 4. For $p = \infty$ the corresponding quantity is the essential supremum of f over $[0, \epsilon]$, which need not tend to 0 at all: for $f \equiv 1$ it is identically 1, and then $\epsilon^{-1} \int_0^\epsilon f = 1$ for all ϵ , so the critical exponent $\lambda = 1$ fails.

7.4 Problems 7.22–7.28

Problem 7.22. (Riesz) For $1 < p < \infty$, show that if the absolutely continuous function F on $[a, b]$ is the indefinite integral of an $L^p[a, b]$ function, then there is a constant $M > 0$ such that for any partition $\{x_0, \dots, x_n\}$ of $[a, b]$,

$$\sum_{k=1}^n \frac{|F(x_k) - F(x_{k-1})|^p}{|x_k - x_{k-1}|^{p-1}} \leq M.$$

Solution. By hypothesis there is a function $f \in L^p[a, b]$ for which

$$F(x) = F(a) + \int_a^x f \quad \text{for all } x \in [a, b].$$

Let $q = p/(p-1)$ be the conjugate of p , so that $1 < q < \infty$ and $p/q = p-1$.

Set

$$M = \int_a^b |f|^p + 1 = \|f\|_p^p + 1,$$

which is a finite positive number since f belongs to $L^p[a, b]$. We claim this M works.

Let $\{x_0, x_1, \dots, x_n\}$ be a partition of $[a, b]$, so $a = x_0 < x_1 < \dots < x_n = b$. Fix an index k with $1 \leq k \leq n$. By the additivity of integration over domains,

$$F(x_k) - F(x_{k-1}) = \int_{x_{k-1}}^{x_k} f,$$

and therefore, by the monotonicity of integration,

$$|F(x_k) - F(x_{k-1})| \leq \int_{x_{k-1}}^{x_k} |f|.$$

Apply Hölder's Inequality (Theorem 1 of this chapter) on the interval $[x_{k-1}, x_k]$ to the pair of functions $|f|$, which belongs to $L^p[x_{k-1}, x_k]$, and the function identically equal to 1, which belongs to $L^q[x_{k-1}, x_k]$ because the interval has finite measure. We obtain

$$\int_{x_{k-1}}^{x_k} |f| \cdot 1 \leq \left[\int_{x_{k-1}}^{x_k} |f|^p \right]^{1/p} \left[\int_{x_{k-1}}^{x_k} 1^q \right]^{1/q} = \left[\int_{x_{k-1}}^{x_k} |f|^p \right]^{1/p} (x_k - x_{k-1})^{1/q}.$$

Combining the two displays and raising to the p -th power (legitimate, since $t \mapsto t^p$ is increasing on $[0, \infty)$),

$$|F(x_k) - F(x_{k-1})|^p \leq \left[\int_{x_{k-1}}^{x_k} |f|^p \right] (x_k - x_{k-1})^{p/q} = \left[\int_{x_{k-1}}^{x_k} |f|^p \right] (x_k - x_{k-1})^{p-1},$$

where we used $p/q = p(1 - 1/p) = p - 1$. Since $x_k - x_{k-1} = |x_k - x_{k-1}| > 0$, we may divide by $|x_k - x_{k-1}|^{p-1}$ to get

$$\frac{|F(x_k) - F(x_{k-1})|^p}{|x_k - x_{k-1}|^{p-1}} \leq \int_{x_{k-1}}^{x_k} |f|^p.$$

Now sum over $k = 1, \dots, n$. Since the intervals $[x_{k-1}, x_k]$ have pairwise disjoint interiors and their union is $[a, b]$, the additivity of integration over domains gives

$$\sum_{k=1}^n \frac{|F(x_k) - F(x_{k-1})|^p}{|x_k - x_{k-1}|^{p-1}} \leq \sum_{k=1}^n \int_{x_{k-1}}^{x_k} |f|^p = \int_a^b |f|^p < M.$$

Since the partition was arbitrary and M depends only on f , the proof is complete.

We remark on the mechanism: Hölder's Inequality was applied separately on each subinterval, and the exponent bookkeeping $p/q = p - 1$ is exactly what makes the factor $(x_k - x_{k-1})^{1/q}$ cancel against the denominator $|x_k - x_{k-1}|^{p-1}$, leaving behind on the k -th term only the local mass $\int_{x_{k-1}}^{x_k} |f|^p$. These local masses sum to $\int_a^b |f|^p$ over any partition whatsoever, which is why a single constant M serves for all partitions simultaneously. Note also that the hypothesis $p > 1$ is used only through the existence of the finite conjugate exponent q ; for $p = 1$ the displayed sum reduces to the total variation sums of F , which are bounded by $\int_a^b |f|$ by the same argument.

Problem 7.23. Provide an example of a Cauchy sequence of real numbers that is not rapidly Cauchy.

Solution. Here $X = \mathbb{R}$ normed by the absolute value. Recall the definition: a sequence $\{a_n\}$ in X is rapidly Cauchy provided there is a convergent series of positive numbers $\sum_{k=1}^{\infty} \epsilon_k$ for which $|a_{k+1} - a_k| \leq \epsilon_k^2$ for all k .

Take

$$a_n = \frac{1}{n} \quad \text{for each natural number } n.$$

First, the sequence is Cauchy. Indeed $\{a_n\}$ converges to 0 in $\mathbb{R}$, and by Proposition 4 every convergent sequence in a normed linear space is Cauchy. (Directly: given $\epsilon > 0$ choose $N > 2/\epsilon$; then for $m, n \geq N$ we have $|a_n - a_m| \leq a_n + a_m \leq 2/N < \epsilon$.)

Second, the sequence is not rapidly Cauchy. Suppose, to get a contradiction, that it were. Then there would be a convergent series $\sum_{k=1}^{\infty} \epsilon_k$ of positive numbers with

$$|a_{k+1} - a_k| \leq \epsilon_k^2 \quad \text{for all } k.$$

But

$$|a_{k+1} - a_k| = \left| \frac{1}{k+1} - \frac{1}{k} \right| = \frac{1}{k(k+1)},$$

so that $\epsilon_k^2 \geq \frac{1}{k(k+1)}$ and hence, since $\epsilon_k > 0$,

$$\epsilon_k \geq \frac{1}{\sqrt{k(k+1)}} \geq \frac{1}{k+1} \quad \text{for all } k,$$

the last inequality because $k(k+1) \leq (k+1)^2$. Therefore, for each n ,

$$\sum_{k=1}^n \epsilon_k \geq \sum_{k=1}^n \frac{1}{k+1},$$

and the harmonic series diverges, so the partial sums on the right are unbounded. Thus $\sum_{k=1}^{\infty} \epsilon_k$ diverges, contradicting the choice of $\{\epsilon_k\}$. Hence $\{1/n\}$ is a Cauchy sequence of real numbers that is not rapidly Cauchy.

A remark on what is really going on. The computation isolates the general criterion. A sequence $\{a_n\}$ of real numbers is rapidly Cauchy if and only if $\sum_{k=1}^{\infty} \sqrt{|a_{k+1} - a_k|} < \infty$. For necessity, argue as above: $\epsilon_k \geq \sqrt{|a_{k+1} - a_k|}$. For sufficiency, put $\epsilon_k = \max\{\sqrt{|a_{k+1} - a_k|}, 2^{-k}\} > 0$; then $\epsilon_k^2 \geq |a_{k+1} - a_k|$ and $\sum_k \epsilon_k \leq \sum_k \sqrt{|a_{k+1} - a_k|} + \sum_k 2^{-k} < \infty$. So being rapidly Cauchy is a genuine strengthening of being Cauchy: it forces the increments to be summable at a square-root rate, which the increments $1/[k(k+1)]$ of $\{1/n\}$ fail to be, their square roots being comparable to the harmonic terms $1/k$. This also shows Proposition 5 is sharp: $\{1/n\}$ certainly has rapidly Cauchy subsequences, for instance $\{1/2^k\}$, whose increments are $2^{-(k+1)}$ with $\epsilon_k = 2^{-k/2}$ summable, but the full sequence is not rapidly Cauchy.

Problem 7.24. Let X be a normed linear space. Assume that $\{f_n\} \rightarrow f$ in X , $\{g_n\} \rightarrow g$ in X , and α and β are real numbers. Show that

$$\{\alpha f_n + \beta g_n\} \rightarrow \alpha f + \beta g \text{ in } X.$$

Solution. Since X is a linear space and f_n, f, g_n, g all belong to X , each $\alpha f_n + \beta g_n$ and also $\alpha f + \beta g$ belong to X . So the assertion to be proved is that

$$\lim_{n \rightarrow \infty} \|(\alpha f_n + \beta g_n) - (\alpha f + \beta g)\| = 0.$$

Fix a natural number n . Regrouping in the linear space X ,

$$(\alpha f_n + \beta g_n) - (\alpha f + \beta g) = \alpha[f_n - f] + \beta[g_n - g].$$

By the triangle inequality for the norm and then the positive homogeneity of the norm,

$$\|(\alpha f_n + \beta g_n) - (\alpha f + \beta g)\| \leq \|\alpha[f_n - f]\| + \|\beta[g_n - g]\| = |\alpha| \|f_n - f\| + |\beta| \|g_n - g\|.$$

Now let $\epsilon > 0$. Since $\{f_n\} \rightarrow f$ in X , there is a natural number N_1 such that

$$\|f_n - f\| < \frac{\epsilon}{2(|\alpha| + 1)} \quad \text{for all } n \geq N_1,$$

and since $\{g_n\} \rightarrow g$ in X , there is a natural number N_2 such that

$$\|g_n - g\| < \frac{\epsilon}{2(|\beta| + 1)} \quad \text{for all } n \geq N_2.$$

(The harmless +1 in the denominators covers the possibility that α or β vanishes.) Set $N = \max\{N_1, N_2\}$. Then for all $n \geq N$,

$$\|(\alpha f_n + \beta g_n) - (\alpha f + \beta g)\| \leq |\alpha| \cdot \frac{\epsilon}{2(|\alpha| + 1)} + |\beta| \cdot \frac{\epsilon}{2(|\beta| + 1)} < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon,$$

where we used $|\alpha|/(|\alpha| + 1) < 1$ and $|\beta|/(|\beta| + 1) < 1$.

Since $\epsilon > 0$ was arbitrary,

$$\lim_{n \rightarrow \infty} \|(\alpha f_n + \beta g_n) - (\alpha f + \beta g)\| = 0,$$

that is, $\{\alpha f_n + \beta g_n\} \rightarrow \alpha f + \beta g$ in X .

Equivalently and more briefly: the right-hand side $|\alpha| \|f_n - f\| + |\beta| \|g_n - g\|$ of the displayed estimate is a sequence of nonnegative real numbers that converges to $|\alpha| \cdot 0 + |\beta| \cdot 0 = 0$, by the algebra of limits of sequences of real numbers; the squeeze principle then forces $\|(\alpha f_n + \beta g_n) - (\alpha f + \beta g)\| \rightarrow 0$. Nothing beyond the three norm axioms was used, so the conclusion holds in every normed linear space; in particular it holds in $L^p(E)$ for $1 \leq p \leq \infty$, where it says that if $\{f_n\} \rightarrow f$ and $\{g_n\} \rightarrow g$ with respect to the $L^p(E)$ norm then $\{\alpha f_n + \beta g_n\} \rightarrow \alpha f + \beta g$ with respect to that norm. The special case $\alpha = \beta = 1$ says that addition is continuous with respect to the norm, and the case $\beta = 0$ says that scalar multiplication by a fixed scalar is continuous.

Problem 7.25. Assume that E has finite measure and $1 \leq p_1 < p_2 \leq \infty$. Show that if $\{f_n\} \rightarrow f$ in $L^{p_2}(E)$, then $\{f_n\} \rightarrow f$ in $L^{p_1}(E)$.

Solution. Since $m(E) < \infty$ and $1 \leq p_1 < p_2 \leq \infty$, Corollary 3 of this chapter tells us that

$$L^{p_2}(E) \subseteq L^{p_1}(E), \quad \|h\|_{p_1} \leq c \|h\|_{p_2} \quad \text{for all } h \in L^{p_2}(E),$$

where the constant c depends only on $m(E)$, p_1 and p_2 : namely

$$c = [m(E)]^{\frac{1}{p_1} - \frac{1}{p_2}} \quad \text{if } p_2 < \infty, \quad c = [m(E)]^{\frac{1}{p_1}} \quad \text{if } p_2 = \infty.$$

By hypothesis f and every f_n belong to $L^{p_2}(E)$, so by the inclusion just quoted f and every f_n belong to $L^{p_1}(E)$ as well. Thus the assertion that $\{f_n\} \rightarrow f$ in $L^{p_1}(E)$ makes sense, and what must be shown is that $\|f_n - f\|_{p_1} \rightarrow 0$.

Fix n . The difference $f_n - f$ belongs to $L^{p_2}(E)$, since $L^{p_2}(E)$ is a linear space. Applying the inequality of Corollary 3 to $h = f_n - f$,

$$\|f_n - f\|_{p_1} \leq c \|f_n - f\|_{p_2} \quad \text{for all } n.$$

By hypothesis $\lim_{n \rightarrow \infty} \|f_n - f\|_{p_2} = 0$, and c is a fixed finite constant, so the right-hand side tends to 0. Since $0 \leq \|f_n - f\|_{p_1} \leq c \|f_n - f\|_{p_2}$, the squeeze principle for sequences of real numbers gives

$$\lim_{n \rightarrow \infty} \|f_n - f\|_{p_1} = 0,$$

that is, $\{f_n\} \rightarrow f$ in $L^{p_1}(E)$.

For completeness we recall the proof of the inequality of Corollary 3, since it is the whole content of the exercise. Suppose first $p_2 < \infty$. Put $p = p_2/p_1 > 1$ and let q be its conjugate, so $1/q = 1 - p_1/p_2$. For $h \in L^{p_2}(E)$ the function $|h|^{p_1}$ belongs to $L^p(E)$, because $\int_E (|h|^{p_1})^p = \int_E |h|^{p_2} < \infty$, while $g = \chi_E$ belongs to $L^q(E)$ because $m(E) < \infty$. Hölder's Inequality gives

$$\int_E |h|^{p_1} = \int_E |h|^{p_1} \cdot \chi_E \leq \left[\int_E |h|^{p_2} \right]^{1/p} \left[\int_E \chi_E \right]^{1/q} = \|h\|_{p_2}^{p_1} [m(E)]^{1-p_1/p_2}.$$

Raising to the power $1/p_1$ yields $\|h\|_{p_1} \leq [m(E)]^{\frac{1}{p_1} - \frac{1}{p_2}} \|h\|_{p_2}$. If instead $p_2 = \infty$, then $|h| \leq \|h\|_{\infty}$ a.e. on E , so

$$\int_E |h|^{p_1} \leq \|h\|_{\infty}^{p_1} m(E),$$

and taking $1/p_1$ powers gives $\|h\|_{p_1} \leq [m(E)]^{1/p_1} \|h\|_\infty$.

Note where finiteness of $m(E)$ is used: it is what makes χ_E belong to $L^q(E)$, respectively what makes the last integral finite. The conclusion genuinely fails without it. On $E = \mathbb{R}$, with $p_1 = 1$ and $p_2 = 2$, put $f = 0$ and $f_n = n^{-1}\chi_{[0, n]}$. Then

$$\|f_n\|_2 = \left[\int_0^n n^{-2} \right]^{1/2} = n^{-1/2} \rightarrow 0, \quad \|f_n\|_1 = \int_0^n n^{-1} = 1 \quad \text{for all } n,$$

so $\{f_n\} \rightarrow 0$ in $L^2(\mathbb{R})$ but $\{f_n\}$ does not converge to 0 in $L^1(\mathbb{R})$.

Problem 7.26. (The L^p Dominated Convergence Theorem) Let $\{f_n\}$ be a sequence of measurable functions that converges pointwise a.e. on E to f . For $1 \leq p < \infty$, suppose there is a function g in $L^p(E)$ such that for all n , $|f_n| \leq g$ a.e. on E . Prove that $\{f_n\} \rightarrow f$ in $L^p(E)$.

Solution. By possibly excising from E a set of measure zero we may assume that g is real-valued, that $\{f_n\} \rightarrow f$ pointwise on all of E , and that $|f_n| \leq g$ on all of E for every n : indeed, the union of the countably many exceptional sets, one for the pointwise convergence and one for each of the inequalities $|f_n| \leq g$, together with the set where $g = \infty$ (which has measure zero since $g \in L^p(E)$), is a set of measure zero, and excising a set of measure zero changes neither the hypotheses nor any of the integrals below.

First, every function in sight belongs to $L^p(E)$. Each f_n is measurable and $|f_n|^p \leq g^p$ on E , and g^p is integrable over E because $g \in L^p(E)$; by the monotonicity of integration for nonnegative measurable functions, $\int_E |f_n|^p \leq \int_E g^p < \infty$, so $f_n \in L^p(E)$. Moreover f is measurable, being the pointwise limit on E of the sequence of measurable functions $\{f_n\}$ (Proposition 9 of Chapter 3), and letting $n \rightarrow \infty$ in the inequality $|f_n(x)| \leq g(x)$ gives

$$|f(x)| \leq g(x) \quad \text{for all } x \in E.$$

Hence $\int_E |f|^p \leq \int_E g^p < \infty$ and $f \in L^p(E)$ too.

Now consider the sequence of nonnegative measurable functions $\{h_n\}$ defined by

$$h_n = |f_n - f|^p \quad \text{on } E.$$

Two observations.

- (i) $\{h_n\} \rightarrow 0$ pointwise on E . For each $x \in E$ we have $f_n(x) \rightarrow f(x)$ in $\mathbb{R}$, hence $|f_n(x) - f(x)| \rightarrow 0$, and since $t \mapsto t^p$ is continuous on $[0, \infty)$, $h_n(x) = |f_n(x) - f(x)|^p \rightarrow 0$.
- (ii) $\{h_n\}$ is dominated by a fixed integrable function. For each $x \in E$ and each n ,

$$|f_n(x) - f(x)| \leq |f_n(x)| + |f(x)| \leq g(x) + g(x) = 2g(x),$$

so that

$$0 \leq h_n(x) = |f_n(x) - f(x)|^p \leq 2^p [g(x)]^p.$$

The function $2^p g^p$ is integrable over E , again because g belongs to $L^p(E)$.

By the Lebesgue Dominated Convergence Theorem of Chapter 4, applied to the sequence $\{h_n\}$ of measurable functions on E , which converges pointwise on E to 0 and is dominated in absolute value by the integrable function $2^p g^p$,

$$\lim_{n \rightarrow \infty} \int_E |f_n - f|^p = \lim_{n \rightarrow \infty} \int_E h_n = \int_E 0 = 0.$$

Taking p -th roots, $\lim_{n \rightarrow \infty} \|f_n - f\|_p = 0$, that is,

$$\{f_n\} \rightarrow f \text{ in } L^p(E).$$

Two remarks. First, no assumption is made about $m(E)$; the domination by a single L^p function supplies both the uniform integrability and the tightness of $\{|f_n - f|^p\}$ that would be needed to invoke the Vitali Convergence Theorem instead. Second, the statement fails for $p = \infty$ in this form: on $E = [0, 1]$ the sequence $f_n = \chi_{[0, 1/n]}$ is dominated by $g = \chi_{[0, 1]} \in L^\infty[0, 1]$ and converges pointwise a.e. to $f = 0$, but $\|f_n - f\|_\infty = 1$ for every n .

Problem 7.27. For E a measurable set and $1 \leq p < \infty$, assume $\{f_n\} \rightarrow f$ in $L^p(E)$. Show that there is a subsequence $\{f_{n_k}\}$ and a function $g \in L^p(E)$ for which $|f_{n_k}| \leq g$ a.e. on E for all k .

Solution. By possibly excising from E a set of measure zero we may assume that f and each f_n are real-valued on E ; this is legitimate since a function in $L^p(E)$ is finite a.e. on E and there are countably many functions in question.

Since $\lim_{n \rightarrow \infty} \|f_n - f\|_p = 0$, we may choose inductively a strictly increasing sequence of natural numbers $\{n_k\}$ for which

$$\|f_{n_k} - f\|_p \leq \frac{1}{2^k} \quad \text{for all } k.$$

Indeed, having chosen $n_1 < \dots < n_{k-1}$, the convergence provides an index N with $\|f_n - f\|_p \leq 2^{-k}$ for all $n \geq N$, and we take $n_k = \max\{N, n_{k-1} + 1\}$.

Define, for each natural number N , the nonnegative measurable function

$$g_N = |f| + \sum_{k=1}^N |f_{n_k} - f| \quad \text{on } E,$$

and define

$$g(x) = \lim_{N \rightarrow \infty} g_N(x) = |f(x)| + \sum_{k=1}^{\infty} |f_{n_k}(x) - f(x)| \quad \text{for } x \in E,$$

the limit existing in $[0, \infty]$ because $\{g_N(x)\}$ is an increasing sequence of nonnegative real numbers. As a pointwise limit of measurable functions, g is measurable, by Proposition 9 of Chapter 3.

We claim $g \in L^p(E)$. Each g_N belongs to $L^p(E)$ and, by Minkowski's Inequality applied N times,

$$\|g_N\|_p \leq \|f\|_p + \sum_{k=1}^N \|f_{n_k} - f\|_p \leq \|f\|_p + \sum_{k=1}^N \frac{1}{2^k} \leq \|f\|_p + 1 =: C,$$

a bound independent of N . Now $\{g_N^p\}$ is an increasing sequence of nonnegative measurable functions on E converging pointwise on E to g^p (the map $t \mapsto t^p$ being increasing and continuous on $[0, \infty]$). By the Monotone Convergence Theorem of Chapter 4,

$$\int_E g^p = \lim_{N \rightarrow \infty} \int_E g_N^p = \lim_{N \rightarrow \infty} \|g_N\|_p^p \leq C^p < \infty.$$

Hence g^p is integrable over E . In particular g is finite a.e. on E ; redefining g to be 0 on the set of measure zero where it takes the value ∞ changes nothing in what follows, and with this convention g is a real-valued measurable function on E with $\int_E |g|^p < \infty$, so

$$g \in L^p(E).$$

Finally, the domination. Fix k and $x \in E$. Since $|f_{n_k}(x) - f(x)|$ is one of the terms of the series defining $g(x)$, and all terms are nonnegative,

$$|f_{n_k}(x)| \leq |f(x)| + |f_{n_k}(x) - f(x)| \leq |f(x)| + \sum_{j=1}^{\infty} |f_{n_j}(x) - f(x)| = g(x).$$

This holds for every $x \in E$ outside the set of measure zero on which g was redefined, and therefore

$$|f_{n_k}| \leq g \quad \text{a.e. on } E, \quad \text{for all } k,$$

as required.

Observe as a by-product that the same g dominates $|f|$, and that on $E \sim \{g = \infty\}$ the series $\sum_k |f_{n_k} - f|$ converges, so $\{f_{n_k}\} \rightarrow f$ pointwise a.e. on E . This recovers, along the way, the last assertion of the Riesz-Fischer Theorem: a sequence convergent in $L^p(E)$ has a subsequence convergent pointwise a.e. on E to the same limit.

Problem 7.28. Assume E has finite measure and $1 \leq p < \infty$. Suppose $\{f_n\}$ is a sequence of measurable functions that converges pointwise a.e. on E to f . For $1 \leq p < \infty$, show that $\{f_n\} \rightarrow f$ in $L^p(E)$ if there is a $\theta > 0$ such that $\{f_n\}$ belongs to and is bounded as a subset of $L^{p+\theta}(E)$.

Solution. Write $r = p + \theta$, so $1 \leq p < r < \infty$. By hypothesis every f_n belongs to $L^r(E)$ and there is a constant $M \geq 0$ with

$$\|f_n\|_r \leq M \quad \text{for all } n.$$

Since $m(E) < \infty$, Corollary 3 of this chapter gives $L^r(E) \subseteq L^p(E)$, so $\{f_n\}$ is in particular a sequence in $L^p(E)$.

Step 1: the limit f belongs to $L^p(E)$.

The function f is measurable, being the pointwise limit a.e. on E of measurable functions (Proposition 9 of Chapter 3). The sequence of nonnegative measurable functions $\{|f_n|^r\}$ converges pointwise a.e. on E to $|f|^r$, so Fatou's Lemma of Chapter 4 gives

$$\int_E |f|^r \leq \liminf_{n \rightarrow \infty} \int_E |f_n|^r = \liminf_{n \rightarrow \infty} \|f_n\|_r^r \leq M^r < \infty.$$

Hence $f \in L^r(E)$, and again by Corollary 3, $f \in L^p(E)$.

Step 2: $\{|f_n|^p\}$ is uniformly integrable over E .

Set

$$s = \frac{r}{p} = \frac{p + \theta}{p} > 1,$$

and consider the family $\mathcal{F} = \{|f_n|^p : n \in \mathbb{N}\}$ of functions on E . Each member belongs to $L^s(E)$, since

$$\int_E (|f_n|^p)^s = \int_E |f_n|^r \leq M^r < \infty,$$

and, taking s -th roots,

$$\| |f_n|^p \|_s = \left[\int_E |f_n|^r \right]^{p/r} = \|f_n\|_r^p \leq M^p \quad \text{for all } n.$$

So $\mathcal{F}$ is a family of functions in $L^s(E)$ with $1 < s < \infty$ that is bounded in $L^s(E)$ by the constant M^p . By Corollary 2 of this chapter, $\mathcal{F}$ is uniformly integrable over E .

For the reader who prefers the estimate in the open: let t be the conjugate of s , so $1/t = 1 - p/r = \theta/r$. If $A \subseteq E$ is measurable, Hölder's Inequality applied to $|f_n|^p \in L^s(A)$ and $\chi_A \in L^t(A)$ gives

$$\int_A |f_n|^p \leq \left[\int_A |f_n|^r \right]^{p/r} [m(A)]^{1/t} \leq M^p [m(A)]^{\theta/r},$$

so given $\epsilon > 0$ the choice $\delta = (\epsilon/(M^p + 1))^{r/\theta}$ responds to the ϵ challenge, uniformly in n .

Step 3: $\{|f_n|^p\}$ is tight over E .

Tightness over E requires, for each $\epsilon > 0$, a measurable subset $E_0 \subseteq E$ of finite measure with $\int_{E \sim E_0} |f_n|^p < \epsilon$ for all n . Since $m(E) < \infty$ by hypothesis, take $E_0 = E$; then $E \sim E_0 = \emptyset$ and the integrals are 0. So the family is tight over E , trivially.

Step 4: conclusion.

We have a sequence $\{f_n\}$ in $L^p(E)$ that converges pointwise a.e. on E to the function f , which belongs to $L^p(E)$ by Step 1, and by Steps 2 and 3 the sequence $\{|f_n|^p\}$ is uniformly integrable and tight over E . Theorem 8 of this chapter therefore yields

$$\{f_n\} \rightarrow f \text{ in } L^p(E).$$

Two remarks on the hypotheses. The finiteness of $m(E)$ cannot be dropped: on $E = \mathbb{R}$ with $p = 1$ and $\theta = 1$, the sequence $f_n = n^{-1} \chi_{[0,n]}$ satisfies $\|f_n\|_2 = n^{-1/2} \leq 1$ and converges pointwise to $f = 0$, yet $\|f_n - f\|_1 = 1$ for all n ; here tightness fails. Nor can the higher-integrability bound be dropped: on $E = [0, 1]$ the sequence $f_n = n \chi_{(0, 1/n]}$ converges pointwise on $[0, 1]$ to 0 and is bounded in no $L^{1+\theta}[0, 1]$, and indeed $\|f_n\|_1 = 1$ for all n , so $\{f_n\}$ does not converge to 0 in $L^1[0, 1]$; here uniform integrability fails. The role of the exponent gap $\theta > 0$ is exactly to buy, via Hölder's Inequality, the uniform smallness of $\int_A |f_n|^p$ on sets A of small measure.

7.5 Problems 7.29–7.35

Problem 7.29. Consider the linear space of polynomials on $[a, b]$ normed by $\|\cdot\|_{\max}$ norm. Is this normed linear space a Banach space?

Solution. No. The space is not complete, so it is not a Banach space.

Write $\mathcal{P}$ for the linear space of (restrictions to $[a, b]$ of) real polynomials, normed by

$$\|p\|_{\max} = \max_{x \in [a, b]} |p(x)|.$$

This is a norm: the maximum is attained since a polynomial is continuous on the compact interval $[a, b]$, positive homogeneity and the triangle inequality are inherited from the absolute value, and $\|p\|_{\max} = 0$ forces p to vanish at every point of $[a, b]$, hence at infinitely many points, so p is the zero polynomial. Thus $\mathcal{P}$ is a linear subspace of $C[a, b]$ carrying the maximum norm, and, as noted in this section, convergence with respect to $\|\cdot\|_{\max}$ is exactly uniform convergence on $[a, b]$.

We exhibit a Cauchy sequence in $\mathcal{P}$ that fails to converge in $\mathcal{P}$. For $x \in [a, b]$ put $t = t(x) = (x - a)/(b - a)$, so that t ranges over $[0, 1]$, and define, for each natural number n ,

$$p_n(x) = \sum_{k=0}^n \frac{1}{k!} \left(\frac{x-a}{b-a} \right)^k.$$

Each p_n is a polynomial in x , so p_n belongs to $\mathcal{P}$.

The sequence $\{p_n\}$ is Cauchy in $\mathcal{P}$. Indeed, for $m > n$ and $x \in [a, b]$,

$$|p_m(x) - p_n(x)| = \left| \sum_{k=n+1}^m \frac{t^k}{k!} \right| \leq \sum_{k=n+1}^m \frac{1}{k!} \leq \sum_{k=n+1}^{\infty} \frac{1}{k!},$$

since $0 \leq t \leq 1$. Hence

$$\|p_m - p_n\|_{\max} \leq \sum_{k=n+1}^{\infty} \frac{1}{k!} \quad \text{for all } m > n.$$

The series $\sum_{k=0}^{\infty} 1/k!$ converges (to e), so its tails tend to 0; given $\epsilon > 0$, choose N with $\sum_{k=N+1}^{\infty} 1/k! < \epsilon$ and then $\|p_m - p_n\|_{\max} < \epsilon$ for all $m, n \geq N$. Thus $\{p_n\}$ is Cauchy.

Suppose, to get a contradiction, that $\{p_n\}$ converged in $\mathcal{P}$ to some polynomial q . Convergence in the maximum norm implies uniform, hence pointwise, convergence on $[a, b]$. But for each fixed $x \in [a, b]$, $p_n(x)$ is the n -th partial sum of the exponential series evaluated at $t = (x - a)/(b - a)$, so

$$\lim_{n \rightarrow \infty} p_n(x) = e^{(x-a)/(b-a)}.$$

By uniqueness of pointwise limits,

$$q(x) = e^{(x-a)/(b-a)} \quad \text{for all } x \in [a, b].$$

Since the right-hand side is everywhere positive, q is not the zero polynomial; let d be its degree. Differentiate the last identity $d+1$ times on the open interval (a, b) . The left-hand side gives $q^{(d+1)} \equiv 0$, because differentiating a polynomial of degree d more than d times yields 0. The right-hand side gives

$$\frac{d^{d+1}}{dx^{d+1}} e^{(x-a)/(b-a)} = \frac{1}{(b-a)^{d+1}} e^{(x-a)/(b-a)} > 0 \quad \text{for all } x \in (a, b).$$

This is a contradiction. Hence no polynomial q is the limit of $\{p_n\}$ in $\mathcal{P}$.

Therefore $\mathcal{P}$ contains a Cauchy sequence with no limit in $\mathcal{P}$, so $\mathcal{P}$, normed by the maximum norm, is not complete and is not a Banach space.

A second proof, once one knows that $C[a, b]$ with the maximum norm is complete (Problem 31): the Weierstrass Approximation Theorem, quoted in Section 7.4, says $\mathcal{P}$ is dense in $C[a, b]$, while $\mathcal{P} \neq C[a, b]$, since for instance $x \mapsto e^x$ is continuous but is not a polynomial (by the derivative argument just given). A complete subspace of a normed linear space is closed in it, and a dense proper subset is not closed. Hence $\mathcal{P}$ is not complete.

Problem 7.30. Let $\{f_n\}$ be a sequence in $C[a, b]$ and $\sum_{k=1}^{\infty} a_k$ a convergent series of positive numbers such that

$$\|f_{k+1} - f_k\|_{\max} \leq a_k \quad \text{for all } k.$$

Prove that

$$|f_{n+k}(x) - f_k(x)| \leq \|f_{n+k} - f_k\|_{\max} \leq \sum_{j=n}^{\infty} a_j \quad \text{for all } k, n \text{ and all } x \in [a, b].$$

Conclude that there is a function $f \in C[a, b]$ such that $\{f_n\} \rightarrow f$ uniformly on $[a, b]$.

Solution. A remark on the printed display first. As it stands the subscripts do not match: with k fixed and n large the left side compares f_{n+k} with f_k , and telescoping only bounds that by $\sum_{j=k}^{\infty} a_j$, which need not be at most $\sum_{j=n}^{\infty} a_j$ when $n > k$. The intended inequality is the one recorded as (6) in this section, namely with the second index n rather than k :

$$|f_{n+k}(x) - f_n(x)| \leq \|f_{n+k} - f_n\|_{\max} \leq \sum_{j=n}^{\infty} a_j \quad \text{for all } n, k \text{ and all } x \in [a, b].$$

That is what we prove; the printed form follows from it whenever $k \geq n$, since then $\sum_{j=k}^{\infty} a_j \leq \sum_{j=n}^{\infty} a_j$. Step 1: the pointwise bound. By the very definition of the maximum norm on $C[a, b]$, for any g in $C[a, b]$ and any x in $[a, b]$,

$$|g(x)| \leq \max_{y \in [a, b]} |g(y)| = \|g\|_{\max}.$$

Applying this to $g = f_{n+k} - f_n$, which belongs to $C[a, b]$ because $C[a, b]$ is a linear space, gives

$$|f_{n+k}(x) - f_n(x)| \leq \|f_{n+k} - f_n\|_{\max} \quad \text{for all } x \in [a, b].$$

Step 2: the norm bound. Fix natural numbers n and k . Telescoping,

$$f_{n+k} - f_n = \sum_{j=n}^{n+k-1} [f_{j+1} - f_j],$$

so by the triangle inequality for the norm, applied $k-1$ times, and the hypothesis $\|f_{j+1} - f_j\|_{\max} \leq a_j$,

$$\|f_{n+k} - f_n\|_{\max} \leq \sum_{j=n}^{n+k-1} \|f_{j+1} - f_j\|_{\max} \leq \sum_{j=n}^{n+k-1} a_j \leq \sum_{j=n}^{\infty} a_j,$$

the last inequality because the a_j are positive, so that a partial sum of a tail is at most the whole tail. Combining Steps 1 and 2 gives the asserted chain of inequalities.

Step 3: construction of the limit function. Since $\sum_{k=1}^{\infty} a_k$ converges, its tails

$$R_n = \sum_{j=n}^{\infty} a_j$$

are finite and $\lim_{n \rightarrow \infty} R_n = 0$.

Fix $x \in [a, b]$. By Steps 1 and 2, $|f_{n+k}(x) - f_n(x)| \leq R_n$ for all n and k ; since $R_n \rightarrow 0$, the sequence of real numbers $\{f_n(x)\}$ is Cauchy. The real numbers are complete, so this sequence converges. Define

$$f(x) = \lim_{n \rightarrow \infty} f_n(x) \quad \text{for } x \in [a, b].$$

Step 4: the convergence is uniform. Fix n and $x \in [a, b]$ and let $k \rightarrow \infty$ in the inequality $|f_{n+k}(x) - f_n(x)| \leq R_n$. Since $f_{n+k}(x) \rightarrow f(x)$ and the absolute value is continuous,

$$|f(x) - f_n(x)| \leq R_n \quad \text{for all } x \in [a, b] \text{ and all } n.$$

The bound R_n does not depend on x and tends to 0: given $\epsilon > 0$, choose N with $R_n < \epsilon$ for $n \geq N$; then $|f(x) - f_n(x)| < \epsilon$ for all $n \geq N$ and all $x \in [a, b]$. Thus $\{f_n\} \rightarrow f$ uniformly on $[a, b]$.
 Step 5: f is continuous. This is the standard $\epsilon/3$ argument. Let $x_0 \in [a, b]$ and $\epsilon > 0$. Choose n with $\sup_{x \in [a, b]} |f(x) - f_n(x)| \leq R_n < \epsilon/3$. Since f_n is continuous at x_0 , there is a $\delta > 0$ such that $|f_n(x) - f_n(x_0)| < \epsilon/3$ whenever $x \in [a, b]$ and $|x - x_0| < \delta$. For such x ,

$$|f(x) - f(x_0)| \leq |f(x) - f_n(x)| + |f_n(x) - f_n(x_0)| + |f_n(x_0) - f(x_0)| < \frac{\epsilon}{3} + \frac{\epsilon}{3} + \frac{\epsilon}{3} = \epsilon.$$

Hence f is continuous at x_0 ; as x_0 was arbitrary, f belongs to $C[a, b]$.

Therefore there is a function $f \in C[a, b]$ with $\{f_n\} \rightarrow f$ uniformly on $[a, b]$, that is, $\{f_n\} \rightarrow f$ in $C[a, b]$ normed by the maximum norm, and moreover $\|f - f_n\|_{\max} \leq \sum_{j=n}^{\infty} a_j$ for every n .

Problem 7.31. Use the preceding problem to show that $C[a, b]$, normed by the maximum norm, is a Banach space.

Solution. Recall first that $C[a, b]$, the linear space of continuous real-valued functions on the closed, bounded interval $[a, b]$, is normed by

$$\|f\|_{\max} = \max_{x \in [a, b]} |f(x)|,$$

the maximum being attained by the Extreme Value Theorem. We must show that every Cauchy sequence in $C[a, b]$ converges to a function in $C[a, b]$.

Let $\{f_n\}$ be a Cauchy sequence in $C[a, b]$.

Step 1: extraction of a subsequence with rapidly decreasing successive differences. We construct inductively a strictly increasing sequence of natural numbers $\{n_k\}$ such that

$$\|f_{n_{k+1}} - f_{n_k}\|_{\max} \leq \left(\frac{1}{2}\right)^k \quad \text{for all } k.$$

Since $\{f_n\}$ is Cauchy, for each natural number k the Cauchy property applied with $\epsilon = (1/2)^k$ supplies a natural number M_k such that

$$\|f_n - f_m\|_{\max} \leq \left(\frac{1}{2}\right)^k \quad \text{for all } n, m \geq M_k.$$

Set $n_1 = M_1$ and, inductively, $n_{k+1} = \max\{M_{k+1}, n_k + 1\}$. Then $\{n_k\}$ is strictly increasing, and $n_k \geq M_k$ for every k (for $k = 1$ by definition, and for $k \geq 2$ because $n_k = \max\{M_k, n_{k-1} + 1\} \geq M_k$). Since both n_{k+1} and n_k are at least $n_k \geq M_k$, the displayed estimate with this k gives

$$\|f_{n_{k+1}} - f_{n_k}\|_{\max} \leq \left(\frac{1}{2}\right)^k.$$

Step 2: the subsequence converges in $C[a, b]$. Put $g_k = f_{n_k}$ and $a_k = (1/2)^k$. Then $\{g_k\}$ is a sequence in $C[a, b]$, the a_k are positive, the geometric series $\sum_{k=1}^{\infty} (1/2)^k$ converges (to 1), and by Step 1

$$\|g_{k+1} - g_k\|_{\max} \leq a_k \quad \text{for all } k.$$

These are exactly the hypotheses of the preceding problem. Hence there is a function f in $C[a, b]$ such that $\{g_k\} \rightarrow f$ uniformly on $[a, b]$. As observed at the start of this section, for a sequence and a function in $C[a, b]$, convergence in the maximum norm is the same as uniform convergence on $[a, b]$. Therefore the subsequence $\{f_{n_k}\}$ of $\{f_n\}$ converges to f in $C[a, b]$.

Step 3: the whole sequence converges. The sequence $\{f_n\}$ is Cauchy in the normed linear space $C[a, b]$ and has a subsequence that converges in $C[a, b]$ to f . By Proposition 4 of this chapter, a Cauchy sequence in a normed linear space converges if it has a convergent subsequence. Hence $\{f_n\} \rightarrow f$ in $C[a, b]$.

Since every Cauchy sequence in $C[a, b]$ converges to a function in $C[a, b]$, the space $C[a, b]$ is complete, that is, $C[a, b]$ normed by the maximum norm is a Banach space.

Problem 7.32. Let $\{f_n\}$ be a sequence in $L^\infty(E)$ and $\sum_{k=1}^\infty a_k$ a convergent series of positive numbers such that

$$\|f_{k+1} - f_k\|_\infty \leq a_k \quad \text{for all } k.$$

Prove that there is a subset E_0 of E which has measure zero and

$$|f_{n+k}(x) - f_k(x)| \leq \|f_{n+k} - f_k\|_\infty \leq \sum_{j=n}^\infty a_j \quad \text{for all } k, n \text{ and all } x \in E \sim E_0.$$

Conclude that there is a function $f \in L^\infty(E)$ such that $\{f_n\} \rightarrow f$ uniformly on $E \sim E_0$.

Solution. As in the preceding problem, the subscripts in the printed display are misaligned: what is true, and what is needed, is the inequality with second index n ,

$$|f_{n+k}(x) - f_n(x)| \leq \|f_{n+k} - f_n\|_\infty \leq \sum_{j=n}^\infty a_j \quad \text{for all } n, k \text{ and all } x \in E \sim E_0,$$

which is the analogue for $L^\infty(E)$ of (6) of this section. This is what we prove. (The printed form follows for $k \geq n$, since then $\sum_{j=k}^\infty a_j \leq \sum_{j=n}^\infty a_j$.)

Step 1: choice of the exceptional set E_0 . Recall from Section 7.1 that for g in $L^\infty(E)$ the essential supremum $\|g\|_\infty$, defined as the infimum of the essential upper bounds of $|g|$, is itself an essential upper bound for $|g|$; indeed, if $M_i \downarrow \|g\|_\infty$ with each M_i an essential upper bound, then $\{x \in E \mid |g(x)| > \|g\|_\infty\} = \bigcup_i \{x \in E \mid |g(x)| > M_i\}$ is a countable union of sets of measure zero. Thus

$$|g(x)| \leq \|g\|_\infty \quad \text{for almost all } x \in E.$$

Consequently, for each natural number n , the set

$$A_n = \{x \in E \mid |f_n(x)| > \|f_n\|_\infty\}$$

has measure zero, and for all natural numbers n and k the set

$$B_{n,k} = \{x \in E \mid |f_{n+k}(x) - f_n(x)| > \|f_{n+k} - f_n\|_\infty\}$$

has measure zero, since $f_{n+k} - f_n$ belongs to $L^\infty(E)$ ($L^\infty(E)$ is a linear space). Define

$$E_0 = \left(\bigcup_{n=1}^\infty A_n \right) \cup \left(\bigcup_{n=1}^\infty \bigcup_{k=1}^\infty B_{n,k} \right).$$

This is a countable union of sets of measure zero, so by the countable subadditivity of measure, $m(E_0) = 0$. Note that on $E \sim E_0$ every f_n is finite, since there $|f_n(x)| \leq \|f_n\|_\infty < \infty$; hence all the differences below are honest differences of real numbers.

Step 2: the two inequalities. Fix n and k . Since $x \in E \sim E_0$ implies $x \notin B_{n,k}$, we have

$$|f_{n+k}(x) - f_n(x)| \leq \|f_{n+k} - f_n\|_\infty \quad \text{for all } x \in E \sim E_0.$$

For the second inequality, telescope and use the triangle inequality for $\|\cdot\|_\infty$, exactly as in (6) of this section:

$$f_{n+k} - f_n = \sum_{j=n}^{n+k-1} [f_{j+1} - f_j], \quad \|f_{n+k} - f_n\|_\infty \leq \sum_{j=n}^{n+k-1} \|f_{j+1} - f_j\|_\infty \leq \sum_{j=n}^{n+k-1} a_j \leq \sum_{j=n}^\infty a_j,$$

the last step because the a_j are positive, so a partial sum of a tail is at most the whole tail. This establishes the asserted chain of inequalities on $E \sim E_0$.

Step 3: construction of f . Since $\sum_{k=1}^{\infty} a_k$ converges, its tails $R_n = \sum_{j=n}^{\infty} a_j$ are finite and $R_n \rightarrow 0$. Fix x in $E \sim E_0$. By Step 2, $|f_{n+k}(x) - f_n(x)| \leq R_n$ for all n, k , so $\{f_n(x)\}$ is a Cauchy sequence of real numbers, hence convergent since $\mathbb{R}$ is complete. Define

$$f(x) = \lim_{n \rightarrow \infty} f_n(x) \text{ for } x \in E \sim E_0, \quad f(x) = 0 \text{ for } x \in E_0.$$

Each f_n is measurable, hence so is $f_n \cdot \chi_{E \sim E_0}$, and f is the pointwise limit on E of the measurable functions $f_n \cdot \chi_{E \sim E_0}$; by Proposition 9 of Chapter 3, a pointwise limit of a sequence of measurable functions is measurable, so f is measurable on E .

Step 4: f belongs to $L^\infty(E)$ and the convergence is uniform off E_0 . Fix n and $x \in E \sim E_0$ and let $k \rightarrow \infty$ in $|f_{n+k}(x) - f_n(x)| \leq R_n$; by continuity of the absolute value,

$$|f(x) - f_n(x)| \leq R_n \text{ for all } x \in E \sim E_0 \text{ and all } n.$$

Taking $n = 1$ we get, for $x \in E \sim E_0$,

$$|f(x)| \leq |f_1(x)| + R_1 \leq \|f_1\|_\infty + \sum_{j=1}^{\infty} a_j < \infty,$$

so $|f|$ is bounded above by the constant $\|f_1\|_\infty + \sum_{j=1}^{\infty} a_j$ except on the set E_0 of measure zero. Thus f is measurable and essentially bounded, that is, f belongs to $L^\infty(E)$.

Finally, the bound R_n in the displayed inequality is independent of x and tends to 0: given $\epsilon > 0$ choose N with $R_n < \epsilon$ for $n \geq N$; then $|f(x) - f_n(x)| < \epsilon$ for all $n \geq N$ and all $x \in E \sim E_0$. Hence $\{f_n\} \rightarrow f$ uniformly on $E \sim E_0$. Since E_0 has measure zero, R_n is an essential upper bound for $|f - f_n|$, so $\|f - f_n\|_\infty \leq R_n \rightarrow 0$ and $\{f_n\} \rightarrow f$ in $L^\infty(E)$ as well.

Problem 7.33. Use the preceding problem to show that $L^\infty(E)$ is a Banach space.

Solution. Recall that $L^\infty(E)$ is the linear space of (equivalence classes, under equality almost everywhere, of) essentially bounded measurable functions on E , normed by the essential supremum

$$\|f\|_\infty = \text{ess sup}_E |f| = \inf\{M \geq 0 \mid |f| \leq M \text{ a.e. on } E\},$$

which was shown in Section 7.1 to be a norm on $L^\infty(E)$. We must show that every Cauchy sequence in $L^\infty(E)$ converges, with respect to $\|\cdot\|_\infty$, to a function in $L^\infty(E)$.

Let $\{f_n\}$ be a Cauchy sequence in $L^\infty(E)$.

Step 1: extraction of a subsequence with rapidly decreasing successive differences. Exactly as in Problem 31, we construct inductively a strictly increasing sequence of natural numbers $\{n_k\}$ with

$$\|f_{n_{k+1}} - f_{n_k}\|_\infty \leq \left(\frac{1}{2}\right)^k \text{ for all } k.$$

Indeed, since $\{f_n\}$ is Cauchy, for each natural number k there is a natural number M_k such that $\|f_n - f_m\|_\infty \leq (1/2)^k$ for all $n, m \geq M_k$. Set $n_1 = M_1$ and, inductively, $n_{k+1} = \max\{M_{k+1}, n_k + 1\}$. Then $\{n_k\}$ is strictly increasing and $n_{k+1} > n_k \geq M_k$, so $\|f_{n_{k+1}} - f_{n_k}\|_\infty \leq (1/2)^k$.

Step 2: the subsequence converges. Put $g_k = f_{n_k}$ and $a_k = (1/2)^k$. Then $\{g_k\}$ is a sequence in $L^\infty(E)$, the numbers a_k are positive, the geometric series $\sum_{k=1}^{\infty} (1/2)^k$ converges, and $\|g_{k+1} - g_k\|_\infty \leq a_k$ for all k . These are the hypotheses of the preceding problem. Hence there is a set $E_0 \subseteq E$ of measure zero and a function f in $L^\infty(E)$ such that $\{g_k\} \rightarrow f$ uniformly on $E \sim E_0$. As observed at the start of this section, for a sequence and a function in $L^\infty(E)$, convergence in $L^\infty(E)$ is equivalent to uniform convergence on the complement of a set of measure zero. Therefore the subsequence $\{f_{n_k}\}$ converges to f in $L^\infty(E)$. (Concretely, the estimate established in the preceding problem gives $\|f - g_k\|_\infty \leq \sum_{j=k}^{\infty} (1/2)^j = (1/2)^{k-1} \rightarrow 0$.)

Step 3: the whole sequence converges. The sequence $\{f_n\}$ is Cauchy in the normed linear space $L^\infty(E)$ and possesses a subsequence converging in $L^\infty(E)$ to f . By Proposition 4 of this chapter, $\{f_n\} \rightarrow f$ in $L^\infty(E)$.

Thus every Cauchy sequence in $L^\infty(E)$ converges to a function in $L^\infty(E)$: the space $L^\infty(E)$ is complete, hence a Banach space. This is the assertion that the text of Section 7.3 makes and defers to the present problem; note that it is not covered by the Riesz-Fischer Theorem or by Theorem 6, both of which are stated only for $1 \leq p < \infty$.

Problem 7.34. Prove that for $1 \leq p \leq \infty$, ℓ^p is a Banach space.

Solution. Here ℓ^p , for $1 \leq p < \infty$, is the linear space of real sequences $a = (a_1, a_2, \dots)$ for which $\sum_{k=1}^\infty |a_k|^p < \infty$, normed by

$$\|a\|_p = \left(\sum_{k=1}^\infty |a_k|^p \right)^{1/p},$$

and ℓ^∞ is the linear space of bounded real sequences, normed by $\|a\|_\infty = \sup_k |a_k|$. That these are linear spaces and that $\|\cdot\|_p$ is a norm on ℓ^p was established in Problem 12 (Minkowski's Inequality in ℓ^p); for $p = \infty$ the norm properties are immediate from those of the absolute value together with $\sup_k |a_k + b_k| \leq \sup_k |a_k| + \sup_k |b_k|$.

Throughout, write a sequence in ℓ^p as $\{a^{(n)}\}_{n=1}^\infty$, where $a^{(n)} = (a_1^{(n)}, a_2^{(n)}, \dots)$, so that $a_k^{(n)}$ is the k -th term of the n -th sequence. The key observation, valid for every p with $1 \leq p \leq \infty$, is that for each fixed index k the coordinate functional is bounded by the norm:

$$|a_k| \leq \|a\|_p \quad \text{for all } a \in \ell^p \text{ and all } k.$$

For $p = \infty$ this is the definition of the supremum; for $p < \infty$ it holds because $|a_k|^p \leq \sum_{i=1}^\infty |a_i|^p$ and $t \mapsto t^{1/p}$ is increasing on $[0, \infty)$.

Case $1 \leq p < \infty$. Let $\{a^{(n)}\}$ be a Cauchy sequence in ℓ^p .

Step 1: the coordinatewise limit. Fix k . By the observation above applied to $a^{(n)} - a^{(m)}$,

$$|a_k^{(n)} - a_k^{(m)}| \leq \|a^{(n)} - a^{(m)}\|_p \quad \text{for all } n, m.$$

Since $\{a^{(n)}\}$ is Cauchy in ℓ^p , the right side is small for large n, m , so $\{a_k^{(n)}\}_n$ is a Cauchy sequence of real numbers. The real numbers are complete, so this sequence converges; define

$$a_k = \lim_{n \rightarrow \infty} a_k^{(n)}, \quad a = (a_1, a_2, \dots).$$

Step 2: $a^{(n)} - a$ lies in ℓ^p with small norm. Let $\epsilon > 0$. Choose a natural number N such that

$$\|a^{(n)} - a^{(m)}\|_p \leq \epsilon \quad \text{for all } n, m \geq N,$$

that is,

$$\sum_{k=1}^\infty |a_k^{(n)} - a_k^{(m)}|^p \leq \epsilon^p \quad \text{for all } n, m \geq N.$$

Fix $n \geq N$ and a natural number K . Discarding all but the first K terms of this series of nonnegative numbers gives

$$\sum_{k=1}^K |a_k^{(n)} - a_k^{(m)}|^p \leq \epsilon^p \quad \text{for all } m \geq N.$$

This is a finite sum, and by Step 1 each summand converges as $m \rightarrow \infty$ to $|a_k^{(n)} - a_k|^p$ (the maps $t \mapsto |t|$ and $t \mapsto t^p$ are continuous). Letting $m \rightarrow \infty$ therefore yields

$$\sum_{k=1}^K |a_k^{(n)} - a_k|^p \leq \epsilon^p.$$

The bound is independent of K ; letting $K \rightarrow \infty$, the increasing sequence of partial sums has a finite limit and

$$\sum_{k=1}^{\infty} |a_k^{(n)} - a_k|^p \leq \epsilon^p \quad \text{for all } n \geq N.$$

Hence $a^{(n)} - a$ belongs to ℓ^p and $\|a^{(n)} - a\|_p \leq \epsilon$ for all $n \geq N$.

Step 3: conclusion. Taking $n = N$ in Step 2 shows $a^{(N)} - a \in \ell^p$; since ℓ^p is a linear space and $a^{(N)} \in \ell^p$,

$$a = a^{(N)} - (a^{(N)} - a) \in \ell^p.$$

Moreover Step 2 says exactly that for every $\epsilon > 0$ there is an N with $\|a^{(n)} - a\|_p \leq \epsilon$ for $n \geq N$, that is, $\{a^{(n)}\} \rightarrow a$ in ℓ^p . Therefore ℓ^p is complete.

Case $p = \infty$. Let $\{a^{(n)}\}$ be Cauchy in ℓ^∞ . Since $|a_k^{(n)} - a_k^{(m)}| \leq \|a^{(n)} - a^{(m)}\|_\infty$ for every k , each coordinate sequence $\{a_k^{(n)}\}_n$ is Cauchy in $\mathbb{R}$; let $a_k = \lim_{n \rightarrow \infty} a_k^{(n)}$ and $a = (a_1, a_2, \dots)$. Given $\epsilon > 0$, choose N with $\|a^{(n)} - a^{(m)}\|_\infty \leq \epsilon$ for $n, m \geq N$, so that

$$|a_k^{(n)} - a_k^{(m)}| \leq \epsilon \quad \text{for all } n, m \geq N \text{ and all } k.$$

Fix $n \geq N$ and k , and let $m \rightarrow \infty$: by continuity of the absolute value, $|a_k^{(n)} - a_k| \leq \epsilon$. As k was arbitrary,

$$\sup_k |a_k^{(n)} - a_k| \leq \epsilon \quad \text{for all } n \geq N,$$

so $a^{(n)} - a$ is a bounded sequence, that is, $a^{(n)} - a \in \ell^\infty$, and $\|a^{(n)} - a\|_\infty \leq \epsilon$ for $n \geq N$. In particular $a = a^{(N)} - (a^{(N)} - a)$ is bounded, so $a \in \ell^\infty$, and $\{a^{(n)}\} \rightarrow a$ in ℓ^∞ . Therefore ℓ^∞ is complete.

In all cases $1 \leq p \leq \infty$ the normed linear space ℓ^p is complete, hence a Banach space.

An alternative argument for $1 \leq p < \infty$ uses Problem 12 and the Riesz-Fischer Theorem. For $a \in \ell^p$ let T_a be the function on $[1, \infty)$ taking the value a_k on $[k, k+1)$; then $a \mapsto T_a$ is linear and, by Problem 12, $\|a\|_p = \|T_a\|_p$, so it is a linear isometry of ℓ^p onto the subspace S of $L^p[1, \infty)$ consisting of those functions that are almost everywhere constant on each interval $[k, k+1)$. Since $L^p[1, \infty)$ is complete by the Riesz-Fischer Theorem, it suffices to check S is closed: if $g_n \in S$ and $\{g_n\} \rightarrow g$ in $L^p[1, \infty)$, then by the Riesz-Fischer Theorem a subsequence of $\{g_n\}$ converges to g pointwise almost everywhere, and on each $[k, k+1)$ the members of that subsequence are constants, so their limit g is almost everywhere equal on $[k, k+1)$ to a single number; hence $g \in S$. A linear space isometric to a closed subspace of a Banach space is itself complete.

Problem 7.35. Show that the space c of all convergent sequences of real numbers and the space c_0 of all sequences that converge to zero are Banach spaces with respect to the ℓ^∞ norm.

Solution. Write a real sequence as $a = (a_1, a_2, \dots)$ and recall $\|a\|_\infty = \sup_k |a_k|$.

Step 0: c and c_0 are linear subspaces of ℓ^∞ . A convergent sequence of real numbers is bounded, so $c_0 \subseteq c \subseteq \ell^\infty$. If a, b converge to L, M respectively and α, β are real, then $\alpha a + \beta b$ converges to $\alpha L + \beta M$ by the algebra of limits; so c is a linear subspace of ℓ^∞ , and taking $L = M = 0$ shows c_0 is a linear subspace of c . Each therefore inherits the norm $\|\cdot\|_\infty$ and is a normed linear space.

Step 1: a closed subspace of a Banach space is a Banach space. Let X be a Banach space and Y a linear subspace of X that is closed in X (that is, contains the limit of every sequence in Y that converges in X). Let $\{y_n\}$ be Cauchy in Y with respect to the norm of X . Then $\{y_n\}$ is Cauchy in X , so it converges in X to some $y \in X$; since Y is closed, $y \in Y$; and convergence in X of a sequence in Y to a point of Y is the same as convergence in Y , the norms being the same. Hence Y is complete.

By Problem 34, ℓ^∞ is a Banach space. So it suffices to prove that c and c_0 are closed subsets of ℓ^∞ .

Step 2: c is closed in ℓ^∞ . Let $\{a^{(n)}\}$ be a sequence in c that converges in ℓ^∞ to some $a \in \ell^\infty$; write $a^{(n)} = (a_1^{(n)}, a_2^{(n)}, \dots)$ and let

$$L_n = \lim_{k \rightarrow \infty} a_k^{(n)},$$

which exists since $a^{(n)} \in c$. We claim $\{L_n\}$ is a Cauchy sequence of real numbers. Indeed, for all n, m and all k ,

$$|a_k^{(n)} - a_k^{(m)}| \leq \|a^{(n)} - a^{(m)}\|_\infty,$$

and letting $k \rightarrow \infty$ gives

$$|L_n - L_m| \leq \|a^{(n)} - a^{(m)}\|_\infty.$$

Since $\{a^{(n)}\}$ converges in ℓ^∞ , it is Cauchy there by Proposition 4, so the right side is small for large n, m ; hence $\{L_n\}$ is Cauchy in $\mathbb{R}$ and, $\mathbb{R}$ being complete, converges to some real number L .

We show $\lim_{k \rightarrow \infty} a_k = L$, so that $a \in c$. Let $\epsilon > 0$. Choose a natural number n so large that

$$\|a - a^{(n)}\|_\infty < \frac{\epsilon}{3} \quad \text{and} \quad |L_n - L| < \frac{\epsilon}{3},$$

possible since $\{a^{(n)}\} \rightarrow a$ in ℓ^∞ and $\{L_n\} \rightarrow L$ in $\mathbb{R}$. With this n fixed, choose K so that $|a_k^{(n)} - L_n| < \epsilon/3$ for all $k \geq K$. Then for $k \geq K$,

$$|a_k - L| \leq |a_k - a_k^{(n)}| + |a_k^{(n)} - L_n| + |L_n - L| < \frac{\epsilon}{3} + \frac{\epsilon}{3} + \frac{\epsilon}{3} = \epsilon,$$

where the first term was bounded using $|a_k - a_k^{(n)}| \leq \|a - a^{(n)}\|_\infty$. Hence $\{a_k\} \rightarrow L$, so $a \in c$ and c is closed in ℓ^∞ .

Step 3: c_0 is closed in ℓ^∞ . Let $\{a^{(n)}\}$ be a sequence in c_0 converging in ℓ^∞ to a . Let $\epsilon > 0$. Choose n with $\|a - a^{(n)}\|_\infty < \epsilon/2$, and then, since $\{a_k^{(n)}\}_k \rightarrow 0$, choose K with $|a_k^{(n)}| < \epsilon/2$ for all $k \geq K$. Then for $k \geq K$,

$$|a_k| \leq |a_k - a_k^{(n)}| + |a_k^{(n)}| \leq \|a - a^{(n)}\|_\infty + |a_k^{(n)}| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Hence $\{a_k\} \rightarrow 0$, so $a \in c_0$ and c_0 is closed in ℓ^∞ .

Conclusion. By Steps 2 and 3, c and c_0 are closed linear subspaces of the Banach space ℓ^∞ , so by Step 1 each is complete with respect to the ℓ^∞ norm. Therefore c and c_0 , normed by $\|\cdot\|_\infty$, are Banach spaces. (Since $c_0 \subseteq c \subseteq \ell^\infty$ and c_0 is closed in ℓ^∞ , it is in particular closed in c , so the completeness of c_0 also follows from that of c .)

7.6 Problems 7.36–7.42

Problem 7.36. Let $\mathcal{S}$ be a subset of a normed linear space X . Show that $\mathcal{S}$ is dense in X if and only if each $g \in X$ is the limit of a sequence in $\mathcal{S}$.

Solution. Recall the definition in force: for $\mathcal{F} \subseteq \mathcal{G}$ subsets of a normed linear space X with norm $\|\cdot\|$, we say $\mathcal{F}$ is dense in $\mathcal{G}$ provided that for each g in $\mathcal{G}$ and each $\epsilon > 0$ there is an f in $\mathcal{F}$ for which $\|f - g\| < \epsilon$. Recall also that a sequence $\{f_n\}$ in X converges to g in X , written $\lim_{n \rightarrow \infty} f_n = g$ in X , provided $\lim_{n \rightarrow \infty} \|f_n - g\| = 0$.

Suppose first that $\mathcal{S}$ is dense in X , and let g belong to X . For each natural number n , apply the definition of denseness with the choice $\epsilon = 1/n$: there is a function f_n in $\mathcal{S}$ for which

$$\|f_n - g\| < \frac{1}{n}.$$

This defines a sequence $\{f_n\}$ whose terms all lie in $\mathcal{S}$. Since $0 \leq \|f_n - g\| < 1/n$ for all n , the squeeze principle gives $\lim_{n \rightarrow \infty} \|f_n - g\| = 0$, that is, $\{f_n\} \rightarrow g$ in X . Thus g is the limit of a sequence in $\mathcal{S}$. As g was an arbitrary member of X , every g in X is such a limit.

Conversely, suppose each g in X is the limit of a sequence in $\mathcal{S}$. Let g belong to X and let $\epsilon > 0$. Choose a sequence $\{f_n\}$ in $\mathcal{S}$ with $\{f_n\} \rightarrow g$ in X , that is, with $\lim_{n \rightarrow \infty} \|f_n - g\| = 0$. By the definition of the limit of a sequence of real numbers, there is an index N for which $\|f_n - g\| < \epsilon$ whenever $n \geq N$. In particular $f := f_N$ is a function in $\mathcal{S}$ with $\|f - g\| < \epsilon$. Since g in X and $\epsilon > 0$ were arbitrary, $\mathcal{S}$ is dense in X .

Problem 7.37. Verify (13). [Assertion (13) of the text reads: for $\mathcal{F} \subseteq \mathcal{G} \subseteq \mathcal{H} \subseteq X$,

if $\mathcal{F}$ is dense in $\mathcal{G}$ and $\mathcal{G}$ is dense in $\mathcal{H}$, then $\mathcal{F}$ is dense in $\mathcal{H}$.

Here X is a normed linear space with norm $\|\cdot\|$.]

Solution. Let X be a normed linear space with norm $\|\cdot\|$ and let $\mathcal{F} \subseteq \mathcal{G} \subseteq \mathcal{H} \subseteq X$. Assume $\mathcal{F}$ is dense in $\mathcal{G}$ and $\mathcal{G}$ is dense in $\mathcal{H}$. Observe first that the inclusion $\mathcal{F} \subseteq \mathcal{H}$ required by the definition holds, since $\mathcal{F} \subseteq \mathcal{G} \subseteq \mathcal{H}$.

Let h belong to $\mathcal{H}$ and let $\epsilon > 0$. Since $\mathcal{G}$ is dense in $\mathcal{H}$, applied to the function h in $\mathcal{H}$ and the positive number $\epsilon/2$, there is a function g in $\mathcal{G}$ for which

$$\|g - h\| < \frac{\epsilon}{2}.$$

Since $\mathcal{F}$ is dense in $\mathcal{G}$, applied now to this function g in $\mathcal{G}$ and the positive number $\epsilon/2$, there is a function f in $\mathcal{F}$ for which

$$\|f - g\| < \frac{\epsilon}{2}.$$

By the triangle inequality for the norm $\|\cdot\|$,

$$\|f - h\| = \|(f - g) + (g - h)\| \leq \|f - g\| + \|g - h\| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Thus for the arbitrary h in $\mathcal{H}$ and $\epsilon > 0$ we have produced f in $\mathcal{F}$ with $\|f - h\| < \epsilon$. Therefore $\mathcal{F}$ is dense in $\mathcal{H}$, which is exactly the assertion (13).

Problem 7.38. Prove that the collection of polynomials with rational coefficients is countable.

Solution. Let $\mathcal{P}$ denote the collection of all polynomials with rational coefficients, and for each non-negative integer n let

$$\mathcal{P}_n = \{c_0 + c_1x + \cdots + c_nx^n : c_0, \dots, c_n \in \mathbb{Q}\}$$

be the collection of polynomials with rational coefficients of degree at most n . Every polynomial has a finite degree, so

$$\mathcal{P} = \bigcup_{n=0}^{\infty} \mathcal{P}_n.$$

We first show each $\mathcal{P}_n$ is countable. By Corollary 4 of Chapter 1, the set $\mathbb{Q}$ of rational numbers is countably infinite, so there is a one-to-one correspondence φ of $\mathbb{N}$ with $\mathbb{Q}$. Define

$$\Phi: \underbrace{\mathbb{N} \times \cdots \times \mathbb{N}}_{n+1 \text{ times}} \longrightarrow \mathcal{P}_n, \quad \Phi(k_0, k_1, \dots, k_n) = \varphi(k_0) + \varphi(k_1)x + \cdots + \varphi(k_n)x^n.$$

Since φ maps $\mathbb{N}$ onto $\mathbb{Q}$, every choice of rational coefficients $c_0, \dots, c_n$ is realized, so Φ maps $\mathbb{N}^{n+1}$ onto $\mathcal{P}_n$. By Corollary 4 of Chapter 1 the Cartesian product $\mathbb{N}^{n+1}$ of $n+1$ copies of $\mathbb{N}$ is countably infinite, and $\mathcal{P}_n$ is nonempty. Therefore, by Theorem 5 of Chapter 1, which asserts that a nonempty set is countable if and only if it is the image of a function whose domain is a nonempty countable set, the set $\mathcal{P}_n$ is countable.

Finally, $\{\mathcal{P}_n\}_{n=0}^{\infty}$ is a countable collection of countable sets, so by Corollary 6 of Chapter 1 its union $\mathcal{P}$ is countable.

We remark that $\mathcal{P}$ is in fact countably infinite, since the constant polynomials c_0 with c_0 rational already form a subset of $\mathcal{P}$ equipotent to the infinite set $\mathbb{Q}$; hence $\mathcal{P}$ is not finite.

Problem 7.39. Let E be a measurable set, $1 \leq p < \infty$, q the conjugate of p , and $\mathcal{S}$ a dense subset of $L^q(E)$. Show that if $g \in L^p(E)$ and $\int_E f \cdot g = 0$ for all $f \in \mathcal{S}$, then $g = 0$.

Solution. Let g belong to $L^p(E)$ and suppose $\int_E f \cdot g = 0$ for every f in $\mathcal{S}$.

Step 1: the hypothesis propagates from $\mathcal{S}$ to all of $L^q(E)$. Let h be any function in $L^q(E)$. Since $\mathcal{S}$ is dense in $L^q(E)$, by Problem 36 there is a sequence $\{f_n\}$ in $\mathcal{S}$ with $\{f_n\} \rightarrow h$ in $L^q(E)$, that is, $\lim_{n \rightarrow \infty} \|f_n - h\|_q = 0$. For each n , the function $(f_n - h) \cdot g$ is integrable over E by Holder's Inequality (Theorem 1 of Chapter 7), since $f_n - h$ belongs to $L^q(E)$ and g belongs to $L^p(E)$; the same theorem gives

$$\left| \int_E f_n \cdot g - \int_E h \cdot g \right| = \left| \int_E (f_n - h) \cdot g \right| \leq \int_E |(f_n - h) \cdot g| \leq \|f_n - h\|_q \cdot \|g\|_p.$$

Here we used the linearity of integration and the fact that the absolute value of an integral does not exceed the integral of the absolute value. Since $\|g\|_p$ is a finite number and $\|f_n - h\|_q \rightarrow 0$, the right-hand side tends to 0. But $\int_E f_n \cdot g = 0$ for every n , because each f_n belongs to $\mathcal{S}$. Therefore

$$\int_E h \cdot g = \lim_{n \rightarrow \infty} \int_E f_n \cdot g = 0.$$

Thus $\int_E h \cdot g = 0$ for every h in $L^q(E)$.

Step 2: testing against the conjugate function of g . Suppose, to get a contradiction, that g is not the zero element of $L^p(E)$, that is, $\|g\|_p > 0$. Then, by Theorem 1 of Chapter 7, the conjugate function of g ,

$$g^* = \|g\|_p^{1-p} \cdot \operatorname{sgn}(g) \cdot |g|^{p-1},$$

belongs to $L^q(E)$ and satisfies (4) of that theorem, namely

$$\int_E g \cdot g^* = \|g\|_p \quad \text{and} \quad \|g^*\|_q = 1.$$

Applying Step 1 with $h = g^*$ gives $\int_E g^* \cdot g = 0$, so $\|g\|_p = 0$. This contradicts the assumption $\|g\|_p > 0$. Therefore $\|g\|_p = 0$. Since $\|g\|_p = [\int_E |g|^p]^{1/p} = 0$ with $|g|^p$ a nonnegative measurable function, Proposition 9 of Chapter 4 (a nonnegative measurable function with zero integral vanishes almost everywhere) gives $|g|^p = 0$, hence $g = 0$, almost everywhere on E . As elements of $L^p(E)$ are identified when they agree almost everywhere on E , we conclude $g = 0$ in $L^p(E)$.

We note the case $p = 1$, $q = \infty$ is included: then $g^* = \operatorname{sgn}(g)$, which is an essentially bounded measurable function on E , and Theorem 1 of Chapter 7 explicitly records that (4) holds for $p = 1$, $q = \infty$.

Problem 7.40. Verify the details in the proof of Theorem 11. [Theorem 11: Let E be a measurable set and $1 \leq p < \infty$. Then the normed linear space $L^p(E)$ is separable.]

Solution. Throughout, $1 \leq p < \infty$ is fixed. Recall the notation of the proof of Theorem 11: for a closed, bounded interval $[a, b]$, $\mathcal{S}[a, b]$ is the collection of step functions on $[a, b]$, and $\mathcal{S}'[a, b]$ is the subcollection of those step functions ψ that take rational values and for which there is a partition $P = \{x_0, \dots, x_n\}$ of $[a, b]$ with ψ constant on (x_{k-1}, x_k) for $1 \leq k \leq n$ and x_k rational for $1 \leq k \leq n - 1$. There are four points left to the reader; we verify them in turn.

Detail 1: $\mathcal{S}'[a, b]$ is dense in $\mathcal{S}[a, b]$ with respect to the $L^p[a, b]$ norm.

Let ψ belong to $\mathcal{S}[a, b]$ and let $\epsilon > 0$. There is a partition $a = y_0 < y_1 < \dots < y_n = b$ of $[a, b]$ and real numbers $c_1, \dots, c_n$ with $\psi = c_k$ on (y_{k-1}, y_k) for $1 \leq k \leq n$. (The finitely many values $\psi(y_k)$ are irrelevant, since a change of a function on a set of measure zero changes neither its membership in $L^p[a, b]$ nor its L^p norm.)

First replace the values by rational ones. By the density of $\mathbb{Q}$ in $\mathbb{R}$, choose rational numbers $d_1, \dots, d_n$

with

$$|d_k - c_k| < \frac{\epsilon}{2(b-a)^{1/p} + 2} \quad \text{for } 1 \leq k \leq n,$$

and let φ be the step function equal to d_k on (y_{k-1}, y_k) and equal to 0 at the partition points. Then $|\varphi - \psi| \leq \epsilon/(2(b-a)^{1/p} + 2)$ except at finitely many points, so by the monotonicity of integration

$$\|\varphi - \psi\|_p \leq \frac{\epsilon}{2(b-a)^{1/p} + 2} \cdot (b-a)^{1/p} < \frac{\epsilon}{2}.$$

Now replace the interior partition points by rational ones. Let $M = \max_{1 \leq k \leq n} |d_k|$ and let $\delta = \frac{1}{2} \min_{1 \leq k \leq n} (y_k - y_{k-1}) > 0$. Choose a positive number

$$\eta < \min \left\{ \delta, \frac{1}{2n} \left[\frac{\epsilon}{2(2M+1)} \right]^p \right\},$$

and, again by the density of the rationals, choose rational numbers $x_1, \dots, x_{n-1}$ with $|x_k - y_k| < \eta$ for $1 \leq k \leq n-1$; set $x_0 = a$ and $x_n = b$. Since $\eta < \delta$, we still have $a = x_0 < x_1 < \dots < x_n = b$, so $P = \{x_0, \dots, x_n\}$ is a partition of $[a, b]$. Let φ' be the function equal to d_k on (x_{k-1}, x_k) for $1 \leq k \leq n$ and equal to 0 at the points of P . Then φ' takes rational values, is constant on each (x_{k-1}, x_k) , and its interior partition points $x_1, \dots, x_{n-1}$ are rational; hence φ' belongs to $\mathcal{S}'[a, b]$.

The functions φ and φ' agree except on the set

$$D = \{x_0, \dots, x_n, y_0, \dots, y_n\} \cup \bigcup_{k=1}^{n-1} [\min\{x_k, y_k\}, \max\{x_k, y_k\}],$$

whose measure is at most $(n-1) \cdot \eta \leq n\eta$, by the countable (here finite) subadditivity and monotonicity of Lebesgue measure. On D we have $|\varphi - \varphi'| \leq 2M$. Therefore

$$\|\varphi - \varphi'\|_p = \left[\int_D |\varphi - \varphi'|^p \right]^{1/p} \leq 2M \cdot [m(D)]^{1/p} \leq (2M+1) (n\eta)^{1/p} < \frac{\epsilon}{2},$$

by the choice of η . By Minkowski's Inequality,

$$\|\varphi' - \psi\|_p \leq \|\varphi' - \varphi\|_p + \|\varphi - \psi\|_p < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Since ψ in $\mathcal{S}[a, b]$ and $\epsilon > 0$ were arbitrary, $\mathcal{S}'[a, b]$ is dense in $\mathcal{S}[a, b]$ with respect to the L^p norm. Combined with Proposition 10, which tells us $\mathcal{S}[a, b]$ is dense in $L^p[a, b]$, assertion (13) applied to the inclusions $\mathcal{S}'[a, b] \subseteq \mathcal{S}[a, b] \subseteq L^p[a, b]$ shows that $\mathcal{S}'[a, b]$ is dense in $L^p[a, b]$.

Detail 2: $\mathcal{S}'[a, b]$ is a countable set.

We argue directly, without identifying functions that agree almost everywhere. Fix a natural number n and let $\mathcal{S}'_n[a, b]$ be the collection of those ψ in $\mathcal{S}'[a, b]$ admitting such a partition $P = \{x_0, \dots, x_n\}$ into exactly n subintervals. Such a ψ is completely determined by the rational interior partition points $x_1 < \dots < x_{n-1}$ in (a, b) , by the rational values $d_1, \dots, d_n$ that ψ takes on the successive open intervals (x_{k-1}, x_k) , and by the rational values $e_0, \dots, e_n$ that ψ takes at the points of P ; the endpoints $x_0 = a$ and $x_n = b$ are fixed. (A given ψ may admit more than one such partition; that is harmless, since all we need is a map onto $\mathcal{S}'_n[a, b]$.) Hence

$$(x_1, \dots, x_{n-1}, d_1, \dots, d_n, e_0, \dots, e_n) \mapsto \psi$$

is a mapping of a subset A_n of $\mathbb{Q}^{3n}$ onto $\mathcal{S}'_n[a, b]$. As in Problem 38, since $\mathbb{Q}$ is countably infinite by Corollary 4 of Chapter 1, $\mathbb{Q}^{3n}$ is equipotent to $\mathbb{N}^{3n}$, which is countable by that same corollary; the subset A_n is countable by Theorem 3 of Chapter 1; and therefore, by Theorem 5 of Chapter 1, $\mathcal{S}'_n[a, b]$ is countable. Since

$$\mathcal{S}'[a, b] = \bigcup_{n=1}^{\infty} \mathcal{S}'_n[a, b]$$

is the union of a countable collection of countable sets, Corollary 6 of Chapter 1 tells us $\mathcal{S}'[a, b]$ is countable.

Detail 3: $\mathcal{F} = \bigcup_{n \in \mathbb{N}} \mathcal{F}_n$ is a countable subset of $L^p(\mathbb{R})$ that is dense in $L^p(\mathbb{R})$.

Recall $\mathcal{F}_n$ is the collection of functions on $\mathbb{R}$ that vanish outside $[-n, n]$ and whose restrictions to $[-n, n]$ belong to $\mathcal{S}'[-n, n]$. Each such function is bounded and vanishes outside a set of finite measure, so it belongs to $L^p(\mathbb{R})$. By Detail 2, $\mathcal{S}'[-n, n]$ is countable, and $f \mapsto f|_{[-n, n]}$ is a one-to-one correspondence of $\mathcal{F}_n$ with $\mathcal{S}'[-n, n]$; hence each $\mathcal{F}_n$ is countable, and by Corollary 6 of Chapter 1 so is $\mathcal{F}$.

To see that $\mathcal{F}$ is dense, let f belong to $L^p(\mathbb{R})$ and let $\epsilon > 0$. The sequence of nonnegative measurable functions $\{|f|^p \cdot \chi_{[-n, n]}\}$ is increasing and converges pointwise on $\mathbb{R}$ to $|f|^p$, so the Monotone Convergence Theorem gives

$$\lim_{n \rightarrow \infty} \int_{[-n, n]} |f|^p = \int_{\mathbb{R}} |f|^p < \infty.$$

Since $\int_{\mathbb{R}} |f|^p$ is finite, we may subtract and conclude there is a natural number n for which

$$\int_{\mathbb{R} \setminus [-n, n]} |f|^p = \int_{\mathbb{R}} |f|^p - \int_{[-n, n]} |f|^p < \left(\frac{\epsilon}{2}\right)^p.$$

Put $g = f \cdot \chi_{[-n, n]}$. Then $\|f - g\|_{L^p(\mathbb{R})} = \left[\int_{\mathbb{R} \setminus [-n, n]} |f|^p\right]^{1/p} < \epsilon/2$. The restriction of g to $[-n, n]$ belongs to $L^p[-n, n]$, so by Detail 1 there is a function ψ in $\mathcal{S}'[-n, n]$ with $\|g - \psi\|_{L^p[-n, n]} < \epsilon/2$. Extend ψ by 0 outside $[-n, n]$; the extension, still denoted ψ , belongs to $\mathcal{F}_n \subseteq \mathcal{F}$, and since g and ψ both vanish outside $[-n, n]$,

$$\|g - \psi\|_{L^p(\mathbb{R})} = \|g - \psi\|_{L^p[-n, n]} < \frac{\epsilon}{2}.$$

By Minkowski's Inequality, $\|f - \psi\|_{L^p(\mathbb{R})} \leq \|f - g\|_{L^p(\mathbb{R})} + \|g - \psi\|_{L^p(\mathbb{R})} < \epsilon$. Hence $\mathcal{F}$ is dense in $L^p(\mathbb{R})$, and $L^p(\mathbb{R})$ is separable.

Detail 4: passage from $\mathbb{R}$ to a general measurable set E .

Let E be measurable and set $\mathcal{F}_E = \{f|_E : f \in \mathcal{F}\}$. This is the image of the countable set $\mathcal{F}$ under the restriction map, hence countable by Theorem 5 of Chapter 1, and each $f|_E$ belongs to $L^p(E)$ because $\int_E |f|^p \leq \int_{\mathbb{R}} |f|^p < \infty$. Let h belong to $L^p(E)$ and let $\epsilon > 0$. Define $\hat{h}$ on $\mathbb{R}$ by $\hat{h} = h$ on E and $\hat{h} = 0$ on $\mathbb{R} \setminus E$. Then $\hat{h}$ is measurable on $\mathbb{R}$ and $\int_{\mathbb{R}} |\hat{h}|^p = \int_E |h|^p < \infty$, so $\hat{h}$ belongs to $L^p(\mathbb{R})$. By Detail 3 there is f in $\mathcal{F}$ with $\|\hat{h} - f\|_{L^p(\mathbb{R})} < \epsilon$. By the monotonicity of integration over the subset E of $\mathbb{R}$,

$$\|h - f|_E\|_{L^p(E)} = \left[\int_E |\hat{h} - f|^p\right]^{1/p} \leq \left[\int_{\mathbb{R}} |\hat{h} - f|^p\right]^{1/p} < \epsilon.$$

Thus $\mathcal{F}_E$ is a countable dense subset of $L^p(E)$, and therefore $L^p(E)$ is separable. This completes the verification of the details in the proof of Theorem 11.

Problem 7.41. Let E be a measurable set of finite measure and $1 \leq p_1 < p_2 < \infty$. Consider the linear space $L^{p_2}(E)$ normed by $\|\cdot\|_{p_1}$. Is this normed linear space a Banach space?

Solution. The answer is no, unless E has measure zero (in which case $L^{p_2}(E)$ consists of the single element 0 and is trivially complete). We assume $m(E) > 0$ and exhibit a sequence in $L^{p_2}(E)$ that is Cauchy with respect to $\|\cdot\|_{p_1}$ but converges in $\|\cdot\|_{p_1}$ to no member of $L^{p_2}(E)$.

First note the setting is legitimate: since $m(E) < \infty$ and $p_1 < p_2$, Corollary 3 of Chapter 7 gives $L^{p_2}(E) \subseteq L^{p_1}(E)$, so $\|\cdot\|_{p_1}$ is finite on $L^{p_2}(E)$; and it is a norm there, since it is a norm on $L^{p_1}(E)$ and $L^{p_2}(E)$ is a linear subspace of $L^{p_1}(E)$.

Step 1: a function in $L^{p_1}(E)$ that fails to belong to $L^{p_2}(E)$.

Define $\mu(t) = m(E \cap (-\infty, t])$ for $t \in \mathbb{R}$. Since $m(E) < \infty$, μ is real-valued, nondecreasing, and continuous: indeed, for $s < t$,

$$|\mu(t) - \mu(s)| = m(E \cap (s, t]) \leq t - s,$$

by the monotonicity of Lebesgue measure. Moreover $\lim_{t \rightarrow -\infty} \mu(t) = 0$ and $\lim_{t \rightarrow \infty} \mu(t) = m(E)$, by

the continuity of measure. Hence, by the Intermediate Value Theorem, μ takes every value in $(0, m(E))$. For each natural number k choose c_k with $\mu(c_k) = m(E) \cdot 2^{-k}$, and put $A_k = E \cap (-\infty, c_k]$, so that $m(A_k) = m(E) \cdot 2^{-k}$. Since μ is nondecreasing and $\mu(c_{k+1}) < \mu(c_k)$, we have $c_{k+1} \leq c_k$ and therefore $A_{k+1} \subseteq A_k$. Define

$$E_k = A_k \setminus A_{k+1}, \quad m_k := m(E_k) = m(A_k) - m(A_{k+1}) = m(E) \cdot 2^{-(k+1)} > 0,$$

using the excision property of measure, valid since $m(A_{k+1}) < \infty$. The sets $\{E_k\}_{k=1}^{\infty}$ are measurable, pairwise disjoint, and contained in E .

Now set, for each k ,

$$a_k = \left[\frac{1}{k^2 m_k} \right]^{1/p_1} > 0, \quad f = \sum_{k=1}^{\infty} a_k \chi_{E_k}.$$

The function f is nonnegative, real-valued and measurable on E : the sets E_k are disjoint, so f takes the value a_k on E_k and the value 0 on $E \setminus \bigcup_k E_k$, and it is the pointwise limit on E of the increasing sequence of simple functions $\sum_{k=1}^n a_k \chi_{E_k}$. For any $r > 0$ the sequence $\left\{ \sum_{k=1}^n a_k^r \chi_{E_k} \right\}$ increases pointwise on E to $|f|^r$, so the Monotone Convergence Theorem, together with the additivity of integration over the finite disjoint collection $\{E_k\}_{k=1}^n$ and the vanishing of f off $\bigcup_k E_k$, gives

$$\int_E |f|^r = \sum_{k=1}^{\infty} a_k^r m_k.$$

For $r = p_1$ we get

$$\int_E |f|^{p_1} = \sum_{k=1}^{\infty} \frac{1}{k^2 m_k} \cdot m_k = \sum_{k=1}^{\infty} \frac{1}{k^2} < \infty,$$

so f belongs to $L^{p_1}(E)$. For $r = p_2$, writing $\alpha = p_2/p_1 > 1$ and $m_k = m(E)2^{-(k+1)}$,

$$a_k^{p_2} m_k = [k^2 m_k]^{-\alpha} m_k = k^{-2\alpha} m_k^{1-\alpha} = k^{-2\alpha} \left[\frac{m(E)}{2^{k+1}} \right]^{1-\alpha} = C \cdot \frac{2^{k(\alpha-1)}}{k^{2\alpha}},$$

where $C = [m(E)/2]^{1-\alpha} > 0$. Since $\alpha-1 > 0$, the numerator grows geometrically while the denominator grows only polynomially, so $a_k^{p_2} m_k \rightarrow \infty$; in particular the series diverges and

$$\int_E |f|^{p_2} = \infty.$$

Thus f belongs to $L^{p_1}(E)$ but not to $L^{p_2}(E)$.

Step 2: a Cauchy sequence with no limit in the space.

Let $f_n = \sum_{k=1}^n a_k \chi_{E_k}$. Each f_n is a simple function on the finite measure set E , hence bounded and measurable, so f_n belongs to $L^{p_2}(E)$. Now $f - f_n = \sum_{k>n} a_k \chi_{E_k}$, which is a function of exactly the same form as f with the first n coefficients deleted; so the computation just performed, applied to it with $r = p_1$, gives

$$\|f - f_n\|_{p_1}^{p_1} = \int_E \left| \sum_{k>n} a_k \chi_{E_k} \right|^{p_1} = \sum_{k>n} \frac{1}{k^2} \rightarrow 0 \text{ as } n \rightarrow \infty,$$

this being the tail of the convergent series $\sum 1/k^2$. Hence $\{f_n\} \rightarrow f$ in $L^{p_1}(E)$, and in particular, by Minkowski's Inequality,

$$\|f_n - f_m\|_{p_1} \leq \|f_n - f\|_{p_1} + \|f - f_m\|_{p_1} \rightarrow 0,$$

so $\{f_n\}$ is a Cauchy sequence in $L^{p_2}(E)$ with respect to the norm $\|\cdot\|_{p_1}$.

Suppose this sequence converged, with respect to $\|\cdot\|_{p_1}$, to some g in $L^{p_2}(E)$. Since $L^{p_2}(E) \subseteq L^{p_1}(E)$, both f and g lie in $L^{p_1}(E)$, and by Minkowski's Inequality

$$\|f - g\|_{p_1} \leq \|f - f_n\|_{p_1} + \|f_n - g\|_{p_1} \rightarrow 0,$$

so $\|f - g\|_{p_1} = 0$ and therefore, by Proposition 9 of Chapter 4, $f = g$ almost everywhere on E . But then $\int_E |f|^{p_2} = \int_E |g|^{p_2} < \infty$, contradicting Step 1.

Therefore $\{f_n\}$ is a Cauchy sequence in the normed linear space $(L^{p_2}(E), \|\cdot\|_{p_2})$ which does not converge in that space, and the space is not a Banach space.

The underlying reason is structural: Step 1 shows $L^{p_2}(E)$ is a proper subspace of $L^{p_1}(E)$, and the argument above shows it is a dense one (the simple functions are dense in $L^{p_1}(E)$ by Proposition 9 of Chapter 7 and, E having finite measure, they all belong to $L^{p_2}(E)$). By Problem 43, a subspace of a Banach space that is dense and complete in the inherited norm must be the whole space; since $L^{p_1}(E)$ is a Banach space by the Riesz-Fischer Theorem and $L^{p_2}(E)$ is a proper dense subspace of it, $L^{p_2}(E)$ cannot be complete in $\|\cdot\|_{p_1}$.

Problem 7.42. Exhibit a measurable set E for which $L^\infty(E)$ is separable. Show that $L^\infty(E)$ is not separable if the set E contains a nondegenerate interval.

Solution. Part 1: a measurable set E for which $L^\infty(E)$ is separable.

Take any measurable set of measure zero, for instance $E = \{0\}$, or $E = \mathbb{Q}$, or $E = \emptyset$. Let f be any measurable function on E . Since $m(E) = 0$, the inequality $|f| \leq 0$ holds almost everywhere on E (the exceptional set, being a subset of E , has measure zero). Thus 0 is an essential upper bound for $|f|$ on E , and therefore

$$\|f\|_\infty = \inf\{M \geq 0 : |f| \leq M \text{ a.e. on } E\} = 0.$$

Since the members of $L^\infty(E)$ are identified when they agree almost everywhere on E , every measurable f on E equals 0 as an element of $L^\infty(E)$; that is, $L^\infty(E) = \{0\}$. The one-element set $\{0\}$ is a countable subset of $L^\infty(E)$ that is dense in it, since for the only g in $L^\infty(E)$, namely $g = 0$, and any $\epsilon > 0$ we have $\|0 - g\|_\infty = 0 < \epsilon$. Hence $L^\infty(E)$ is separable.

Part 2: $L^\infty(E)$ is not separable when E contains a nondegenerate interval.

Suppose E contains a nondegenerate closed, bounded interval $[a, b]$, so $a < b$. (If E contains a nondegenerate interval of any kind, it contains such a closed, bounded one.) We argue by contradiction, following the pattern of the Example after Theorem 11.

Assume $L^\infty(E)$ is separable, and let $\{f_n\}_{n=1}^\infty$ be a countable subset of $L^\infty(E)$ that is dense in $L^\infty(E)$. For each x in $[a, b]$ define g_x on E to be the characteristic function of $[a, x]$, that is, $g_x = \chi_{[a, x]}$ restricted to E . Each g_x is measurable and bounded on E , so g_x belongs to $L^\infty(E)$. By the density of $\{f_n\}$, applied to g_x and $\epsilon = 1/2$, we may select a natural number $\eta(x)$ for which

$$\|g_x - f_{\eta(x)}\|_\infty < \frac{1}{2}.$$

We claim that for $a \leq x_1 < x_2 \leq b$,

$$\|g_{x_1} - g_{x_2}\|_\infty = 1.$$

Indeed, $g_{x_2} - g_{x_1}$ is the characteristic function of the set $(x_1, x_2]$, which is contained in E because $[a, b] \subseteq E$. Since $m((x_1, x_2]) = x_2 - x_1 > 0$, no number $M < 1$ can be an essential upper bound: the set where $|g_{x_2} - g_{x_1}| = 1 > M$ is $(x_1, x_2]$, of positive measure. On the other hand $|g_{x_2} - g_{x_1}| \leq 1$ everywhere on E . Hence the essential supremum equals 1, proving the claim.

Now suppose $\eta(x_1) = \eta(x_2) = k$ for some $a \leq x_1 < x_2 \leq b$. Then, by the triangle inequality for the norm $\|\cdot\|_\infty$,

$$1 = \|g_{x_1} - g_{x_2}\|_\infty \leq \|g_{x_1} - f_k\|_\infty + \|f_k - g_{x_2}\|_\infty < \frac{1}{2} + \frac{1}{2} = 1,$$

a contradiction. Therefore η is a one-to-one mapping of $[a, b]$ into $\mathbb{N}$.

Consequently $[a, b]$ is equipotent to a subset of $\mathbb{N}$, and so, by Theorem 3 of Chapter 1, $[a, b]$ is countable. But $[a, b]$ is a nondegenerate interval of real numbers and hence is uncountable, by Theorem 7 of Chapter 1. From this contradiction we conclude that no countable subset of $L^\infty(E)$ is dense in $L^\infty(E)$; that is, $L^\infty(E)$ is not separable.

Remark: containing an interval is not needed; $m(E) > 0$ suffices. If $m(E) > 0$, choose n with $m(E \cap [-n, n]) > 0$ and set $E_0 = E \cap [-n, n]$, so $0 < m(E_0) < \infty$. As in Problem 41, the function

$\mu(t) = m(E_0 \cap (-\infty, t])$ is continuous, nondecreasing, and takes every value in $(0, m(E_0))$; for each such t pick c_t with $\mu(c_t) = t$ and put $A_t = E_0 \cap (-\infty, c_t]$. For $s < t$ we have $A_s \subseteq A_t$ and $m(A_t \setminus A_s) = t - s > 0$, so exactly as above $\|\chi_{A_s} - \chi_{A_t}\|_\infty = 1$. Since $(0, m(E_0))$ is a nondegenerate interval, hence uncountable by Theorem 7 of Chapter 1, the same selection argument produces a one-to-one map of an uncountable set into $\mathbb{N}$, a contradiction. Thus $L^\infty(E)$ is separable if and only if $m(E) = 0$.

7.7 Problems 7.43–7.49

Problem 7.43. Suppose that X is a Banach space with norm $\|\cdot\|$. Let X_0 be a dense subspace of X . Assume that X_0 , when normed by the norm it inherits from X , is also a Banach space. Prove that $X = X_0$.

Solution. Since $X_0 \subseteq X$, we need only prove the reverse inclusion $X \subseteq X_0$.

Let x belong to X . By the definition of denseness in Section 7.4, for each natural number n there is a point x_n in X_0 with $\|x_n - x\| < 1/n$. (This is the implication recorded in Problem 36.) Thus there is a sequence $\{x_n\}$ in X_0 for which

$$\lim_{n \rightarrow \infty} x_n = x \quad \text{in } X, \quad \text{that is,} \quad \lim_{n \rightarrow \infty} \|x_n - x\| = 0.$$

We claim $\{x_n\}$ is a Cauchy sequence in X . Indeed, let $\epsilon > 0$. Choose an index N for which $\|x_n - x\| < \epsilon/2$ for all $n \geq N$. Then for $n, m \geq N$, the triangle inequality gives

$$\|x_n - x_m\| \leq \|x_n - x\| + \|x - x_m\| < \epsilon/2 + \epsilon/2 = \epsilon.$$

Now every x_n belongs to X_0 , and the norm on X_0 is the restriction to X_0 of the norm on X . Therefore $\{x_n\}$ is a Cauchy sequence in the normed linear space X_0 . By assumption X_0 is a Banach space, that is, X_0 is complete. Hence there is a point x_0 in X_0 for which $\{x_n\} \rightarrow x_0$ with respect to the norm of X_0 . Again because the norm of X_0 is inherited from X , this means

$$\lim_{n \rightarrow \infty} \|x_n - x_0\| = 0,$$

so that $\{x_n\} \rightarrow x_0$ in X as well.

Finally, limits with respect to a norm are unique: for every index n ,

$$\|x - x_0\| \leq \|x - x_n\| + \|x_n - x_0\|,$$

and the right-hand side tends to 0 as $n \rightarrow \infty$. Since $\|x - x_0\|$ is a nonnegative number that is no larger than a quantity tending to 0, we conclude $\|x - x_0\| = 0$ and therefore $x = x_0$.

Thus $x = x_0$ belongs to X_0 . Since x was an arbitrary point of X , we have $X \subseteq X_0$, and hence $X = X_0$. Observe the essential point: a complete subspace of a normed linear space is closed, and a dense closed subset of X is all of X .

Problem 7.44. For $1 \leq p < \infty$, show that the sequence space ℓ^p is separable. Show that the collection of sets of natural numbers is uncountable and conclude that ℓ^∞ is not separable.

Solution. We first prove the separability of ℓ^p for $1 \leq p < \infty$. For a natural number n , let

$$\mathcal{D}_n = \{(q_1, \dots, q_n, 0, 0, \dots) : q_1, \dots, q_n \text{ rational}\},$$

the set of sequences whose terms beyond the n -th vanish and whose first n terms are rational. Each such sequence has only finitely many nonzero terms, so it certainly belongs to ℓ^p . The map $(q_1, \dots, q_n) \mapsto (q_1, \dots, q_n, 0, 0, \dots)$ is a one-to-one correspondence of $\mathbb{Q}^n$ with $\mathcal{D}_n$, and a finite Cartesian product of countable sets is countable; hence each $\mathcal{D}_n$ is countable. Therefore

$$\mathcal{D} = \bigcup_{n \in \mathbb{N}} \mathcal{D}_n$$

is a countable union of countable sets and so is countable.

We claim $\mathcal{D}$ is dense in ℓ^p . Let $a = \{a_k\}_{k=1}^\infty$ belong to ℓ^p and let $\epsilon > 0$. Since the series $\sum_{k=1}^\infty |a_k|^p$ converges, its tails tend to 0; choose a natural number N for which

$$\sum_{k=N+1}^\infty |a_k|^p < (\epsilon/2)^p.$$

Let $a^{(N)} = (a_1, \dots, a_N, 0, 0, \dots)$. Then

$$\|a - a^{(N)}\|_p = \left(\sum_{k=N+1}^\infty |a_k|^p \right)^{1/p} < \epsilon/2.$$

By the density of the rational numbers in $\mathbb{R}$, for each $1 \leq k \leq N$ choose a rational q_k with

$$|a_k - q_k|^p < \frac{(\epsilon/2)^p}{N},$$

and set $q = (q_1, \dots, q_N, 0, 0, \dots)$, a member of $\mathcal{D}_N \subseteq \mathcal{D}$. Then

$$\|a^{(N)} - q\|_p = \left(\sum_{k=1}^N |a_k - q_k|^p \right)^{1/p} < \left(N \cdot \frac{(\epsilon/2)^p}{N} \right)^{1/p} = \epsilon/2.$$

By the Minkowski Inequality (that is, the triangle inequality for the ℓ^p norm),

$$\|a - q\|_p \leq \|a - a^{(N)}\|_p + \|a^{(N)} - q\|_p < \epsilon/2 + \epsilon/2 = \epsilon.$$

Thus $\mathcal{D}$ is a countable dense subset of ℓ^p , and ℓ^p is separable.

We next show that the collection of sets of natural numbers is uncountable. Let $\mathcal{P}(\mathbb{N})$ denote the collection of all subsets of $\mathbb{N}$. It is not finite, since the singletons $\{n\}$, $n \in \mathbb{N}$, are infinitely many distinct members. Suppose, to obtain a contradiction, that $\mathcal{P}(\mathbb{N})$ is countable. Then it may be enumerated as $\{A_n\}_{n=1}^\infty$. Define

$$A = \{n \in \mathbb{N} : n \notin A_n\}.$$

Then A is a subset of $\mathbb{N}$, so $A = A_m$ for some natural number m . Ask whether m belongs to A . If $m \in A$, then by the definition of A we have $m \notin A_m = A$, a contradiction. If $m \notin A = A_m$, then by the definition of A we have $m \in A$, again a contradiction. This contradiction shows that $\mathcal{P}(\mathbb{N})$ is uncountable.

Finally we show that ℓ^∞ is not separable. For $A \subseteq \mathbb{N}$, let χ_A denote the sequence whose k -th term is 1 if $k \in A$ and 0 if $k \notin A$. Each χ_A is a bounded sequence, so χ_A belongs to ℓ^∞ . If A and B are distinct subsets of $\mathbb{N}$, there is an index k belonging to one of them and not the other, and for that index the k -th terms of χ_A and χ_B differ by 1; since all terms of $\chi_A - \chi_B$ have absolute value at most 1,

$$\|\chi_A - \chi_B\|_\infty = 1 \quad \text{if } A \neq B.$$

Suppose, to obtain a contradiction, that ℓ^∞ is separable, and let $\{x_n\}_{n=1}^\infty$ be a countable dense subset of ℓ^∞ . For each subset A of $\mathbb{N}$, by density there is a natural number, which we call $\eta(A)$, for which

$$\|\chi_A - x_{\eta(A)}\|_\infty < 1/2.$$

We claim η is one-to-one. Indeed, suppose $A \neq B$ but $\eta(A) = \eta(B) = m$. Then, by the triangle inequality,

$$1 = \|\chi_A - \chi_B\|_\infty \leq \|\chi_A - x_m\|_\infty + \|x_m - \chi_B\|_\infty < 1/2 + 1/2 = 1,$$

which is a contradiction. Hence η is a one-to-one mapping of $\mathcal{P}(\mathbb{N})$ into $\mathbb{N}$, so $\mathcal{P}(\mathbb{N})$ is equipotent to a subset of $\mathbb{N}$ and therefore countable. This contradicts the uncountability of $\mathcal{P}(\mathbb{N})$ just established. Therefore ℓ^∞ is not separable.

This argument is the sequence-space analogue of the example in Section 7.4 showing that $L^\infty[a, b]$ is not separable.

Problem 7.45. Prove Theorem 12. [Theorem 12: Let E be a measurable set and $1 \leq p < \infty$. Then $C_c(E)$ is dense in $L^p(E)$. Here $C_c(E)$ denotes the linear space of continuous real-valued functions on E that vanish outside a bounded set.]

Solution. Let f belong to $L^p(E)$ and let $\epsilon > 0$. We must produce a function g in $C_c(E)$ for which $\|f - g\|_{L^p(E)} < \epsilon$.

Step 1: reduction to $E = \mathbb{R}$. Extend f to a function $\tilde{f}$ on all of $\mathbb{R}$ by setting $\tilde{f} = 0$ on $\mathbb{R} \setminus E$. Then $\tilde{f}$ is measurable and $\int_{\mathbb{R}} |\tilde{f}|^p = \int_E |f|^p < \infty$, so $\tilde{f}$ belongs to $L^p(\mathbb{R})$. If g is a continuous function on $\mathbb{R}$ that vanishes outside a bounded set, then its restriction to E is continuous on E and vanishes outside a bounded set, so this restriction belongs to $C_c(E)$; moreover, since $|f - g|^p \leq |\tilde{f} - g|^p$ on E and $E \subseteq \mathbb{R}$,

$$\|f - g\|_{L^p(E)} \leq \|\tilde{f} - g\|_{L^p(\mathbb{R})}.$$

So it suffices to approximate $\tilde{f}$, in the $L^p(\mathbb{R})$ norm, by a continuous function on $\mathbb{R}$ that vanishes outside a bounded set. Rename $\tilde{f}$ as f .

Step 2: truncation to a bounded interval. For each natural number n , $|f|^p \cdot \chi_{[-n,n]}$ is a nonnegative measurable function and these functions increase pointwise on $\mathbb{R}$ to $|f|^p$. By the Monotone Convergence Theorem,

$$\lim_{n \rightarrow \infty} \int_{[-n,n]} |f|^p = \int_{\mathbb{R}} |f|^p,$$

and since this common value is finite we may choose a natural number n for which

$$\int_{\mathbb{R} \setminus [-n,n]} |f|^p = \int_{\mathbb{R}} |f|^p - \int_{[-n,n]} |f|^p < (\epsilon/3)^p.$$

Set $a = -n$, $b = n$, and $f_1 = f \cdot \chi_{[a,b]}$. Then f_1 belongs to $L^p(\mathbb{R})$ and

$$\|f - f_1\|_{L^p(\mathbb{R})} = \left(\int_{\mathbb{R} \setminus [a,b]} |f|^p \right)^{1/p} < \epsilon/3.$$

Step 3: approximation by a step function. The restriction of f_1 to $[a,b]$ belongs to $L^p[a,b]$. By Proposition 10, the step functions on $[a,b]$ are dense in $L^p[a,b]$, so there is a step function ψ on $[a,b]$ for which

$$\|f_1 - \psi\|_{L^p[a,b]} < \epsilon/3.$$

Extend ψ to $\mathbb{R}$ by setting it equal to 0 outside $[a,b]$. Since f_1 also vanishes outside $[a,b]$, we then have $\|f_1 - \psi\|_{L^p(\mathbb{R})} < \epsilon/3$. By the definition of a step function there is a partition $a = x_0 < x_1 < \dots < x_m = b$ of $[a,b]$ and numbers $c_1, \dots, c_m$ for which $\psi = c_k$ on the open interval (x_{k-1}, x_k) for $1 \leq k \leq m$. The finitely many partition points form a set of measure zero, so

$$\psi = \sum_{k=1}^m c_k \cdot \chi_{(x_{k-1}, x_k)} \quad \text{a.e. on } \mathbb{R},$$

and hence ψ and this linear combination are the same member of $L^p(\mathbb{R})$.

Step 4: approximation of a characteristic function of an interval by a continuous function. Let (c, d) be a bounded open interval and let $\delta > 0$ with $2\delta < d - c$. Define h_δ on $\mathbb{R}$ by

$$h_\delta(x) = \begin{cases} 0, & x \leq c \text{ or } x \geq d, \\ 1, & c + \delta \leq x \leq d - \delta, \\ (x - c)/\delta, & c < x < c + \delta, \\ (d - x)/\delta, & d - \delta < x < d. \end{cases}$$

This function is piecewise linear and the definitions agree at the junction points, so h_δ is continuous on $\mathbb{R}$; it vanishes outside the bounded set $[c, d]$. Moreover $0 \leq h_\delta \leq 1$ and $h_\delta = \chi_{(c,d)}$ except on the

two intervals $(c, c + \delta)$ and $(d - \delta, d)$ together with the two points c, d . Therefore $|\chi_{(c,d)} - h_\delta| \leq 1$ and this difference vanishes outside a set of measure 2δ , so

$$\|\chi_{(c,d)} - h_\delta\|_{L^p(\mathbb{R})} \leq (2\delta)^{1/p},$$

which tends to 0 as $\delta \rightarrow 0^+$ since $p < \infty$. Hence $\chi_{(c,d)}$ may be approximated in $L^p(\mathbb{R})$, to within any prescribed positive tolerance, by a continuous function on $\mathbb{R}$ that vanishes outside a bounded set.

Step 5: conclusion. Apply Step 4 to each of the intervals (x_{k-1}, x_k) , $1 \leq k \leq m$: choose continuous functions g_k on $\mathbb{R}$, each vanishing outside a bounded set, for which

$$\|\chi_{(x_{k-1}, x_k)} - g_k\|_{L^p(\mathbb{R})} < \frac{\epsilon}{3m(1 + |c_k|)}.$$

Define $g = \sum_{k=1}^m c_k g_k$. As a finite linear combination of continuous functions vanishing outside bounded sets, g is continuous on $\mathbb{R}$ and vanishes outside a bounded set. By the Minkowski Inequality,

$$\|\psi - g\|_{L^p(\mathbb{R})} \leq \sum_{k=1}^m |c_k| \cdot \|\chi_{(x_{k-1}, x_k)} - g_k\|_{L^p(\mathbb{R})} < \sum_{k=1}^m \frac{|c_k| \epsilon}{3m(1 + |c_k|)} \leq \epsilon/3.$$

Therefore, by the Minkowski Inequality once more,

$$\|f - g\|_{L^p(\mathbb{R})} \leq \|f - f_1\|_{L^p(\mathbb{R})} + \|f_1 - \psi\|_{L^p(\mathbb{R})} + \|\psi - g\|_{L^p(\mathbb{R})} < \epsilon/3 + \epsilon/3 + \epsilon/3 = \epsilon.$$

By Step 1, the restriction of g to E belongs to $C_c(E)$ and satisfies $\|f - g\|_{L^p(E)} < \epsilon$. Since f in $L^p(E)$ and $\epsilon > 0$ were arbitrary, $C_c(E)$ is dense in $L^p(E)$.

Problem 7.46. Show that for $1 < p < \infty$ and any two numbers a and b ,

$$\left| \operatorname{sgn}(a) \cdot |a|^{1/p} - \operatorname{sgn}(b) \cdot |b|^{1/p} \right|^p \leq 2^p \cdot |a - b|.$$

Solution. Write $s = 1/p$, so that $0 < s < 1$, and define

$$\varphi(t) = \operatorname{sgn}(t) \cdot |t|^s \quad \text{for } t \in \mathbb{R}.$$

The asserted inequality is $|\varphi(a) - \varphi(b)|^p \leq 2^p |a - b|$, and since both sides are nonnegative and $t \mapsto t^{1/p}$ is increasing on $[0, \infty)$, it is equivalent to

$$|\varphi(a) - \varphi(b)| \leq 2 |a - b|^s.$$

Call this last inequality (*).

We first record a lemma.

Lemma (subadditivity of $t \mapsto t^s$ for $0 < s < 1$): for all $u, v \geq 0$,

$$(u + v)^s \leq u^s + v^s.$$

Indeed, if $u = v = 0$ this is trivial. Otherwise let $T = u + v > 0$. Since $0 \leq u/T \leq 1$ and $0 < s < 1$, we have $(u/T)^s \geq u/T$, because for $0 \leq x \leq 1$ raising to a power smaller than 1 increases the number: $x^s = x \cdot x^{s-1} \geq x$ as $x^{s-1} \geq 1$ when $0 < x \leq 1$ and $s - 1 < 0$ (and the inequality is clear when $x = 0$). Likewise $(v/T)^s \geq v/T$. Adding,

$$\frac{u^s + v^s}{T^s} \geq \frac{u}{T} + \frac{v}{T} = 1,$$

which is the assertion.

Now we prove (*). Note that φ is odd, $\varphi(-t) = -\varphi(t)$, so replacing the pair (a, b) by $(-a, -b)$ changes neither side of (*); and both sides of (*) are unchanged when a and b are interchanged. We use these two symmetries to reduce to two cases.

Case 1: a and b have the same sign, where we count 0 as having either sign. After replacing (a, b) by $(-a, -b)$ if necessary we may assume $a \geq 0$ and $b \geq 0$, and after interchanging a and b if necessary we

may assume $a \geq b \geq 0$. Then $\varphi(a) = a^s$ and $\varphi(b) = b^s$, and $|a - b| = a - b$. Apply the Lemma with $u = a - b \geq 0$ and $v = b \geq 0$:

$$a^s = (u + v)^s \leq (a - b)^s + b^s,$$

so that

$$|\varphi(a) - \varphi(b)| = a^s - b^s \leq (a - b)^s = |a - b|^s \leq 2|a - b|^s.$$

Case 2: a and b have strictly opposite signs. Interchanging a and b if necessary, we may assume $a > 0 > b$. Then

$$\varphi(a) - \varphi(b) = a^s + |b|^s, \quad |a - b| = a + |b|.$$

Since $t \mapsto t^s$ is increasing on $[0, \infty)$ and both a and $|b|$ are at most $a + |b|$,

$$a^s + |b|^s \leq (a + |b|)^s + (a + |b|)^s = 2(a + |b|)^s = 2|a - b|^s.$$

Hence $|\varphi(a) - \varphi(b)| \leq 2|a - b|^s$ in this case as well.

In both cases (*) holds. Raising both sides of (*) to the power $p > 0$, which preserves the inequality between nonnegative numbers, gives

$$\left| \operatorname{sgn}(a) \cdot |a|^{1/p} - \operatorname{sgn}(b) \cdot |b|^{1/p} \right|^p \leq 2^p \left(|a - b|^{1/p} \right)^p = 2^p \cdot |a - b|,$$

which is the desired inequality.

Problem 7.47. Show that for $1 < p < \infty$ and any two numbers a and b ,

$$|\operatorname{sgn}(a) \cdot |a|^p - \operatorname{sgn}(b) \cdot |b|^p| \leq p \cdot |a - b| (|a| + |b|)^{p-1}.$$

Solution. Define

$$\psi(t) = \operatorname{sgn}(t) \cdot |t|^p \quad \text{for } t \in \mathbb{R},$$

so that $\psi(t) = t^p$ for $t \geq 0$ and $\psi(t) = -(-t)^p$ for $t \leq 0$; in particular $\psi(0) = 0$ and ψ is odd.

We claim that ψ is differentiable on all of $\mathbb{R}$ with

$$\psi'(t) = p|t|^{p-1} \quad \text{for all } t \in \mathbb{R}.$$

For $t > 0$ we have $\psi = t^p$ in a neighborhood of t , so $\psi'(t) = p t^{p-1} = p|t|^{p-1}$. For $t < 0$ we have $\psi(t) = -(-t)^p$ in a neighborhood of t , so by the chain rule

$$\psi'(t) = -p(-t)^{p-1} \cdot (-1) = p(-t)^{p-1} = p|t|^{p-1}.$$

At $t = 0$, for $h \neq 0$,

$$\frac{\psi(h) - \psi(0)}{h} = \frac{\operatorname{sgn}(h)|h|^p}{h} = \frac{|h|^p}{|h|} = |h|^{p-1},$$

where we used $\operatorname{sgn}(h)/h = 1/|h|$. Since $p > 1$, the exponent $p - 1$ is positive, so $|h|^{p-1} \rightarrow 0$ as $h \rightarrow 0$. Hence $\psi'(0) = 0 = p \cdot |0|^{p-1}$, and the claim is proved.

Now let a and b be real numbers. If $a = b$ both sides of the asserted inequality equal 0 and there is nothing to prove, so assume $a \neq b$. The function ψ is differentiable, hence continuous, on the closed interval with endpoints a and b and differentiable on its interior. By the Mean Value Theorem there is a number c strictly between a and b for which

$$\psi(a) - \psi(b) = \psi'(c) (a - b) = p|c|^{p-1} (a - b).$$

Since c lies between a and b , we have $|c| \leq \max\{|a|, |b|\} \leq |a| + |b|$. As $p - 1 > 0$, the function $t \mapsto t^{p-1}$ is increasing on $[0, \infty)$, so $|c|^{p-1} \leq (|a| + |b|)^{p-1}$. Therefore

$$|\operatorname{sgn}(a)|a|^p - \operatorname{sgn}(b)|b|^p| = |\psi(a) - \psi(b)| = p|c|^{p-1} |a - b| \leq p \cdot |a - b| (|a| + |b|)^{p-1},$$

as was to be shown.

Problem 7.48. (Mazur) Let E be a measurable set and $1 < p < \infty$. For f in $L^1(E)$, define the function $\Phi(f)$ on E by

$$\Phi(f)(x) = \operatorname{sgn}(f(x)) |f(x)|^{1/p}.$$

Show that $\Phi(f)$ belongs to $L^p(E)$. Moreover, use Problem 46 to show that

$$\|\Phi(f) - \Phi(g)\|_p \leq 2^p \cdot \|f - g\|_1 \quad \text{for all } f, g \text{ in } L^1(E).$$

From this conclude that Φ is a continuous mapping of $L^1(E)$ into $L^p(E)$ in the sense that if $\{f_n\} \rightarrow f$ in $L^1(E)$, then $\{\Phi(f_n)\} \rightarrow \Phi(f)$ in $L^p(E)$. Then show that Φ is one-to-one and its image is $L^p(E)$. Find a formula for the inverse mapping. Use the preceding problem to conclude that the inverse mapping Φ^{-1} is a continuous mapping from $L^p(E)$ to $L^1(E)$.

Solution. Throughout, let $q = p/(p-1)$ be the conjugate of p , and define the two functions on $\mathbb{R}$

$$\varphi(t) = \operatorname{sgn}(t) |t|^{1/p}, \quad \psi(t) = \operatorname{sgn}(t) |t|^p,$$

so that $\Phi(f) = \varphi \circ f$.

Both φ and ψ are continuous on $\mathbb{R}$: each is continuous on $(0, \infty)$ and on $(-\infty, 0)$ by the continuity of powers, each is odd, and each tends to 0 as $t \rightarrow 0$. Moreover φ and ψ are strictly increasing on $\mathbb{R}$: on $[0, \infty)$ the functions $t \mapsto t^{1/p}$ and $t \mapsto t^p$ are strictly increasing and vanish only at 0, and both φ and ψ are odd, so each is negative on $(-\infty, 0)$, zero at 0, positive on $(0, \infty)$, and strictly increasing on each of the two half-lines. Finally, for all t ,

$$\psi(\varphi(t)) = \operatorname{sgn}(t) \left(|t|^{1/p}\right)^p = t \quad \text{and likewise} \quad \varphi(\psi(t)) = t,$$

using $\operatorname{sgn}(\varphi(t)) = \operatorname{sgn}(t)$ and $\operatorname{sgn}(\psi(t)) = \operatorname{sgn}(t)$. So φ is a bijection of $\mathbb{R}$ onto $\mathbb{R}$ with inverse ψ .

A preliminary remark on representatives. If f belongs to $L^1(E)$ then $|f|$ is a nonnegative integrable function, and if h belongs to $L^p(E)$ then $|h|^p$ is; so by Proposition 13 of Chapter 4 each such function is finite almost everywhere on E . The formulas below involve φ and ψ , which are defined only on $\mathbb{R}$, so throughout we work with a representative that is real-valued at every point of E ; altering a function on a set of measure zero changes neither the equivalence class it names nor any of the integrals computed below, so nothing depends on the choice.

Step 1: $\Phi(f)$ belongs to $L^p(E)$. Let f be in $L^1(E)$. Since f is measurable and φ is continuous on all of $\mathbb{R}$, the composition $\Phi(f) = \varphi \circ f$ is measurable. Furthermore, for all x in E ,

$$|\Phi(f)(x)|^p = \left(|f(x)|^{1/p}\right)^p = |f(x)|,$$

and $|f|$ is integrable over E . Hence $\int_E |\Phi(f)|^p = \int_E |f| < \infty$, so $\Phi(f)$ belongs to $L^p(E)$ and in fact

$$\|\Phi(f)\|_p = \|f\|_1^{1/p}.$$

Note also that if $f = g$ a.e. on E then $\Phi(f) = \Phi(g)$ a.e. on E , so Φ is well defined as a mapping of $L^1(E)$ into $L^p(E)$.

Step 2: the Lipschitz-type estimate. Let f, g belong to $L^1(E)$. By Problem 46, applied at each point x of E with $a = f(x)$ and $b = g(x)$,

$$|\Phi(f)(x) - \Phi(g)(x)|^p \leq 2^p |f(x) - g(x)| \quad \text{for all } x \in E.$$

Integrating this inequality between nonnegative measurable functions over E and using the monotonicity and linearity of integration,

$$\|\Phi(f) - \Phi(g)\|_p^p = \int_E |\Phi(f) - \Phi(g)|^p \leq 2^p \int_E |f - g| = 2^p \cdot \|f - g\|_1.$$

Equivalently, taking p -th roots,

$$\|\Phi(f) - \Phi(g)\|_p \leq 2 \cdot \|f - g\|_1^{1/p}.$$

A remark on the inequality as printed. The displayed assertion in the statement of the problem is

$$\|\Phi(f) - \Phi(g)\|_p \leq 2^p \cdot \|f - g\|_1,$$

with no exponent on the left-hand norm, and this is not correct as it stands. Indeed, take $E = [0, 1]$, $p = 2$, $g \equiv 0$, and $f \equiv c$ for a constant c with $0 < c < 1$. Then $\|f - g\|_1 = c$ while $\Phi(f) \equiv c^{1/2}$, so $\|\Phi(f) - \Phi(g)\|_2 = c^{1/2}$. The printed inequality would assert $c^{1/2} \leq 4c$, that is, $c \geq 1/16$; taking $c = 1/100$ gives $1/10 > 4/100$, a contradiction. The failure is intrinsic and not a matter of the constant: the left side is comparable to $\|f - g\|_1^{1/p}$, which dominates any fixed multiple of $\|f - g\|_1$ as $\|f - g\|_1 \rightarrow 0$, since $1/p < 1$.

The inequality that Problem 46 actually yields is the one displayed above for the p -th power of the norm, equivalently the $1/p$ -Holder estimate

$$\|\Phi(f) - \Phi(g)\|_p \leq 2 \cdot \|f - g\|_1^{1/p},$$

and this is what is used in what follows. It serves the purpose the problem intends, namely to force the continuity of Φ ; the printed form is a misprint for $\|\Phi(f) - \Phi(g)\|_p^p \leq 2^p \cdot \|f - g\|_1$.

Step 3: Φ is continuous. Suppose $\{f_n\} \rightarrow f$ in $L^1(E)$, that is, $\|f_n - f\|_1 \rightarrow 0$. By Step 2,

$$\|\Phi(f_n) - \Phi(f)\|_p \leq 2 \|f_n - f\|_1^{1/p} \rightarrow 0,$$

since $t \mapsto t^{1/p}$ is continuous at 0 with value 0. Thus $\{\Phi(f_n)\} \rightarrow \Phi(f)$ in $L^p(E)$, so Φ is continuous.

Step 4: Φ is one-to-one. Suppose f, g belong to $L^1(E)$ and $\Phi(f) = \Phi(g)$ in $L^p(E)$, that is, $\varphi(f(x)) = \varphi(g(x))$ for almost all x in E . Since φ is one-to-one on $\mathbb{R}$, it follows that $f(x) = g(x)$ for almost all x in E , that is, $f = g$ in $L^1(E)$.

Step 5: the image of Φ is all of $L^p(E)$, and the inverse formula. Let h belong to $L^p(E)$ and define

$$f = \psi \circ h, \quad \text{that is,} \quad f(x) = \operatorname{sgn}(h(x)) |h(x)|^p.$$

Since h is measurable and ψ is continuous on $\mathbb{R}$, f is measurable; and $|f| = |h|^p$ is integrable over E because h belongs to $L^p(E)$. Hence f belongs to $L^1(E)$, with $\|f\|_1 = \|h\|_p^p$. Moreover, since $\varphi \circ \psi$ is the identity on $\mathbb{R}$,

$$\Phi(f)(x) = \varphi(\psi(h(x))) = h(x) \quad \text{for all } x \in E.$$

So h lies in the image of Φ . Together with Step 4, Φ is a one-to-one mapping of $L^1(E)$ onto $L^p(E)$, and its inverse is given by

$$\Phi^{-1}(h)(x) = \operatorname{sgn}(h(x)) |h(x)|^{p-1} \quad \text{for } h \in L^p(E).$$

Step 6: Φ^{-1} is continuous. Let h, k belong to $L^p(E)$. By Problem 47, applied pointwise with $a = h(x)$ and $b = k(x)$,

$$|\Phi^{-1}(h)(x) - \Phi^{-1}(k)(x)| \leq p |h(x) - k(x)| (|h(x)| + |k(x)|)^{p-1} \quad \text{for all } x \in E.$$

The function $(|h| + |k|)^{p-1}$ belongs to $L^q(E)$, since

$$\int_E [(|h| + |k|)^{p-1}]^q = \int_E (|h| + |k|)^{(p-1) \cdot \frac{p}{p-1}} = \int_E (|h| + |k|)^p = \| |h| + |k| \|_p^p < \infty,$$

the finiteness following from the Minkowski Inequality, which gives $\| |h| + |k| \|_p \leq \|h\|_p + \|k\|_p < \infty$. Reading the same computation as an identity of norms,

$$\|(|h| + |k|)^{p-1}\|_q = \| |h| + |k| \|_p^{p/q} = \| |h| + |k| \|_p^{p-1} \leq (\|h\|_p + \|k\|_p)^{p-1},$$

where we used $p/q = p - 1$ and again the Minkowski Inequality. Now integrate the pointwise estimate over E and apply Holder's Inequality with the conjugate exponents p and q :

$$\begin{aligned} \|\Phi^{-1}(h) - \Phi^{-1}(k)\|_1 &= \int_E |\Phi^{-1}(h) - \Phi^{-1}(k)| \\ &\leq p \int_E |h - k| \cdot (|h| + |k|)^{p-1} \\ &\leq p \|h - k\|_p \cdot \|(|h| + |k|)^{p-1}\|_q \\ &\leq p (\|h\|_p + \|k\|_p)^{p-1} \|h - k\|_p. \end{aligned}$$

Suppose now that $\{h_n\} \rightarrow h$ in $L^p(E)$. Since $|\|h_n\|_p - \|h\|_p| \leq \|h_n - h\|_p \rightarrow 0$, the sequence of numbers $\{\|h_n\|_p\}$ is bounded, say $\|h_n\|_p \leq M$ for all n . Taking $k = h_n$ in the estimate just proved,

$$\|\Phi^{-1}(h_n) - \Phi^{-1}(h)\|_1 \leq p(M + \|h\|_p)^{p-1} \|h_n - h\|_p \rightarrow 0.$$

Therefore $\{\Phi^{-1}(h_n)\} \rightarrow \Phi^{-1}(h)$ in $L^1(E)$, so Φ^{-1} is a continuous mapping of $L^p(E)$ onto $L^1(E)$.

Problem 7.49. Use the preceding problem to show that the separability of $L^1(E)$ implies the separability of $L^p(E)$, for $1 < p < \infty$.

Solution. Assume $L^1(E)$ is separable and let $1 < p < \infty$. Let $\mathcal{D}$ be a countable dense subset of $L^1(E)$, enumerated as $\mathcal{D} = \{f_n\}_{n=1}^\infty$, with repetitions allowed in case $\mathcal{D}$ is finite. Let $\Phi: L^1(E) \rightarrow L^p(E)$ be the Mazur mapping of the preceding problem,

$$\Phi(f)(x) = \operatorname{sgn}(f(x)) |f(x)|^{1/p}.$$

Define

$$\Phi(\mathcal{D}) = \{\Phi(f_n) : n \in \mathbb{N}\}.$$

By the preceding problem each $\Phi(f_n)$ belongs to $L^p(E)$, and $\Phi(\mathcal{D})$ is the image of a countable set under a mapping, hence is countable.

We claim $\Phi(\mathcal{D})$ is dense in $L^p(E)$. Let h belong to $L^p(E)$ and let $\epsilon > 0$. By the preceding problem Φ maps $L^1(E)$ onto $L^p(E)$, so there is a function f in $L^1(E)$ with $\Phi(f) = h$; explicitly, $f = \Phi^{-1}(h)$ is given by $f(x) = \operatorname{sgn}(h(x)) |h(x)|^p$. Since $\mathcal{D}$ is dense in $L^1(E)$, there is an index n for which

$$\|f - f_n\|_1 < \left(\frac{\epsilon}{2}\right)^p.$$

By the estimate established in the preceding problem, namely

$$\|\Phi(u) - \Phi(v)\|_p^p \leq 2^p \|u - v\|_1, \quad \text{that is,} \quad \|\Phi(u) - \Phi(v)\|_p \leq 2 \|u - v\|_1^{1/p},$$

valid for all u, v in $L^1(E)$ (this is the pointwise inequality of Problem 46 integrated over E ; as noted in the solution to the preceding problem, this, and not the form printed there, is the correct estimate), we conclude

$$\|h - \Phi(f_n)\|_p = \|\Phi(f) - \Phi(f_n)\|_p \leq 2 \|f - f_n\|_1^{1/p} < 2 \cdot \frac{\epsilon}{2} = \epsilon.$$

Thus every function in $L^p(E)$ can be approximated to within an arbitrary positive tolerance, in the $L^p(E)$ norm, by a member of the countable set $\Phi(\mathcal{D})$. Hence $\Phi(\mathcal{D})$ is a countable dense subset of $L^p(E)$, and $L^p(E)$ is separable.

The argument is simply that a continuous surjection carries a dense set onto a dense set: since Φ is continuous and onto, and $\mathcal{D}$ is dense in $L^1(E)$, the image $\Phi(\mathcal{D})$ is dense in $L^p(E)$; countability is preserved under images. This gives a second proof of the separability of $L^p(E)$ for $1 < p < \infty$, granted the case $p = 1$ of Theorem 11.

7.8 Problems 7.50–7.51

Problem 7.50. For $[a, b]$ a nondegenerate closed, bounded interval, show that there is no continuous mapping Φ from $L^1[a, b]$ onto $L^\infty[a, b]$.

Solution. Here, as in Problem 48, a mapping Φ between normed linear spaces is called continuous provided that whenever $\{f_n\} \rightarrow f$ in the domain, $\{\Phi(f_n)\} \rightarrow \Phi(f)$ in the target. (Since both $L^1[a, b]$ and $L^\infty[a, b]$ are metric spaces, this sequential continuity is the same as continuity in the sense of the norm topologies, so nothing is lost by using this formulation.)

The proof rests on two facts already established in this section: $L^1[a, b]$ is separable, while $L^\infty[a, b]$ is not.

Indeed, by Theorem 11, applied with $E = [a, b]$ and $p = 1$, the normed linear space $L^1[a, b]$ is separable; let

$$D = \{f_1, f_2, f_3, \dots\}$$

be a countable dense subset of $L^1[a, b]$. On the other hand, the Example following Theorem 11 shows that for a nondegenerate closed, bounded interval $[a, b]$ the normed linear space $L^\infty[a, b]$ is not separable. That Example is exactly where the nondegeneracy of $[a, b]$ enters: it considers the family $\{\chi_{[a, x]}\}_{a \leq x \leq b}$, for which

$$\|\chi_{[a, x_1]} - \chi_{[a, x_2]}\|_\infty = 1 \text{ whenever } a \leq x_1 < x_2 \leq b,$$

and it deduces that a countable dense subset $\{h_n\}_{n=1}^\infty$ of $L^\infty[a, b]$ would furnish, by assigning to each x in $[a, b]$ an index $\eta(x)$ with $\|\chi_{[a, x]} - h_{\eta(x)}\|_\infty < 1/2$, a one-to-one map η of $[a, b]$ into the natural numbers; this is impossible because $a < b$ forces $[a, b]$ to be uncountable.

Now argue by contradiction. Suppose Φ is a continuous mapping of $L^1[a, b]$ onto $L^\infty[a, b]$. Consider the image of the countable dense set D ,

$$\Phi(D) = \{\Phi(f_1), \Phi(f_2), \Phi(f_3), \dots\},$$

which is a countable subset of $L^\infty[a, b]$. We claim $\Phi(D)$ is dense in $L^\infty[a, b]$.

To see this, let g belong to $L^\infty[a, b]$. Since Φ maps $L^1[a, b]$ onto $L^\infty[a, b]$, there is a function f in $L^1[a, b]$ for which $\Phi(f) = g$. Since D is dense in $L^1[a, b]$, by Problem 36 there is a sequence $\{g_k\}_{k=1}^\infty$ of functions belonging to D for which $\{g_k\} \rightarrow f$ in $L^1[a, b]$. By the continuity of Φ ,

$$\{\Phi(g_k)\} \rightarrow \Phi(f) = g \text{ in } L^\infty[a, b].$$

Thus g is the limit, with respect to the $L^\infty[a, b]$ norm, of a sequence of functions belonging to $\Phi(D)$. Since g was an arbitrary function in $L^\infty[a, b]$, another application of Problem 36 tells us that $\Phi(D)$ is dense in $L^\infty[a, b]$.

Therefore $\Phi(D)$ is a countable dense subset of $L^\infty[a, b]$, that is, $L^\infty[a, b]$ is separable. This contradicts the Example cited above. We conclude that no such Φ exists: there is no continuous mapping of $L^1[a, b]$ onto $L^\infty[a, b]$.

Two remarks are worth recording. First, no linearity of Φ was used; the obstruction is purely topological, namely that separability is inherited by continuous images. Second, the same argument shows more generally that for any measurable set E and any $1 \leq p < \infty$ there is no continuous mapping of $L^p(E)$ onto $L^\infty(E)$ whenever E contains a nondegenerate interval, since $L^p(E)$ is separable by Theorem 11 while $L^\infty(E)$ is then not separable by Problem 42.

Problem 7.51. Use Lusin's Theorem to prove Theorem 12.

Solution. Theorem 12 asserts: for E a measurable set and $1 \leq p < \infty$, the linear space $C_c(E)$ of continuous real-valued functions on E that vanish outside a bounded set is dense in $L^p(E)$. Lusin's Theorem asserts: if u is a real-valued measurable function on E , then for each $\eta > 0$ there is a continuous function v on $\mathbb{R}$ and a closed set F contained in E for which $u = v$ on F and $m(E \setminus F) < \eta$. (The theorem is proved in Section 3.3 for $m(E) < \infty$, and Problem 29 of Chapter 3 extends it to sets of infinite measure, so we may use it for an arbitrary measurable set E .)

Let f belong to $L^p(E)$ and let $\epsilon > 0$. We must produce a function in $C_c(E)$ within ϵ of f in the $L^p(E)$ norm. We do so in three steps: first replace f by a bounded function vanishing outside a bounded set, then apply Lusin's Theorem to that function and repair the resulting continuous function so that it too is bounded and of bounded support, and finally estimate.

Step 1: reduction to a bounded function of bounded support. Since f belongs to $L^p(E)$, $|f|^p$ is integrable over E , and therefore, by Proposition 15 of Chapter 4 applied to $|f|^p$, $|f|^p$ is finite a.e. on E ; hence so is $|f|$. Let E_0 be the set of measure zero on which $|f| = \infty$. Redefine f to be 0 on E_0 . This alters f only on a set of measure zero, so it changes neither the equivalence class of f in $L^p(E)$ nor the value of $\|f - g\|_p$ for any g ; observe that we do not shrink the domain E , since the function we must finally produce is required to be continuous on all of E . We may therefore assume f is real-valued on

all of E . For each natural number n define the truncation

$$h_n(x) = \begin{cases} f(x) & \text{if } x \in E, |x| \leq n \text{ and } |f(x)| \leq n, \\ 0 & \text{otherwise on } E. \end{cases}$$

Each h_n is measurable, since it is f multiplied by the characteristic function of the measurable set $\{x \in E : |x| \leq n, |f(x)| \leq n\}$. Moreover $|h_n| \leq |f|$ on E for all n , and $\{h_n\} \rightarrow f$ pointwise on E : given $x \in E$, for all $n \geq \max\{|x|, |f(x)|\}$ we have $h_n(x) = f(x)$. Consequently

$$|h_n - f|^p \leq (|h_n| + |f|)^p \leq 2^p |f|^p \text{ on } E \text{ for all } n,$$

and $\{|h_n - f|^p\} \rightarrow 0$ pointwise on E . Since $|f|^p$ is integrable over E , the Lebesgue Dominated Convergence Theorem gives $\lim_{n \rightarrow \infty} \int_E |h_n - f|^p = 0$, that is, $\{h_n\} \rightarrow f$ in $L^p(E)$. Fix a natural number $n \geq 1$ for which

$$\|f - h_n\|_p < \epsilon/2,$$

and write $h = h_n$ and $M = n$. Thus h is a real-valued measurable function on E with $|h| \leq M$ on E and $h = 0$ on $\{x \in E : |x| > n\}$, and $M \geq 1$.

Step 2: Lusin's Theorem. Define

$$\eta = \frac{1}{2} \left(\frac{\epsilon}{4M} \right)^p > 0.$$

By Lusin's Theorem applied to the real-valued measurable function h on E (here E is an arbitrary measurable set, which is legitimate by the extension recorded above), there is a continuous function g_0 on $\mathbb{R}$ and a closed set F contained in E for which

$$h = g_0 \text{ on } F \text{ and } m(E \setminus F) < \eta.$$

The function g_0 need be neither bounded nor of bounded support, so we repair it by two continuous surgeries, each of which leaves the values on F unchanged.

First, truncate in the range. Define $\tau : \mathbb{R} \rightarrow \mathbb{R}$ by $\tau(t) = \max\{-M, \min\{t, M\}\}$. Then τ is continuous, $|\tau| \leq M$, and $\tau(t) = t$ whenever $|t| \leq M$. Set $g_1 = \tau \circ g_0$. Then g_1 is continuous on $\mathbb{R}$ with $|g_1| \leq M$, and for $x \in F$ we have $g_0(x) = h(x)$ with $|h(x)| \leq M$, so

$$g_1(x) = \tau(h(x)) = h(x) \text{ for all } x \in F.$$

Second, cut off in the domain. Define $\varphi : \mathbb{R} \rightarrow \mathbb{R}$ by

$$\varphi(x) = \begin{cases} 1 & \text{if } |x| \leq n, \\ n+1-|x| & \text{if } n < |x| < n+1, \\ 0 & \text{if } |x| \geq n+1. \end{cases}$$

Then φ is continuous on $\mathbb{R}$, $0 \leq \varphi \leq 1$, and φ vanishes outside the bounded set $[-n-1, n+1]$. Define

$$g = g_1 \cdot \varphi \text{ on } \mathbb{R}.$$

Then g is continuous on $\mathbb{R}$, $|g| \leq M$, and g vanishes outside $[-n-1, n+1]$. Hence the restriction of g to E is a continuous real-valued function on E that vanishes outside a bounded set, that is, g belongs to $C_c(E)$. It is worth pausing on the fact that g also belongs to $L^p(E)$: a member of $C_c(E)$ need not be p -integrable, since continuity on E does not force boundedness on the bounded set outside of which the function vanishes, as the function $x \mapsto 1/x$ on $E = (0, 1)$ shows. Our g is however bounded, and so

$$\int_E |g|^p \leq M^p \cdot m(E \cap [-n-1, n+1]) \leq M^p(2n+2) < \infty.$$

Thus g belongs to $L^p(E)$, and the quantity $\|f - g\|_p$ estimated below is finite and the Minkowski Inequality is available.

We claim $g = h$ on F . Let $x \in F$. If $|x| \leq n$, then $\varphi(x) = 1$ and hence $g(x) = g_1(x) = h(x)$. If $|x| > n$, then, because x belongs to E and h vanishes on $\{x \in E : |x| > n\}$, we have $h(x) = 0$; therefore

$g_1(x) = h(x) = 0$ and so $g(x) = g_1(x)\varphi(x) = 0 = h(x)$. In either case $g(x) = h(x)$, and the claim is proved.

Step 3: the estimate. Since $h - g$ vanishes on F and $|h - g| \leq |h| + |g| \leq 2M$ on E ,

$$\int_E |h - g|^p = \int_{E \sim F} |h - g|^p \leq (2M)^p \cdot m(E \sim F) < (2M)^p \eta.$$

By the choice of η made in Step 2,

$$(2M)^p \eta = \frac{1}{2} \left(\frac{2M\epsilon}{4M} \right)^p = \frac{1}{2} \left(\frac{\epsilon}{2} \right)^p < \left(\frac{\epsilon}{2} \right)^p,$$

and therefore

$$\|h - g\|_p = \left(\int_E |h - g|^p \right)^{1/p} < \epsilon/2.$$

Finally, by the Minkowski Inequality (the triangle inequality for the $L^p(E)$ norm),

$$\|f - g\|_p \leq \|f - h\|_p + \|h - g\|_p < \epsilon/2 + \epsilon/2 = \epsilon.$$

Since f in $L^p(E)$ and $\epsilon > 0$ were arbitrary, and g belongs to $C_c(E)$, we conclude that $C_c(E)$ is dense in $L^p(E)$. This is Theorem 12.

8.1 Problems 8.1–8.7

Problem 8.1. Verify (8), that is, verify that for a bounded linear functional T on a normed linear space X ,

$$\|T\|_* = \sup\{T(f) \mid f \in X, \|f\| \leq 1\}.$$

Solution. Recall the definition preceding (8): T is bounded provided there is an $M \geq 0$ for which the inequality (5),

$$|T(f)| \leq M \cdot \|f\| \quad \text{for all } f \in X,$$

holds, and $\|T\|_*$ is the infimum of the set $\mathcal{M}$ of all such M . Since T is bounded, $\mathcal{M}$ is a nonempty set of nonnegative numbers, so $\|T\|_* = \inf \mathcal{M}$ is a well-defined nonnegative number.

Write $B = \{f \in X \mid \|f\| \leq 1\}$ and

$$S = \sup\{T(f) \mid f \in B\}.$$

First observe that $S = \sup\{|T(f)| \mid f \in B\}$. Indeed, B is symmetric: if f belongs to B then so does $-f$, since $\|-f\| = |-1| \cdot \|f\| = \|f\| \leq 1$. By the linearity of T , $T(-f) = -T(f)$. Hence the set $\{T(f) \mid f \in B\}$ is symmetric about 0, and therefore its supremum equals the supremum of the absolute values of its members. In particular $S \geq T(0) = 0$.

We now show $S \leq \|T\|_*$ and $S \geq \|T\|_*$.

Let M belong to $\mathcal{M}$. For f in B we have, by (5), $|T(f)| \leq M \cdot \|f\| \leq M$. Taking the supremum over f in B gives $S \leq M$. Since M was an arbitrary member of $\mathcal{M}$, S is a lower bound for $\mathcal{M}$, and therefore

$$S \leq \inf \mathcal{M} = \|T\|_*.$$

Conversely, we claim S itself belongs to $\mathcal{M}$. Let f belong to X . If $f = 0$, then $T(f) = 0$ by linearity and (5) holds trivially with $M = S$ since $S \geq 0$. If $f \neq 0$, then $\|f\| > 0$ and the vector $h = f/\|f\|$ satisfies $\|h\| = 1$, so h belongs to B and hence $|T(h)| \leq S$. By the linearity of T , $T(h) = T(f)/\|f\|$, so

$$|T(f)| = \|f\| \cdot |T(h)| \leq S \cdot \|f\|.$$

Thus S belongs to $\mathcal{M}$, and therefore $\|T\|_* = \inf \mathcal{M} \leq S$.

Combining the two inequalities, $\|T\|_* = S$, which is (8).

Two remarks are worth recording, since they are used repeatedly in this section. First, the argument above shows that the infimum defining $\|T\|_*$ is attained: $\|T\|_* = S$ belongs to $\mathcal{M}$, so (5) holds with $M = \|T\|_*$, that is,

$$|T(f)| \leq \|T\|_* \cdot \|f\| \quad \text{for all } f \in X.$$

Second, by the linearity of T , applying this to $f - h$ yields (6):

$$|T(f) - T(h)| = |T(f - h)| \leq \|T\|_* \cdot \|f - h\| \quad \text{for all } f, h \in X.$$

Problem 8.2. Prove Proposition 1: Let X be a normed linear space. Then the collection of bounded linear functionals on X is a linear space on which $\|\cdot\|_*$ is a norm. This normed linear space is called the dual space of X and denoted by X^* .

Solution. Throughout we use the characterization (8) established in the preceding problem, together with the two consequences recorded there: the infimum defining $\|T\|_*$ is attained, and

$$\|T\|_* = \sup\{|T(f)| \mid f \in X, \|f\| \leq 1\}.$$

Let $\mathcal{L}$ denote the linear space of all linear functionals on X , with the pointwise linear operations

$$(\alpha \cdot T + \beta \cdot S)(f) = \alpha \cdot T(f) + \beta \cdot S(f),$$

and let X^* be the subset of $\mathcal{L}$ consisting of the bounded ones.

Step 1: X^* is a linear subspace of $\mathcal{L}$. The zero functional is bounded, so X^* is nonempty. Let T and S belong to X^* and let α, β be real numbers. The functional $\alpha \cdot T + \beta \cdot S$ is linear, since a pointwise linear combination of linear functionals is linear. Moreover, for f in X , by the triangle inequality in $\mathbb{R}$ and the boundedness of T and S ,

$$|(\alpha \cdot T + \beta \cdot S)(f)| \leq |\alpha| \cdot |T(f)| + |\beta| \cdot |S(f)| \leq (|\alpha| \cdot \|T\|_* + |\beta| \cdot \|S\|_*) \cdot \|f\|.$$

Hence $\alpha \cdot T + \beta \cdot S$ is bounded, and so belongs to X^* . Thus X^* is a linear space.

Step 2: $\|\cdot\|_*$ is a norm on X^* . We verify the three defining properties.

Nonnegativity and definiteness. By construction $\|T\|_*$ is the infimum of a nonempty set of nonnegative numbers, so $\|T\|_* \geq 0$. If $T = 0$, then $M = 0$ satisfies (5), so $\|T\|_* = 0$. Conversely, suppose $\|T\|_* = 0$. Since the infimum is attained, (5) holds with $M = 0$, that is, $|T(f)| \leq 0 \cdot \|f\| = 0$ for all f in X . Hence $T(f) = 0$ for all f , that is, $T = 0$.

Positive homogeneity. Let T belong to X^* and let α be a real number. Using the supremum formula,

$$\|\alpha \cdot T\|_* = \sup_{\|f\| \leq 1} |\alpha \cdot T(f)| = \sup_{\|f\| \leq 1} |\alpha| \cdot |T(f)| = |\alpha| \cdot \sup_{\|f\| \leq 1} |T(f)| = |\alpha| \cdot \|T\|_*,$$

where the third equality is the elementary fact that $\sup(c \cdot A) = c \cdot \sup A$ for a nonempty set A of reals bounded above and a constant $c \geq 0$.

The triangle inequality. Let T and S belong to X^* . For each f in X with $\|f\| \leq 1$,

$$|(T + S)(f)| \leq |T(f)| + |S(f)| \leq \|T\|_* + \|S\|_*.$$

Thus $\|T\|_* + \|S\|_*$ is an upper bound for the set whose supremum is $\|T + S\|_*$, and therefore

$$\|T + S\|_* \leq \|T\|_* + \|S\|_*.$$

Hence $\|\cdot\|_*$ is a norm on the linear space X^* , which completes the proof.

Problem 8.3. Let T be a linear functional on a normed linear space X . Show that T is bounded if and only if the continuity property (7) holds, that is, if and only if

$$\text{whenever } \{f_n\} \rightarrow f \text{ in } X, \text{ then } \{T(f_n)\} \rightarrow T(f).$$

Solution. Suppose first that T is bounded. Let $\{f_n\}$ be a sequence in X converging to f in X , that is, $\lim_{n \rightarrow \infty} \|f_n - f\| = 0$. By (6),

$$|T(f_n) - T(f)| \leq \|T\|_* \cdot \|f_n - f\| \quad \text{for all } n.$$

The right-hand side converges to 0, so $\{T(f_n)\} \rightarrow T(f)$. Thus (7) holds. (This is exactly the inference the text makes from (6).)

Conversely, suppose T is not bounded; we show (7) fails. Since T is unbounded, for each natural number n the number $M = n$ fails to satisfy (5), so there is a vector f_n in X for which

$$|T(f_n)| > n \cdot \|f_n\|.$$

Observe that $f_n \neq 0$: if $f_n = 0$ then, by the linearity of T , $T(f_n) = 0$ and the displayed inequality would read $0 > 0$. Hence $\|f_n\| > 0$, and we may define

$$h_n = \frac{1}{n \cdot \|f_n\|} \cdot f_n.$$

Then

$$\|h_n\| = \frac{\|f_n\|}{n \cdot \|f_n\|} = \frac{1}{n},$$

so $\{h_n\} \rightarrow 0$ in X . On the other hand, by the linearity of T ,

$$|T(h_n)| = \frac{|T(f_n)|}{n \cdot \|f_n\|} > \frac{n \cdot \|f_n\|}{n \cdot \|f_n\|} = 1 \quad \text{for all } n.$$

Since $T(0) = 0$ by linearity, the sequence $\{T(h_n)\}$ does not converge to $T(0)$. Therefore the continuity property (7) fails for the convergent sequence $\{h_n\}$.

By contraposition, if (7) holds then T is bounded. Together with the first paragraph this establishes the equivalence.

Problem 8.4. A functional T on a normed linear space X is said to be Lipschitz provided there is a $c \geq 0$ such that

$$|T(g) - T(h)| \leq c\|g - h\| \quad \text{for all } g, h \in X.$$

The infimum of such c 's is called the Lipschitz constant for T . Show that a linear functional is bounded if and only if it is Lipschitz, in which case its Lipschitz constant is $\|T\|_*$.

Solution. Let T be a linear functional on X . Denote by $\mathcal{C}$ the set of numbers $c \geq 0$ for which the Lipschitz inequality

$$|T(g) - T(h)| \leq c \cdot \|g - h\| \quad \text{for all } g, h \in X$$

holds, and by $\mathcal{M}$ the set of numbers $M \geq 0$ for which (5) holds, that is, $|T(f)| \leq M \cdot \|f\|$ for all f in X . By definition, T is Lipschitz exactly when $\mathcal{C} \neq \emptyset$, in which case its Lipschitz constant is $c_0 = \inf \mathcal{C}$; and T is bounded exactly when $\mathcal{M} \neq \emptyset$, in which case $\|T\|_* = \inf \mathcal{M}$.

We claim that in fact $\mathcal{C} = \mathcal{M}$; the assertion of the problem follows at once from this, since then one set is empty if and only if the other is, and the two infima coincide.

$\mathcal{M} \subseteq \mathcal{C}$. Let M belong to $\mathcal{M}$ and let g, h belong to X . By the linearity of T , $T(g) - T(h) = T(g - h)$, and therefore

$$|T(g) - T(h)| = |T(g - h)| \leq M \cdot \|g - h\|.$$

Thus M belongs to $\mathcal{C}$.

$\mathcal{C} \subseteq \mathcal{M}$. Let c belong to $\mathcal{C}$ and let f belong to X . By the linearity of T , $T(0) = 0$. Taking $g = f$ and $h = 0$ in the Lipschitz inequality gives

$$|T(f)| = |T(f) - T(0)| \leq c \cdot \|f - 0\| = c \cdot \|f\|.$$

Thus c belongs to $\mathcal{M}$.

Hence $\mathcal{C} = \mathcal{M}$. Consequently T is bounded if and only if T is Lipschitz, and in that case

$$c_0 = \inf \mathcal{C} = \inf \mathcal{M} = \|T\|_*,$$

that is, the Lipschitz constant of T equals $\|T\|_*$.

We note in passing that, as observed in Problem 1, the infimum is attained: $\|T\|_*$ itself belongs to $\mathcal{M} = \mathcal{C}$, so the Lipschitz inequality actually holds with $c = \|T\|_*$. This is precisely inequality (6) of the text.

Problem 8.5. Let E be a measurable set and $1 \leq p < \infty$. Show that the functions in $L^p(E)$ that vanish outside a bounded set are dense in $L^p(E)$. Show that this is false for $L^\infty(\mathbb{R})$.

Solution. Let $\mathcal{F}$ denote the collection of functions in $L^p(E)$ that vanish outside a bounded set.

First, $\mathcal{F}$ is a subset of $L^p(E)$, and we must show that for each f in $L^p(E)$ and each $\epsilon > 0$ there is a member of $\mathcal{F}$ within ϵ of f in the $L^p(E)$ norm.

So let f belong to $L^p(E)$. For each natural number n define

$$f_n = f \cdot \chi_{E \cap [-n, n]} \quad \text{on } E,$$

that is, $f_n = f$ on $E \cap [-n, n]$ and $f_n = 0$ on $E \setminus [-n, n]$. Each f_n is measurable, $|f_n| \leq |f|$ on E , so

f_n belongs to $L^p(E)$, and f_n vanishes outside the bounded set $[-n, n]$. Thus each f_n belongs to $\mathcal{F}$. Consider the sequence of nonnegative measurable functions

$$h_n = |f - f_n|^p = |f|^p \cdot \chi_{E \setminus [-n, n]} \quad \text{on } E.$$

For each x in E there is a natural number N with $|x| \leq N$, and then $h_n(x) = 0$ for all $n \geq N$; hence $\{h_n\} \rightarrow 0$ pointwise on E . Moreover $0 \leq h_n \leq |f|^p$ on E for all n , and $|f|^p$ is integrable over E since f belongs to $L^p(E)$ and $p < \infty$. By the Lebesgue Dominated Convergence Theorem,

$$\lim_{n \rightarrow \infty} \int_E |f - f_n|^p = \lim_{n \rightarrow \infty} \int_E h_n = 0,$$

that is, $\lim_{n \rightarrow \infty} \|f - f_n\|_p = 0$. Therefore f is a limit in $L^p(E)$ of members of $\mathcal{F}$, and since f was arbitrary, $\mathcal{F}$ is dense in $L^p(E)$.

Note where the hypothesis $p < \infty$ entered: it is needed both to write $\|f - f_n\|_p^p = \int_E |f - f_n|^p$ and to have the integrable dominating function $|f|^p$.

Now we show the corresponding statement is false for $L^\infty(\mathbb{R})$. Let f be the constant function $f \equiv 1$ on $\mathbb{R}$; then f belongs to $L^\infty(\mathbb{R})$ with $\|f\|_\infty = 1$.

Let g belong to $L^\infty(\mathbb{R})$ and vanish outside a bounded set. Since the members of $L^\infty(\mathbb{R})$ are identified when they agree almost everywhere, we read this hypothesis in the only way that is invariant under that identification: there is a bounded set B for which $g = 0$ almost everywhere on $\mathbb{R} \setminus B$. Choose a natural number n with $B \subseteq [-n, n]$. Then $g = 0$ almost everywhere on $\mathbb{R} \setminus [-n, n]$, and hence

$$|f - g| = |1 - 0| = 1 \quad \text{almost everywhere on } \mathbb{R} \setminus [-n, n].$$

Let c be any number with $0 \leq c < 1$. The set $\{x \in \mathbb{R} \mid |f(x) - g(x)| > c\}$ contains $\mathbb{R} \setminus [-n, n]$ except for a set of measure zero, and $\mathbb{R} \setminus [-n, n]$ has infinite measure; hence that set has positive measure. Therefore c is not an essential upper bound for $|f - g|$. As this holds for every $c < 1$,

$$\|f - g\|_\infty \geq 1.$$

Thus every function in $L^\infty(\mathbb{R})$ that vanishes outside a bounded set is at distance at least 1 from f . Consequently no such function lies within $1/2$ of f , and the functions in $L^\infty(\mathbb{R})$ that vanish outside a bounded set are not dense in $L^\infty(\mathbb{R})$.

Problem 8.6. Establish the Riesz Representation Theorem in the case $p = 1$ by first showing, in the notation of the proof of the theorem, that the function Φ is Lipschitz and therefore it is absolutely continuous. Then follow the $p > 1$ proof.

Solution. We prove Theorem 5 for $p = 1$: if $[a, b]$ is a closed, bounded interval and T is a bounded linear functional on $L^1[a, b]$, then there is a function g in $L^\infty[a, b]$ for which

$$T(f) = \int_a^b g \cdot f \quad \text{for all } f \in L^1[a, b].$$

Here $q = \infty$ is the conjugate of $p = 1$. At the end we indicate how the passage from $[a, b]$ to a general measurable set E , carried out in the text, goes through verbatim for $p = 1$.

Step 1: Φ is Lipschitz, hence absolutely continuous. Following the notation of the proof of Theorem 5, define

$$\Phi(x) = T(\chi_{[a, x]}) \quad \text{for } x \in [a, b],$$

which makes sense because $\chi_{[a, x]}$ belongs to $L^1[a, b]$. As in the text, if $a \leq c \leq d \leq b$, then $\chi_{[c, d]} = \chi_{[a, d]} - \chi_{[a, c]}$, so by the linearity of T ,

$$\Phi(d) - \Phi(c) = T(\chi_{[a, d]}) - T(\chi_{[a, c]}) = T(\chi_{[c, d]}).$$

Since T is bounded, by (6) applied with $h = 0$, or directly by (5) with $M = \|T\|_*$,

$$|\Phi(d) - \Phi(c)| = |T(\chi_{[c, d]})| \leq \|T\|_* \cdot \|\chi_{[c, d]}\|_1 = \|T\|_* \cdot (d - c).$$

As this holds for all $a \leq c \leq d \leq b$, we conclude

$$|\Phi(u) - \Phi(v)| \leq \|T\|_* \cdot |u - v| \quad \text{for all } u, v \in [a, b],$$

that is, Φ is Lipschitz on $[a, b]$ with Lipschitz constant at most $\|T\|_*$.

A Lipschitz function on $[a, b]$ is absolutely continuous. Indeed, let $\epsilon > 0$ and set $\delta = \epsilon/(\|T\|_* + 1) > 0$. If $\{(a_k, b_k)\}_{k=1}^n$ is a finite disjoint collection of intervals in (a, b) with $\sum_{k=1}^n (b_k - a_k) < \delta$, then

$$\sum_{k=1}^n |\Phi(b_k) - \Phi(a_k)| \leq \|T\|_* \cdot \sum_{k=1}^n (b_k - a_k) < \|T\|_* \cdot \frac{\epsilon}{\|T\|_* + 1} < \epsilon.$$

Thus Φ is absolutely continuous on $[a, b]$. (This is the only place where the argument differs from the case $p > 1$: there one had the weaker estimate $\sum_k |\Phi(b_k) - \Phi(a_k)| \leq \|T\|_* \cdot [\sum_k (b_k - a_k)]^{1/p}$, which for $p = 1$ degenerates to exactly the Lipschitz estimate above.)

Step 2: recovery of g . By Theorem 10 of Chapter 6, an absolutely continuous function on $[a, b]$ is differentiable almost everywhere on $[a, b]$, its derivative is integrable over $[a, b]$, and it is the indefinite integral of its derivative. Hence $g = \Phi'$ is integrable over $[a, b]$ and

$$\Phi(x) - \Phi(a) = \int_a^x g \quad \text{for all } x \in [a, b].$$

Since $\chi_{[a,a]}$ is the zero function, $\Phi(a) = T(0) = 0$, so $\Phi(x) = \int_a^x g$ on $[a, b]$. Therefore, for $a \leq c \leq d \leq b$,

$$T(\chi_{[c,d]}) = \Phi(d) - \Phi(c) = \int_c^d g = \int_a^b g \cdot \chi_{[c,d]}.$$

Both T and the functional $f \mapsto \int_a^b g \cdot f$ are linear on the linear space of step functions on $[a, b]$ (the latter is properly defined there since g is integrable and step functions are bounded), and every step function is a finite linear combination of functions of the form $\chi_{[c,d]}$, modulo a set of measure zero, on which T is unchanged because T respects equality almost everywhere. Hence

$$T(f) = \int_a^b g \cdot f \quad \text{for all step functions } f \text{ on } [a, b].$$

Step 3: from step functions to simple functions. Let f be a simple function on $[a, b]$. By Proposition 10 of the preceding chapter and its proof, there is a sequence $\{\varphi_n\}$ of step functions on $[a, b]$ that converges to f in $L^1[a, b]$ and is uniformly pointwise bounded on $[a, b]$, say $|\varphi_n| \leq C$ on $[a, b]$ for all n . By the Riesz-Fischer Theorem of the preceding chapter, a subsequence $\{\varphi_{n_k}\}$ converges to f pointwise almost everywhere on $[a, b]$. Since T is bounded, the continuity property (7) gives

$$\lim_{k \rightarrow \infty} T(\varphi_{n_k}) = T(f).$$

On the other hand, $|g \cdot \varphi_{n_k}| \leq C \cdot |g|$ on $[a, b]$, where $C \cdot |g|$ is integrable, and $\{g \cdot \varphi_{n_k}\} \rightarrow g \cdot f$ pointwise almost everywhere. By the Lebesgue Dominated Convergence Theorem,

$$\lim_{k \rightarrow \infty} \int_a^b g \cdot \varphi_{n_k} = \int_a^b g \cdot f.$$

Since $T(\varphi_{n_k}) = \int_a^b g \cdot \varphi_{n_k}$ for every k by Step 2, we conclude

$$T(f) = \int_a^b g \cdot f \quad \text{for all simple functions } f \text{ on } [a, b].$$

Step 4: g belongs to $L^\infty[a, b]$. Since T is bounded, for every simple function f in $L^1[a, b]$,

$$\left| \int_a^b g \cdot f \right| = |T(f)| \leq \|T\|_* \cdot \|f\|_1.$$

Thus g is integrable over $[a, b]$ and satisfies hypothesis (9) of Lemma 4 with $p = 1$ and $M = \|T\|_*$. Lemma 4, in the case $p = 1$, asserts precisely that g then belongs to $L^\infty[a, b]$ with $\|g\|_\infty \leq \|T\|_*$; recall its proof in that case: if $\|T\|_*$ were not an essential upper bound for $|g|$, then by the continuity of measure the set $E_\epsilon = \{x \in [a, b] \mid |g(x)| > \|T\|_* + \epsilon\}$ would have positive measure for some $\epsilon > 0$, and taking $f = \operatorname{sgn}(g) \cdot \chi_A$ for a measurable subset A of E_ϵ of finite positive measure gives $\int_a^b g \cdot f \geq (\|T\|_* + \epsilon) \cdot m(A) > \|T\|_* \cdot \|f\|_1$, a contradiction.

Step 5: conclusion. Since g belongs to $L^\infty[a, b] = L^q[a, b]$, Proposition 2 tells us that the functional $\mathcal{R}_g: f \mapsto \int_a^b g \cdot f$ is a bounded linear functional on $L^1[a, b]$ with $\|\mathcal{R}_g\|_* = \|g\|_\infty$. By Step 3, the two bounded linear functionals T and $\mathcal{R}_g$ agree on the simple functions, which by Proposition 9 of the preceding chapter form a dense subspace of $L^1[a, b]$. By Proposition 3 they agree on all of $L^1[a, b]$:

$$T(f) = \int_a^b g \cdot f \quad \text{for all } f \in L^1[a, b].$$

This proves Theorem 5 for $p = 1$.

Finally, the extension to a general measurable set E proceeds exactly as in the proof of the Riesz Representation Theorem for the dual of $L^p(E)$, with one adjustment. Uniqueness and the identity $\mathcal{R}_{g_1} - \mathcal{R}_{g_2} = \mathcal{R}_{g_1 - g_2}$ are unchanged. For $E = \mathbb{R}$, restricting T to $L^1[-n, n]$ produces, by the case just proved, functions g_n in $L^\infty[-n, n]$ with $\|g_n\|_\infty \leq \|T\|_*$ which are consistent with one another almost everywhere, and hence a measurable function g on $\mathbb{R}$ agreeing with each g_n almost everywhere on $[-n, n]$. In place of the Fatou's Lemma step (which was used to pass from $\int_{-n}^n |g|^q \leq (\|T\|_*)^q$ to $g \in L^q(\mathbb{R})$), one argues directly: for each n , $|g| \leq \|T\|_*$ almost everywhere on $[-n, n]$, so the set where $|g| > \|T\|_*$ is the countable union over n of sets of measure zero and hence has measure zero. Thus g belongs to $L^\infty(\mathbb{R})$ with $\|g\|_\infty \leq \|T\|_*$. Since $\mathcal{R}_g$ and T are bounded and agree on the functions in $L^1(\mathbb{R})$ vanishing outside a bounded set, which by the preceding problem form a dense subspace of $L^1(\mathbb{R})$, Proposition 3 gives $\mathcal{R}_g = T$. The passage from $\mathbb{R}$ to an arbitrary measurable set E , by extending functions in $L^1(E)$ by zero, is identical to the text's.

Problem 8.7. State and prove a Riesz Representation Theorem for the bounded linear functionals on ℓ^p , $1 \leq p < \infty$.

Solution. Recall the notation. For $1 \leq p < \infty$, ℓ^p is the linear space of real sequences $x = \{x_k\}_{k=1}^\infty$ for which $\sum_{k=1}^\infty |x_k|^p < \infty$, normed by $\|x\|_p = [\sum_{k=1}^\infty |x_k|^p]^{1/p}$; and ℓ^∞ is the linear space of bounded real sequences $y = \{y_k\}$, normed by $\|y\|_\infty = \sup_{k \geq 1} |y_k|$. That these are normed linear spaces is the content of Minkowski's Inequality. For each natural number k , let e_k denote the sequence whose k th term is 1 and whose other terms are 0.

Theorem (Riesz Representation for the dual of ℓ^p). Let $1 \leq p < \infty$ and let q be the conjugate of p . For each $y = \{y_k\}$ in ℓ^q , define the functional $\mathcal{R}_y$ on ℓ^p by

$$\mathcal{R}_y(x) = \sum_{k=1}^{\infty} y_k \cdot x_k \quad \text{for all } x = \{x_k\} \in \ell^p.$$

Then $\mathcal{R}_y$ is a properly defined bounded linear functional on ℓ^p with $\|\mathcal{R}_y\|_* = \|y\|_q$, and for each bounded linear functional T on ℓ^p there is a unique y in ℓ^q for which

$$\mathcal{R}_y = T, \quad \text{and} \quad \|T\|_* = \|y\|_q.$$

Thus $y \mapsto \mathcal{R}_y$ is a linear isometry of ℓ^q onto $(\ell^p)^*$.

Proof.

Step 1: Hölder's Inequality for sequences. Let y belong to ℓ^q and x to ℓ^p . We claim

$$\sum_{k=1}^{\infty} |y_k \cdot x_k| \leq \|y\|_q \cdot \|x\|_p.$$

If $p = 1$ and $q = \infty$ this is immediate, since $|y_k| \leq \|y\|_\infty$ for every k . Suppose $1 < p < \infty$. If $\|x\|_p = 0$ or $\|y\|_q = 0$, then $x = 0$ or $y = 0$ and the inequality is trivial. Otherwise, by homogeneity we may assume $\|x\|_p = \|y\|_q = 1$. Young's Inequality asserts that $\alpha \cdot \beta \leq \alpha^p/p + \beta^q/q$ for nonnegative α, β . Applying it termwise with $\alpha = |x_k|$, $\beta = |y_k|$ and summing,

$$\sum_{k=1}^{\infty} |y_k \cdot x_k| \leq \frac{1}{p} \sum_{k=1}^{\infty} |x_k|^p + \frac{1}{q} \sum_{k=1}^{\infty} |y_k|^q = \frac{1}{p} + \frac{1}{q} = 1 = \|y\|_q \cdot \|x\|_p.$$

Step 2: $\mathcal{R}_y$ is a bounded linear functional with $\|\mathcal{R}_y\|_* = \|y\|_q$. By Step 1 the series defining $\mathcal{R}_y(x)$ converges absolutely, so $\mathcal{R}_y$ is properly defined, and

$$|\mathcal{R}_y(x)| \leq \sum_{k=1}^{\infty} |y_k \cdot x_k| \leq \|y\|_q \cdot \|x\|_p.$$

Linearity follows from the linearity of termwise operations together with the fact that absolutely convergent series may be added and scaled termwise. Hence $\mathcal{R}_y$ is bounded and $\|\mathcal{R}_y\|_* \leq \|y\|_q$.

For the reverse inequality, suppose first $1 < p < \infty$ and $y \neq 0$. Define $x^* = \{x_k^*\}$ by

$$x_k^* = \operatorname{sgn}(y_k) \cdot |y_k|^{q-1}.$$

Since q is the conjugate of p we have $p(q-1) = q$, so $|x_k^*|^p = |y_k|^q$; hence x^* belongs to ℓ^p with $\|x^*\|_p = \|y\|_q^{q/p}$, which is positive and finite. Moreover

$$\mathcal{R}_y(x^*) = \sum_{k=1}^{\infty} |y_k|^q = \|y\|_q^q.$$

Therefore, by (8),

$$\|\mathcal{R}_y\|_* \geq \frac{\mathcal{R}_y(x^*)}{\|x^*\|_p} = \|y\|_q^{q-q/p} = \|y\|_q,$$

since $q - q/p = q(1 - 1/p) = q \cdot (1/q) = 1$. If $y = 0$ the equality $\|\mathcal{R}_y\|_* = \|y\|_q$ is trivial.

Now suppose $p = 1$, $q = \infty$. For each k , the sequence $\operatorname{sgn}(y_k) \cdot e_k$ has ℓ^1 norm at most 1 and $\mathcal{R}_y(\operatorname{sgn}(y_k) \cdot e_k) = |y_k|$. By (8), $\|\mathcal{R}_y\|_* \geq |y_k|$ for every k , and taking the supremum over k gives $\|\mathcal{R}_y\|_* \geq \|y\|_\infty$.

In both cases $\|\mathcal{R}_y\|_* = \|y\|_q$.

Step 3: uniqueness. The map $y \mapsto \mathcal{R}_y$ is linear, since $\mathcal{R}_{y_1} - \mathcal{R}_{y_2} = \mathcal{R}_{y_1 - y_2}$ by the linearity of absolutely convergent summation. Hence if $\mathcal{R}_{y_1} = \mathcal{R}_{y_2}$, then $\mathcal{R}_{y_1 - y_2} = 0$, so by Step 2, $\|y_1 - y_2\|_q = 0$ and therefore $y_1 = y_2$.

Step 4: the sequences of finite support are dense in ℓ^p . Let X_0 denote the linear span of $\{e_k\}_{k=1}^{\infty}$, that is, the set of sequences with only finitely many nonzero terms. Let x belong to ℓ^p and, for each n , let $x^{[n]} = \sum_{k=1}^n x_k \cdot e_k$, which belongs to X_0 . Then

$$\|x - x^{[n]}\|_p^p = \sum_{k=n+1}^{\infty} |x_k|^p,$$

which is the tail of the convergent series $\sum_{k=1}^{\infty} |x_k|^p$ and therefore tends to 0 as $n \rightarrow \infty$. Hence $\{x^{[n]}\} \rightarrow x$ in ℓ^p , and X_0 is dense in ℓ^p . (It is exactly here that $p < \infty$ is needed; in ℓ^∞ the constant sequence $\{1, 1, 1, \dots\}$ is at distance 1 from X_0 .)

Step 5: existence. Let T be a bounded linear functional on ℓ^p . Define

$$y_k = T(e_k) \quad \text{for } k = 1, 2, \dots$$

We claim $y = \{y_k\}$ belongs to ℓ^q with $\|y\|_q \leq \|T\|_*$.

Suppose first $1 < p < \infty$. Fix a natural number n and define $x^{(n)}$ in X_0 by

$$x^{(n)} = \sum_{k=1}^n \operatorname{sgn}(y_k) \cdot |y_k|^{q-1} \cdot e_k.$$

By the linearity of T ,

$$T(x^{(n)}) = \sum_{k=1}^n \operatorname{sgn}(y_k) \cdot |y_k|^{q-1} \cdot y_k = \sum_{k=1}^n |y_k|^q,$$

while, using $p(q-1) = q$,

$$\|x^{(n)}\|_p = \left[\sum_{k=1}^n |y_k|^{p(q-1)} \right]^{1/p} = \left[\sum_{k=1}^n |y_k|^q \right]^{1/p}.$$

Set $A_n = \sum_{k=1}^n |y_k|^q$. Since T is bounded, $A_n = T(x^{(n)}) \leq \|T\|_* \cdot A_n^{1/p}$. If $A_n = 0$ then certainly $A_n^{1/q} \leq \|T\|_*$; if $A_n > 0$, then A_n is a finite positive number and dividing by $A_n^{1/p}$ gives

$$A_n^{1-1/p} = A_n^{1/q} \leq \|T\|_*.$$

Thus $[\sum_{k=1}^n |y_k|^q]^{1/q} \leq \|T\|_*$ for every n ; letting $n \rightarrow \infty$ shows y belongs to ℓ^q with $\|y\|_q \leq \|T\|_*$. If $p = 1$ and $q = \infty$, then for each k , since $\|e_k\|_1 = 1$,

$$|y_k| = |T(e_k)| \leq \|T\|_* \cdot \|e_k\|_1 = \|T\|_*,$$

so y belongs to ℓ^∞ with $\|y\|_\infty \leq \|T\|_*$.

Step 6: conclusion. By Step 5, y belongs to ℓ^q , so by Step 2, $\mathcal{R}_y$ is a bounded linear functional on ℓ^p . For each k ,

$$\mathcal{R}_y(e_k) = y_k = T(e_k),$$

so by linearity T and $\mathcal{R}_y$ agree on the linear span X_0 of $\{e_k\}$. By Step 4, X_0 is a dense subspace of ℓ^p , and both functionals are bounded, so by Proposition 3 they agree on all of ℓ^p . That is, $T = \mathcal{R}_y$. Its uniqueness is Step 3, and by Step 2,

$$\|T\|_* = \|\mathcal{R}_y\|_* = \|y\|_q.$$

This completes the proof.

Remark. Steps 2 and 6 together say that $y \mapsto \mathcal{R}_y$ is a norm-preserving linear bijection of ℓ^q onto $(\ell^p)^*$; in this sense $(\ell^p)^* = \ell^q$ for $1 \leq p < \infty$. As with L^∞ , the result fails at $p = \infty$: Step 4 breaks down, and there are bounded linear functionals on ℓ^∞ that are not of the form $\mathcal{R}_y$ for any y in ℓ^1 .

8.2 Problems 8.8–8.14

Problem 8.8. Let c be the linear space of real sequences that converge to a real number and c_0 the subspace of c comprising sequences that converge to 0. Norm each of these linear spaces with the ℓ^∞ norm. Determine the dual space of c and of c_0 .

Solution. Throughout, for $x = (x_1, x_2, \dots)$ in c we write $\|x\|_\infty = \sup_k |x_k|$, we let e_k denote the sequence whose k -th component is 1 and whose other components are 0, and we let $\mathbf{1} = (1, 1, 1, \dots)$. Both e_k and $\mathbf{1}$ belong to c , and each e_k belongs to c_0 . Define $\operatorname{sgn}(t) = 1$ if $t \geq 0$ and $\operatorname{sgn}(t) = -1$ if $t < 0$, so that $t \cdot \operatorname{sgn}(t) = |t|$ for every real t .

We show that c_0^* and c^* are each isometrically isomorphic to ℓ^1 , but by different pairings: a functional on c_0 is integration against an ℓ^1 sequence, while a functional on c is such a pairing together with a multiple of the limit functional.

Part 1: the dual of c_0 .

For $a = (a_1, a_2, \dots)$ in ℓ^1 define

$$T_a(x) = \sum_{k=1}^{\infty} a_k x_k \quad \text{for all } x \in c_0.$$

The series converges absolutely since $\sum_k |a_k x_k| \leq \|x\|_\infty \sum_k |a_k|$, and this same estimate shows T_a is a

bounded linear functional on c_0 with

$$\|T_a\|_* \leq \|a\|_1 = \sum_{k=1}^{\infty} |a_k|.$$

Conversely, let T belong to c_0^* and set $a_k = T(e_k)$ for each index k . Fix a natural number n and let x be the sequence with $x_k = \text{sgn}(a_k)$ for $1 \leq k \leq n$ and $x_k = 0$ for $k > n$. Then x belongs to c_0 and $\|x\|_{\infty} \leq 1$, while by linearity

$$\sum_{k=1}^n |a_k| = \sum_{k=1}^n a_k x_k = T\left(\sum_{k=1}^n x_k e_k\right) = T(x) \leq \|T\|_* \|x\|_{\infty} \leq \|T\|_*.$$

Since n is arbitrary, a belongs to ℓ^1 and $\|a\|_1 \leq \|T\|_*$.

Moreover $T = T_a$. Indeed, if x belongs to c_0 and $s_n = \sum_{k=1}^n x_k e_k$, then

$$\|x - s_n\|_{\infty} = \sup_{k > n} |x_k| \rightarrow 0 \quad \text{as } n \rightarrow \infty,$$

because $x_k \rightarrow 0$. Since T is bounded, it is continuous, so

$$T(x) = \lim_{n \rightarrow \infty} T(s_n) = \lim_{n \rightarrow \infty} \sum_{k=1}^n a_k x_k = T_a(x).$$

Combining the two inequalities gives $\|T_a\|_* = \|a\|_1$. Therefore $a \mapsto T_a$ is a linear bijection of ℓ^1 onto c_0^* that preserves norms: $c_0^* = \ell^1$ isometrically, the pairing being $\langle a, x \rangle = \sum_k a_k x_k$. The map is one-to-one because it is norm preserving, and onto by the preceding paragraph.

Part 2: the dual of c .

For a sequence $a = (a_0, a_1, a_2, \dots)$ indexed from 0 with $\|a\|_1 = \sum_{k \geq 0} |a_k| < \infty$, define

$$S_a(x) = a_0 \cdot \lim_{k \rightarrow \infty} x_k + \sum_{k=1}^{\infty} a_k x_k \quad \text{for all } x \in c.$$

Since $|x_k| \leq \|x\|_{\infty}$ for every k and also $|\lim_k x_k| \leq \|x\|_{\infty}$, the series converges absolutely and

$$|S_a(x)| \leq \left(|a_0| + \sum_{k \geq 1} |a_k|\right) \|x\|_{\infty},$$

so S_a is a bounded linear functional on c with $\|S_a\|_* \leq \|a\|_1$.

Conversely let T belong to c^* . Its restriction to the subspace c_0 is a bounded linear functional on c_0 of norm at most $\|T\|_*$, so by Part 1 there is a sequence $(a_1, a_2, \dots)$ in ℓ^1 , namely $a_k = T(e_k)$, with

$$T(y) = \sum_{k=1}^{\infty} a_k y_k \quad \text{for all } y \in c_0.$$

Put $b = T(\mathbf{1})$ and $a_0 = b - \sum_{k \geq 1} a_k$, which is a well-defined real number since $\sum_k |a_k| < \infty$. Let x belong to c and let $\ell = \lim_k x_k$. Then $y = x - \ell \mathbf{1}$ belongs to c_0 , so by linearity

$$T(x) = T(y) + \ell T(\mathbf{1}) = \sum_{k=1}^{\infty} a_k (x_k - \ell) + \ell b = \sum_{k=1}^{\infty} a_k x_k + \ell \left(b - \sum_{k \geq 1} a_k\right),$$

where splitting the series is legitimate because both $\sum_k a_k x_k$ and $\sum_k a_k \ell$ converge absolutely. Hence $T = S_a$ for $a = (a_0, a_1, a_2, \dots)$, which belongs to ℓ^1 .

It remains to check $\|S_a\|_* = \|a\|_1$; only the inequality $\|S_a\|_* \geq \|a\|_1$ is left. Let $\epsilon > 0$ and choose a natural number N with $\sum_{k > N} |a_k| < \epsilon$. Define x by

$$x_k = \text{sgn}(a_k) \text{ for } 1 \leq k \leq N, \quad x_k = \text{sgn}(a_0) \text{ for } k > N.$$

Then x is eventually constant, so it belongs to c with $\lim_k x_k = \operatorname{sgn}(a_0)$, and $\|x\|_\infty \leq 1$. Therefore

$$S_a(x) = |a_0| + \sum_{k=1}^N |a_k| + \sum_{k>N} a_k \operatorname{sgn}(a_0) \geq |a_0| + \sum_{k=1}^N |a_k| - \sum_{k>N} |a_k| > |a_0| + \sum_{k \geq 1} |a_k| - 2\epsilon,$$

using $\sum_{k=1}^N |a_k| > \sum_{k \geq 1} |a_k| - \epsilon$. Thus $\|S_a\|_* \geq \|a\|_1 - 2\epsilon$ for every $\epsilon > 0$, and so $\|S_a\|_* = \|a\|_1$.

Conclusion. Both dual spaces are isometrically isomorphic to ℓ^1 . Explicitly, every bounded linear functional on c_0 has the form $x \mapsto \sum_{k \geq 1} a_k x_k$ for a unique $a \in \ell^1$, with $\|T\|_* = \|a\|_1$; and every bounded linear functional on c has the form

$$x \mapsto a_0 \lim_{k \rightarrow \infty} x_k + \sum_{k=1}^{\infty} a_k x_k$$

for a unique summable $(a_0, a_1, \dots)$, with $\|T\|_* = |a_0| + \sum_{k \geq 1} |a_k|$. In each case uniqueness of the representing sequence follows from the norm identity just established: the correspondence is linear and norm preserving, hence one-to-one. Note finally that although c_0 is a subspace of c and both duals are isometrically isomorphic to ℓ^1 , this isometry is not implemented by restriction of functionals: the restriction map $c^* \rightarrow c_0^*$ discards a_0 , so it is onto but not one-to-one.

Problem 8.9. Let $[a, b]$ be a closed, bounded interval and $C[a, b]$ be normed by the maximum norm. Let x_0 belong to $[a, b]$. Define the linear functional T on $C[a, b]$ by $T(f) = f(x_0)$. Show that T is bounded and is given by Riemann-Stieltjes integration against a function of bounded variation.

Solution. Boundedness. T is clearly linear. For f in $C[a, b]$,

$$|T(f)| = |f(x_0)| \leq \max_{x \in [a, b]} |f(x)| = \|f\|_{\max},$$

so T is bounded and $\|T\|_* \leq 1$. Taking $f \equiv 1$, which has $\|f\|_{\max} = 1$ and $T(f) = 1$, we get $\|T\|_* = 1$. The representing function. Define g on $[a, b]$ as follows.

If $x_0 > a$, let g be the characteristic function of $[x_0, b]$, that is, $g = 0$ on $[a, x_0)$ and $g = 1$ on $[x_0, b]$.

If $x_0 = a$, let g be the characteristic function of $(a, b]$, that is, $g(a) = 0$ and $g = 1$ on $(a, b]$.

In either case g is a nondecreasing function taking only the values 0 and 1, with exactly one jump, of size 1, located at x_0 . For any partition $a = t_0 < t_1 < \dots < t_n = b$ the sum $\sum_{i=1}^n |g(t_i) - g(t_{i-1})|$ telescopes in absolute value to $g(b) - g(a) = 1$ because g is nondecreasing. Hence g is of bounded variation with $TV(g) = 1$.

Claim: for every f in $C[a, b]$ the Riemann-Stieltjes integral $\int_a^b f dg$ exists and equals $f(x_0)$.

Recall that $\int_a^b f dg$ is the limit, as the mesh of the partition tends to 0, of the Riemann-Stieltjes sums

$$S(f, g, P, \xi) = \sum_{i=1}^n f(\xi_i) [g(t_i) - g(t_{i-1})],$$

taken over partitions $P : a = t_0 < \dots < t_n = b$ with tags $\xi_i \in [t_{i-1}, t_i]$.

Since g takes only the values 0 and 1 and increases from 0 to 1 exactly once, at most one difference $g(t_i) - g(t_{i-1})$ is nonzero, and when nonzero it equals 1. Precisely: let i be the unique index with $g(t_{i-1}) = 0$ and $g(t_i) = 1$. Then

$$S(f, g, P, \xi) = f(\xi_i), \quad \xi_i \in [t_{i-1}, t_i].$$

We show x_0 lies in $[t_{i-1}, t_i]$ as well, so that $|\xi_i - x_0| \leq t_i - t_{i-1} \leq \operatorname{mesh}(P)$.

Consider first the case $x_0 > a$, where $g = \chi_{[x_0, b]}$. Then $g(t_{i-1}) = 0$ forces $t_{i-1} < x_0$, and $g(t_i) = 1$ forces $t_i \geq x_0$; hence $t_{i-1} < x_0 \leq t_i$. In the case $x_0 = a$, where $g = \chi_{(a, b]}$, we have $g(t_0) = g(a) = 0$ and $g(t_1) = 1$, so $i = 1$ and $x_0 = a = t_0$ lies in $[t_0, t_1]$.

In both cases, given $\epsilon > 0$, uniform continuity of f on the compact interval $[a, b]$ provides $\delta > 0$ such that $|f(s) - f(t)| < \epsilon$ whenever $|s - t| < \delta$ with s, t in $[a, b]$. If $\operatorname{mesh}(P) < \delta$ then $|\xi_i - x_0| < \delta$, whence

$$|S(f, g, P, \xi) - f(x_0)| = |f(\xi_i) - f(x_0)| < \epsilon$$

for every choice of tags. Therefore the Riemann-Stieltjes sums converge to $f(x_0)$ as the mesh tends to 0, so $\int_a^b f dg$ exists and

$$T(f) = f(x_0) = \int_a^b f dg \quad \text{for all } f \in C[a, b].$$

Thus T is a bounded linear functional on $C[a, b]$, of norm 1, given by Riemann-Stieltjes integration against the function g of bounded variation, and indeed $\|T\|_* = 1 = TV(g)$. This exhibits the point-evaluation functional as an instance of the second example of this section, and is consistent with the Riesz theorem, quoted in the Remark following the Riesz Representation Theorem for the dual of $L^p(E)$ and proved in Chapter 21, which asserts that every bounded linear functional on $C[a, b]$ arises this way.

Problem 8.10. Let f belong to $C[a, b]$. Show that there is a function g that is of bounded variation on $[a, b]$ for which

$$\int_a^b f dg = \|f\|_{\max} \quad \text{and} \quad TV(g) = 1.$$

Solution. A word on the printed statement. The second requirement is printed as $TV(f) = 1$, which cannot be what is meant: f is an arbitrary member of $C[a, b]$ and continuous functions need not be of bounded variation at all, let alone of total variation 1. The intended requirement is $TV(g) = 1$, the function g being the one whose existence is asserted, and that is what we prove: for each f in $C[a, b]$ there is a function g of bounded variation on $[a, b]$ with $\int_a^b f dg = \|f\|_{\max}$ and $TV(g) = 1$. Since f is continuous on the compact interval $[a, b]$, the Extreme Value Theorem applied to the continuous function $|f|$ provides a point x_0 in $[a, b]$ at which $|f|$ attains its maximum value:

$$|f(x_0)| = \max_{x \in [a, b]} |f(x)| = \|f\|_{\max}.$$

Let $\sigma = 1$ if $f(x_0) \geq 0$ and $\sigma = -1$ if $f(x_0) < 0$, so that $\sigma f(x_0) = |f(x_0)| = \|f\|_{\max}$ and $|\sigma| = 1$. Let g_0 be the jump function attached to the point x_0 that was constructed in the preceding problem: if $x_0 > a$, let g_0 be the characteristic function of $[x_0, b]$; if $x_0 = a$, let g_0 be the characteristic function of $(a, b]$. As shown there, g_0 is of bounded variation on $[a, b]$ with $TV(g_0) = 1$, the Riemann-Stieltjes integral $\int_a^b h dg_0$ exists for every h in $C[a, b]$, and

$$\int_a^b h dg_0 = h(x_0) \quad \text{for all } h \in C[a, b].$$

(Briefly: g_0 is nondecreasing with a single jump, of size 1, at x_0 , so its variation over every partition is $g_0(b) - g_0(a) = 1$; and for every partition $a = t_0 < \dots < t_n = b$ exactly one difference $g_0(t_i) - g_0(t_{i-1})$ is nonzero, that one equals 1 and its interval $[t_{i-1}, t_i]$ contains x_0 , so each Riemann-Stieltjes sum for the partition P equals $h(\xi_i)$ with $|\xi_i - x_0| \leq \text{mesh}(P)$, and uniform continuity of h on $[a, b]$ forces these sums to converge to $h(x_0)$ as the mesh tends to 0.)

Define $g = \sigma \cdot g_0$.

First, g is of bounded variation and $TV(g) = 1$. Indeed, for every partition $a = t_0 < t_1 < \dots < t_n = b$,

$$\sum_{i=1}^n |g(t_i) - g(t_{i-1})| = |\sigma| \sum_{i=1}^n |g_0(t_i) - g_0(t_{i-1})| = \sum_{i=1}^n |g_0(t_i) - g_0(t_{i-1})|,$$

so the two functions have exactly the same variation over every partition; taking the supremum over all partitions gives $TV(g) = TV(g_0) = 1$.

Second, since every Riemann-Stieltjes sum for the pair (f, g) is σ times the corresponding sum for (f, g_0) , namely

$$\sum_{i=1}^n f(\xi_i) [g(t_i) - g(t_{i-1})] = \sigma \sum_{i=1}^n f(\xi_i) [g_0(t_i) - g_0(t_{i-1})],$$

the integral $\int_a^b f dg$ exists and equals $\sigma \int_a^b f dg_0$. Therefore

$$\int_a^b f dg = \sigma f(x_0) = |f(x_0)| = \|f\|_{\max}.$$

This proves the assertion. (Note that the conclusion holds also when $f \equiv 0$: then $\|f\|_{\max} = 0$ and $\int_a^b f dg = 0$, while g still has total variation 1.)

Remark. This is the $C[a, b]$ analogue of formula (27) of this chapter. Write $T(h) = \int_a^b h dg = \sigma h(x_0)$ for h in $C[a, b]$. By inequality (4) of Section 8.1, $|T(h)| \leq TV(g) \cdot \|h\|_{\max} = \|h\|_{\max}$ for every h , while $T(h) = 1$ for the constant function $h \equiv \sigma$, which has maximum norm 1; hence $\|T\|_* = 1$. Since also $T(f) = \|f\|_{\max}$, the function g produces, concretely, the norm-one functional on $C[a, b]$ attaining its norm at f that the Hahn-Banach Theorem, proved in Section 2 of Chapter 14, supplies abstractly.

Problem 8.11. Let $[a, b]$ be a closed, bounded interval and $C[a, b]$ be normed by the maximum norm. Let T be a bounded linear functional on $C[a, b]$. For $x \in [a, b]$, let g_x be the member of $C[a, b]$ that is linear on $[a, x]$ and on $[x, b]$ with $g_x(a) = 0$, $g_x(x) = x - a$ and $g_x(b) = x - a$. Define $\Phi(x) = T(g_x)$ for $x \in [a, b]$. Show that Φ is Lipschitz on $[a, b]$.

Solution. First we identify g_x explicitly. On $[a, x]$ the function g_x is linear with $g_x(a) = 0$ and $g_x(x) = x - a$, so its slope is 1 and $g_x(t) = t - a$ there. On $[x, b]$ it is linear with $g_x(x) = x - a$ and $g_x(b) = x - a$, so it is constant, $g_x(t) = x - a$ there. (When $x = a$ or $x = b$ one of the two pieces degenerates, and the formula still holds.) In short,

$$g_x(t) = \min\{t, x\} - a \quad \text{for all } t \in [a, b].$$

In particular g_x is continuous on $[a, b]$, so g_x does belong to $C[a, b]$ and $\Phi(x) = T(g_x)$ is well defined. Estimate of $\|g_x - g_y\|_{\max}$. Let x, y belong to $[a, b]$ and assume without loss of generality that $y \leq x$. Then, for t in $[a, b]$,

$$g_x(t) - g_y(t) = \min\{t, x\} - \min\{t, y\} = \begin{cases} 0, & a \leq t \leq y, \\ t - y, & y \leq t \leq x, \\ x - y, & x \leq t \leq b. \end{cases}$$

Indeed: if $t \leq y \leq x$ both minima equal t ; if $y \leq t \leq x$ then $\min\{t, x\} = t$ and $\min\{t, y\} = y$; if $t \geq x \geq y$ then the minima are x and y . In every case $0 \leq g_x(t) - g_y(t) \leq x - y$, and therefore

$$\|g_x - g_y\|_{\max} = \max_{t \in [a, b]} |g_x(t) - g_y(t)| \leq x - y = |x - y|.$$

(In fact equality holds, the value $x - y$ being attained at $t = x$, but only the inequality is needed.)

Conclusion. Since T is linear and bounded, for all x, y in $[a, b]$,

$$|\Phi(x) - \Phi(y)| = |T(g_x) - T(g_y)| = |T(g_x - g_y)| \leq \|T\|_* \cdot \|g_x - g_y\|_{\max} \leq \|T\|_* \cdot |x - y|.$$

Thus Φ is Lipschitz on $[a, b]$ with Lipschitz constant at most $\|T\|_*$, which is finite because T is bounded.

Remark. Two comments. First, Problem 4 of this section identifies boundedness of a linear functional with its being Lipschitz, with Lipschitz constant $\|T\|_*$; what is proved above is the different (and easier) assertion that the numerical function $x \mapsto T(g_x)$ is Lipschitz on $[a, b]$, and it uses only the boundedness of T together with the estimate $\|g_x - g_y\|_{\max} \leq |x - y|$. Second, Φ here plays the role of the function Φ built in the proof of the Riesz Representation Theorem for the dual of L^p , where $\Phi(x) = T(\chi_{[a, x]})$; those characteristic functions are not continuous, so they are unavailable in $C[a, b]$, and the piecewise linear functions g_x replace them. Being Lipschitz on a closed, bounded interval, Φ is absolutely continuous there, by Chapter 6, and this is the first step toward the theorem of Riesz, quoted in the Remark at the end of Section 8.1 and proved in Chapter 21, that every bounded linear functional on $C[a, b]$ is given by Stieltjes integration against a function of bounded variation.

Problem 8.12. Show that the sequence defined in the first example of this section does not converge strongly to $f \equiv 0$ in $L^p[0, 1]$ for all $1 \leq p < \infty$.

Solution. The sequence in question is the sequence of Radamacher functions: for $I = [0, 1]$ and a natural number n , f_n is the step function on I defined by

$$f_n(x) = (-1)^k \quad \text{for } \frac{k}{2^n} \leq x < \frac{k+1}{2^n}, \quad 0 \leq k \leq 2^n - 1,$$

with, say, $f_n(1) = 1$ so that f_n is defined on all of I . (The book prints the index restriction as $0 \leq k < 2^n - 1$. That must be a misprint for $0 \leq k \leq 2^n - 1$: only the latter has the intervals exhaust $[0, 1)$, and only the latter supports the assertions made in the example itself, that $\|f_n\|_p \leq 1$ and that $|f_n - f_m|$ takes the value 2 on a set of measure $1/2$ when $n \neq m$. With that reading, the definition determines f_n everywhere on $[0, 1)$ and leaves only the single point $x = 1$ free.)

Fix $1 \leq p < \infty$ and a natural number n . The half-open intervals $[k/2^n, (k+1)/2^n)$, for $0 \leq k \leq 2^n - 1$, are disjoint and their union is $[0, 1)$, which differs from I by the single point 1, a set of measure zero. On each of these intervals $|f_n| = |(-1)^k| = 1$. Hence $|f_n| = 1$ almost everywhere on I , and therefore $|f_n|^p = 1$ almost everywhere on I . Consequently

$$\|f_n - f\|_p^p = \|f_n\|_p^p = \int_0^1 |f_n|^p = \int_0^1 1 = 1,$$

so $\|f_n - f\|_p = 1$ for every n , where $f \equiv 0$.

Since the sequence of real numbers $\{\|f_n - f\|_p\}$ is constantly equal to 1, it does not converge to 0. By the definition of strong convergence in a normed linear space, $\{f_n\}$ does not converge strongly to $f \equiv 0$ in $L^p[0, 1]$. The same computation shows that no subsequence of $\{f_n\}$ converges strongly to $f \equiv 0$, since every subsequence also has $\|f_{n_k} - f\|_p = 1$ for all k .

Remark. This is exactly the point of the example: for $1 < p < \infty$ the Radamacher sequence does converge weakly to $f \equiv 0$ in $L^p(I)$. Indeed $\{f_n\}$ is bounded in $L^p(I)$, and for x in $[0, 1]$ the integral $\int_0^x f_n$ has absolute value at most 2^{-n} , because on each pair of consecutive intervals of length 2^{-n} the function f_n integrates to 0, leaving at most one incompletely traversed interval of length 2^{-n} on which $|f_n| = 1$. Thus $\lim_{n \rightarrow \infty} \int_0^x f_n = 0 = \int_0^x f$ for all x in $[0, 1]$, and Theorem 11 tells us that $\{f_n\} \rightharpoonup f$ in $L^p(I)$. So this sequence witnesses the failure of the converse of the implication “strong convergence implies weak convergence.”

Problem 8.13. Fix real numbers α and β . For each natural number n , consider the step function f_n defined on $I = [0, 1]$ by

$$f_n(x) = (1 - (-1)^k)\alpha/2 + (1 + (-1)^k)\beta/2 \quad \text{for } k/2^n \leq x < (k+1)/2^n, \quad 0 \leq k < 2^n - 1.$$

For $1 < p < \infty$, show that $\{f_n\}$ converges weakly in $L^p(I)$ to the constant function that takes the value $(\alpha + \beta)/2$. For $\alpha \neq \beta$, show that no subsequence of $\{f_n\}$ converges strongly in $L^p(I)$.

Solution. Throughout, the index k is understood to run over $0 \leq k \leq 2^n - 1$, so that the intervals $[k/2^n, (k+1)/2^n)$ exhaust $[0, 1)$; the printed upper restriction is a misprint. The value of f_n at the single point 1 is irrelevant, since it affects nothing in $L^p(I)$.

Reduction to the Radamacher functions. If k is even then $(-1)^k = 1$ and the defining formula gives $f_n = 0 \cdot \alpha + \beta = \beta$; if k is odd then $(-1)^k = -1$ and the formula gives $f_n = \alpha + 0 \cdot \beta = \alpha$. Let r_n be the n -th Radamacher function of the first example of this section, so $r_n = (-1)^k$ on $[k/2^n, (k+1)/2^n)$. Then, on each such interval,

$$\frac{\alpha + \beta}{2} + \frac{\beta - \alpha}{2} r_n = \begin{cases} \beta, & k \text{ even,} \\ \alpha, & k \text{ odd,} \end{cases}$$

so that, almost everywhere on I ,

$$f_n = \frac{\alpha + \beta}{2} + \frac{\beta - \alpha}{2} r_n.$$

Let f denote the constant function on I with value $(\alpha + \beta)/2$.

Boundedness in $L^p(I)$. Set $M = \max\{|\alpha|, |\beta|\}$. Then $|f_n| \leq M$ almost everywhere on I , so $\|f_n\|_p \leq M \cdot m(I)^{1/p} = M$ for all n : the sequence $\{f_n\}$ is bounded in $L^p(I)$. Also f belongs to $L^p(I)$.

The key estimate. We claim that

$$\left| \int_0^x r_n \right| \leq \frac{1}{2^n} \quad \text{for all } x \in [0, 1] \text{ and all } n.$$

For $x = 1$ this is clear: the 2^n intervals contribute $(-1)^k 2^{-n}$ each, and since 2^n is even these cancel in pairs, so $\int_0^1 r_n = 0$. Let $0 \leq x < 1$ and let m be the integer part of $2^n x$, so $0 \leq m \leq 2^n - 1$ and $m/2^n \leq x < (m+1)/2^n$. Split

$$\int_0^x r_n = \int_0^{m/2^n} r_n + \int_{m/2^n}^x r_n = \frac{1}{2^n} \sum_{k=0}^{m-1} (-1)^k + (-1)^m \left(x - \frac{m}{2^n} \right).$$

The first term is 0 if m is even and $1/2^n$ if m is odd, since consecutive terms of the alternating sum cancel. Write $\delta = x - m/2^n$, so $0 \leq \delta < 1/2^n$. If m is even the total is δ , which lies in $[0, 2^{-n}]$; if m is odd the total is $2^{-n} - \delta$, which lies in $(0, 2^{-n}]$. In both cases the absolute value is at most 2^{-n} , proving the claim.

Weak convergence for $1 < p < \infty$. By the claim and linearity of integration, for each x in $[0, 1]$,

$$\int_0^x f_n = \frac{\alpha + \beta}{2} x + \frac{\beta - \alpha}{2} \int_0^x r_n, \quad \left| \int_0^x f_n - \int_0^x f \right| \leq \frac{|\beta - \alpha|}{2} \cdot \frac{1}{2^n}.$$

Hence $\lim_{n \rightarrow \infty} \int_0^x f_n = \int_0^x f$ for every x in $[0, 1]$ (indeed uniformly in x). Since $\{f_n\}$ is a bounded sequence in $L^p[0, 1]$, f belongs to $L^p[0, 1]$, and $1 < p < \infty$, Theorem 11 tells us that this is necessary and sufficient for weak convergence. Therefore $\{f_n\}$ converges weakly in $L^p(I)$ to the constant function $f \equiv (\alpha + \beta)/2$.

No strongly convergent subsequence when $\alpha \neq \beta$. First compute the norms. Among the indices $0 \leq k \leq 2^n - 1$ there are 2^{n-1} even ones and 2^{n-1} odd ones, and each corresponding interval has measure 2^{-n} . Hence $f_n = \beta$ on a set of measure $1/2$ and $f_n = \alpha$ on a complementary set of measure $1/2$, so for every n

$$\|f_n\|_p^p = \frac{|\alpha|^p + |\beta|^p}{2}, \quad \text{while} \quad \|f\|_p^p = \left| \frac{\alpha + \beta}{2} \right|^p.$$

We claim that for $p > 1$ and $\alpha \neq \beta$,

$$\left| \frac{\alpha + \beta}{2} \right|^p < \frac{|\alpha|^p + |\beta|^p}{2}.$$

Suppose first that $|\alpha| \neq |\beta|$. The function $\varphi(s) = s^p$ on $[0, \infty)$ has $\varphi''(s) = p(p-1)s^{p-2} > 0$ for $s > 0$, so φ' is strictly increasing on $(0, \infty)$ and φ is strictly convex on $[0, \infty)$. Applied to the distinct points $|\alpha|$ and $|\beta|$ this gives

$$\left(\frac{|\alpha| + |\beta|}{2} \right)^p < \frac{|\alpha|^p + |\beta|^p}{2}.$$

Since $|(\alpha + \beta)/2| \leq (|\alpha| + |\beta|)/2$ and φ is nondecreasing on $[0, \infty)$, the claim follows in this case. Suppose next that $|\alpha| = |\beta|$ but $\alpha \neq \beta$. Then $\alpha = -\beta$ and $\alpha \neq 0$, so the left side is 0 while the right side is $|\alpha|^p > 0$; the claim holds here too.

Consequently

$$\|f\|_p < \left(\frac{|\alpha|^p + |\beta|^p}{2} \right)^{1/p} = \liminf_{n \rightarrow \infty} \|f_n\|_p,$$

the sequence $\{\|f_n\|_p\}$ being constant. Corollary 13 states that, for $1 < p < \infty$ and $\{f_n\}$ converging weakly to f in $L^p(E)$, a subsequence of $\{f_n\}$ converges strongly to f if and only if $\|f\|_p = \liminf_{n \rightarrow \infty} \|f_n\|_p$. Since that equality fails, no subsequence of $\{f_n\}$ converges strongly to f .

Finally, no subsequence converges strongly to anything else either. Suppose a subsequence $\{f_{n_j}\}$ converged strongly in $L^p(I)$ to some g . Strong convergence implies weak convergence, so $\{f_{n_j}\} \rightharpoonup g$. But every subsequence of a weakly convergent sequence converges weakly to the same limit, so $\{f_{n_j}\} \rightharpoonup f$ as well. Since weak sequential limits in $L^p(E)$ are unique, $g = f$, contradicting the preceding paragraph. Therefore, for $\alpha \neq \beta$, no subsequence of $\{f_n\}$ converges strongly in $L^p(I)$.

Problem 8.14. Let h be a continuous function defined on all of $\mathbb{R}$ that is periodic of period T and $\int_0^T h = 0$. Let $[a, b]$ be a closed, bounded interval and for each natural number n , define the function f_n on $[a, b]$ by $f_n(x) = h(nx)$. Define $f \equiv 0$ on $[a, b]$. Show that for $1 \leq p < \infty$, $\{f_n\}$ converges weakly to f in $L^p[a, b]$.

Solution. Fix $1 \leq p < \infty$ and let q be the conjugate of p . By Proposition 6, since $f \equiv 0$ it suffices to prove

$$\lim_{n \rightarrow \infty} \int_a^b g \cdot f_n = 0 \quad \text{for every } g \in L^q[a, b].$$

We prove the stronger statement that this holds for every g in $L^1[a, b]$; since $[a, b]$ has finite measure, $L^q[a, b]$ is contained in $L^1[a, b]$ for every q with $1 < q \leq \infty$ (immediately for $q = \infty$, and by Hölder's Inequality for $1 < q < \infty$, taking the conjugate exponent against the function identically 1, which is integrable over $[a, b]$), and for $p = 1$ we have $q = \infty$, while for $p > 1$ we have $1 < q < \infty$. So the stronger statement covers all $1 \leq p < \infty$ at once.

Step 1: h is bounded, and each f_n belongs to $L^p[a, b]$. The function h is continuous on the compact interval $[0, T]$, hence attains a finite maximum there; put $K = \max_{[0, T]} |h|$. Every real number u may be written $u = t + jT$ with $t \in [0, T)$ and j an integer, and $h(u) = h(t)$ by periodicity, so $|h| \leq K$ on all of $\mathbb{R}$. Consequently each $f_n(x) = h(nx)$ is continuous on $[a, b]$ with $|f_n| \leq K$, so f_n belongs to $L^p[a, b]$ and $\|f_n\|_p \leq K(b - a)^{1/p}$. In particular $\{f_n\}$ is bounded in $L^p[a, b]$.

Step 2: the antiderivative of h is bounded. Define

$$H(u) = \int_0^u h \quad \text{for } u \in \mathbb{R}.$$

H is continuous, being an indefinite integral of a continuous function. We claim H is periodic of period T . For any real u ,

$$H(u + T) - H(u) = \int_u^{u+T} h.$$

Substituting $t = s - T$ and using $h(t + T) = h(t)$,

$$\int_T^{u+T} h(s) ds = \int_0^u h(t + T) dt = \int_0^u h,$$

and therefore

$$\int_u^{u+T} h = \int_u^T h + \int_T^{u+T} h = \int_u^T h + \int_0^u h = \int_0^T h = 0.$$

(The manipulations are valid for every real u , the integrals being ordinary Riemann integrals of a continuous function, with the usual orientation convention.) Hence $H(u + T) = H(u)$ for all u . Being continuous and periodic, H is bounded: with $M = \max_{[0, T]} |H|$, the same reduction as in Step 1 gives $|H| \leq M$ on all of $\mathbb{R}$.

Step 3: the integral of f_n over any subinterval tends to 0, uniformly. Let $a \leq c \leq d \leq b$ and let n be a natural number. The change of variable $u = nx$ gives

$$\int_c^d f_n = \int_c^d h(nx) dx = \frac{1}{n} \int_{nc}^{nd} h(u) du = \frac{H(nd) - H(nc)}{n},$$

and hence

$$\left| \int_c^d f_n \right| \leq \frac{2M}{n} \quad \text{for all } a \leq c \leq d \leq b.$$

Step 4: the conclusion for step functions. Let φ be a step function on $[a, b]$: there is a partition $a = x_0 < x_1 < \cdots < x_N = b$ and real numbers $c_1, \dots, c_N$ with $\varphi = c_i$ on the open interval (x_{i-1}, x_i) for each i . The finitely many partition points form a set of measure zero, so

$$\int_a^b \varphi \cdot f_n = \sum_{i=1}^N c_i \int_{x_{i-1}}^{x_i} f_n, \quad \left| \int_a^b \varphi \cdot f_n \right| \leq \frac{2M}{n} \sum_{i=1}^N |c_i|,$$

by Step 3. Since $\sum_{i=1}^N |c_i|$ does not depend on n , we conclude

$$\lim_{n \rightarrow \infty} \int_a^b \varphi \cdot f_n = 0 \quad \text{for every step function } \varphi \text{ on } [a, b].$$

Step 5: the conclusion for every g in $L^1[a, b]$. Let g belong to $L^1[a, b]$ and let $\epsilon > 0$. By Proposition 10 of the preceding chapter, the step functions are dense in $L^1[a, b]$, so there is a step function φ on $[a, b]$ with

$$\|g - \varphi\|_1 < \frac{\epsilon}{2(K+1)}.$$

For every n , since $|f_n| \leq K$ on $[a, b]$,

$$\left| \int_a^b (g - \varphi) \cdot f_n \right| \leq K \int_a^b |g - \varphi| = K \|g - \varphi\|_1 < \frac{\epsilon}{2}.$$

By Step 4 there is a natural number N such that $\left| \int_a^b \varphi \cdot f_n \right| < \epsilon/2$ for all $n \geq N$. Hence for $n \geq N$,

$$\left| \int_a^b g \cdot f_n \right| \leq \left| \int_a^b (g - \varphi) \cdot f_n \right| + \left| \int_a^b \varphi \cdot f_n \right| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Since $\epsilon > 0$ was arbitrary, $\lim_{n \rightarrow \infty} \int_a^b g \cdot f_n = 0$.

Conclusion. Let $1 \leq p < \infty$ and let q be the conjugate of p . Every g in $L^q[a, b]$ belongs to $L^1[a, b]$, so by Step 5,

$$\lim_{n \rightarrow \infty} \int_a^b g \cdot f_n = 0 = \int_a^b g \cdot f \quad \text{for all } g \in L^q[a, b].$$

By Proposition 6, $\{f_n\}$ converges weakly to $f \equiv 0$ in $L^p[a, b]$ for every $1 \leq p < \infty$.

Remark. The Riemann-Lebesgue Lemma, given as an example in this section, is the special case $h(u) = \sin u$, $T = 2\pi$, $[a, b] = [-\pi, \pi]$. Note also that unless $h \equiv 0$ the convergence is not strong for any p : since $|h|^p$ is continuous, periodic of period T and not identically zero, the same argument applied to $|h|^p - \gamma$, where $\gamma = (1/T) \int_0^T |h|^p > 0$, shows $\|f_n\|_p^p = \int_a^b |h(nx)|^p dx \rightarrow \gamma(b-a) > 0$, whereas $\|f\|_p = 0$.

8.3 Problems 8.15–8.21

Problem 8.15. Let $1 < p < \infty$ and f_0 belong to $L^p(\mathbb{R})$. For each natural number n , define $f_n(x) = f_0(x - n)$ for all x . Define $f \equiv 0$ on $\mathbb{R}$. Show that $\{f_n\} \rightharpoonup f$ in $L^p(\mathbb{R})$. Is this true for $p = 1$?

Solution. Throughout, q denotes the conjugate of p ; since $p > 1$ we have $q < \infty$.

Step 1: the sequence is bounded in $L^p(\mathbb{R})$. Lebesgue measure is translation invariant, so for each n ,

$$\int_{\mathbb{R}} |f_n|^p = \int_{\mathbb{R}} |f_0(x - n)|^p dx = \int_{\mathbb{R}} |f_0|^p,$$

that is, $\|f_n\|_p = \|f_0\|_p$ for all n . Hence $\{f_n\}$ is a bounded sequence in $L^p(\mathbb{R})$.

Step 2: verification of the criterion of Theorem 10. Since $\{f_n\}$ is bounded in $L^p(\mathbb{R})$, $f \equiv 0$ belongs to $L^p(\mathbb{R})$, and $p > 1$, Theorem 10 tells us that $\{f_n\} \rightharpoonup f$ in $L^p(\mathbb{R})$ if and only if

$$\lim_{n \rightarrow \infty} \int_A f_n = \int_A f = 0 \quad \text{for every measurable set } A \text{ of finite measure.}$$

So let $A \subseteq \mathbb{R}$ be measurable with $m(A) < \infty$. By the translation invariance of Lebesgue measure,

$$\int_A f_n = \int_A f_0(x-n) dx = \int_{A-n} f_0,$$

where $A-n = \{x-n : x \in A\}$.

Let $\epsilon > 0$. Since $A \cap [-M, M] \uparrow A$ as $M \rightarrow \infty$ and $m(A) < \infty$, the continuity of measure provides an $M > 0$ for which

$$m(A \setminus [-M, M]) < \epsilon.$$

Write $A_M = A \cap [-M, M]$ and $B_M = A \setminus [-M, M]$. Then

$$\left| \int_A f_n \right| \leq \int_{A_M-n} |f_0| + \int_{B_M-n} |f_0|.$$

We estimate the second term with Hölder's Inequality, applied to $|f_0|$ and the characteristic function of $B_M - n$; since $m(B_M - n) = m(B_M) < \epsilon$ and $q < \infty$,

$$\int_{B_M-n} |f_0| \leq \|f_0\|_p \cdot [m(B_M - n)]^{1/q} \leq \|f_0\|_p \cdot \epsilon^{1/q}.$$

This is the only place where $p > 1$ is used, and it is used decisively: for $p = 1$ the factor $[m(B_M - n)]^{1/q}$ is replaced by 1 and the estimate is worthless.

For the first term, observe that $A_M - n \subseteq [-M-n, M-n]$, so again by Hölder's Inequality,

$$\int_{A_M-n} |f_0| \leq \left[\int_{-M-n}^{M-n} |f_0|^p \right]^{1/p} \cdot (2M)^{1/q}.$$

Now $|f_0|^p$ is integrable over $\mathbb{R}$, so the set function $A \mapsto \int_A |f_0|^p$ is a finite measure on the Lebesgue measurable sets. The sets $(-\infty, M-n]$ decrease, as $n \rightarrow \infty$, to the empty set, and so by the continuity of this measure,

$$\lim_{n \rightarrow \infty} \int_{-M-n}^{M-n} |f_0|^p = 0, \quad \text{hence} \quad \lim_{n \rightarrow \infty} \int_{-M-n}^{M-n} |f_0| = 0.$$

Therefore $\lim_{n \rightarrow \infty} \int_{A_M-n} |f_0| = 0$.

Combining the two estimates,

$$\limsup_{n \rightarrow \infty} \left| \int_A f_n \right| \leq \|f_0\|_p \cdot \epsilon^{1/q}.$$

As $\epsilon > 0$ was arbitrary and $q < \infty$, we conclude $\lim_{n \rightarrow \infty} \int_A f_n = 0$. By Theorem 10, $\{f_n\} \rightarrow f \equiv 0$ in $L^p(\mathbb{R})$.

Step 3: the case $p = 1$. The assertion fails. Take $f_0 = \chi_{[0,1]}$, which belongs to $L^1(\mathbb{R})$. Then $f_n = \chi_{[n,n+1]}$. The function $g \equiv 1$ belongs to $L^\infty(\mathbb{R})$, the conjugate space of $L^1(\mathbb{R})$, and

$$\int_{\mathbb{R}} g \cdot f_n = 1 \text{ for all } n, \quad \text{while} \quad \int_{\mathbb{R}} g \cdot f = 0.$$

By Proposition 6, $\{f_n\}$ does not converge weakly to $f \equiv 0$ in $L^1(\mathbb{R})$. (More generally, for any $f_0 \in L^1(\mathbb{R})$ with $\int_{\mathbb{R}} f_0 \neq 0$ the same test function $g \equiv 1$ shows the failure, since $\int_{\mathbb{R}} f_n = \int_{\mathbb{R}} f_0$ for every n .) This is exactly the example presented in the text just before Theorem 12, where the verification of the criterion of Theorem 10 is left as “an exercise in the use of continuity of measure” – which is what Step 2 above carries out.

Problem 8.16. Let E be a measurable set, $\{f_n\}$ a sequence in $L^2(E)$ and f belong to $L^2(E)$.

Suppose

$$\lim_{n \rightarrow \infty} \int_E f_n \cdot f = \lim_{n \rightarrow \infty} \int_E f_n^2 = \int_E f^2.$$

Show that $\{f_n\}$ converges strongly to f in $L^2(E)$.

Solution. Since 2 is its own conjugate, Hölder's Inequality tells us that the product $f_n \cdot f$ of two functions in $L^2(E)$ is integrable over E , so each of the integrals in the hypothesis is a well-defined real number. In particular $\int_E f^2 = \|f\|_2^2$ is finite.

Fix an index n . The function $f_n - f$ belongs to the linear space $L^2(E)$, and

$$(f_n - f)^2 = f_n^2 - 2f_n \cdot f + f^2 \quad \text{pointwise on } E.$$

Each of the three functions on the right is integrable over E : f_n^2 and f^2 because f_n and f belong to $L^2(E)$, and $f_n \cdot f$ by Hölder's Inequality as just observed. Therefore, by the linearity of integration,

$$\|f_n - f\|_2^2 = \int_E (f_n - f)^2 = \int_E f_n^2 - 2 \int_E f_n \cdot f + \int_E f^2.$$

Now pass to the limit. By hypothesis

$$\lim_{n \rightarrow \infty} \int_E f_n^2 = \int_E f^2 \quad \text{and} \quad \lim_{n \rightarrow \infty} \int_E f_n \cdot f = \int_E f^2,$$

and these are limits of real sequences, so by the linearity of convergence for sequences of real numbers,

$$\lim_{n \rightarrow \infty} \|f_n - f\|_2^2 = \int_E f^2 - 2 \int_E f^2 + \int_E f^2 = 0.$$

Hence $\lim_{n \rightarrow \infty} \|f_n - f\|_2 = 0$, that is, $\{f_n\}$ converges strongly to f in $L^2(E)$.

We remark that this computation is precisely the argument used in the text to prove the Radon-Riesz Theorem in the case $p = 2$: there the first hypothesis, $\lim_{n \rightarrow \infty} \int_E f_n \cdot f = \int_E f^2$, is obtained from the weak convergence $\{f_n\} \rightharpoonup f$ in $L^2(E)$ by taking f itself as the test function in Proposition 6 (legitimate because f belongs to $L^2(E) = L^q(E)$), and the second hypothesis is the convergence of the norms.

Problem 8.17. Let E be a measurable set and $1 < p < \infty$. Suppose $\{f_n\}$ is a bounded sequence in $L^p(E)$ and f belongs to $L^p(E)$. Consider the following four properties: (i) $\{f_n\}$ converges pointwise to f almost everywhere on E , (ii) $\{f_n\} \rightharpoonup f$ in $L^p(E)$, (iii) $\{\|f_n\|_p\}$ converges to $\|f\|_p$, and (iv) $\{f_n\} \rightarrow f$ in $L^p(E)$. If $\{f_n\}$ possesses two of these properties, does a subsequence possess all four properties?

Solution. A remark on the statement: the text as printed reads “(iii) $\{\|f_n\|_p\}$ converges to $\{\|f_n\|_p\}$ ”, which is a misprint; the property intended, and the only one that makes the question non-trivial, is that $\{\|f_n\|_p\}$ converges to $\|f\|_p$. We read (iii) that way throughout. Likewise (ii) is weak convergence and (iv) is strong (norm) convergence.

The answer is yes for five of the six pairs, and no for the pair (i), (ii).

We first record three implications that will be used repeatedly. Let $\{f_n\}$ be a bounded sequence in $L^p(E)$ with $1 < p < \infty$ and let $f \in L^p(E)$.

(A) Property (i) implies property (ii). This is exactly Theorem 12: a bounded sequence in $L^p(E)$, $1 < p < \infty$, that converges pointwise a.e. on E to f converges weakly to f in $L^p(E)$.

(B) Properties (ii) and (iii) together imply property (iv). This is the Radon-Riesz Theorem: if $\{f_n\} \rightharpoonup f$ in $L^p(E)$ with $1 < p < \infty$, then $\{f_n\} \rightarrow f$ in $L^p(E)$ if and only if $\lim_{n \rightarrow \infty} \|f_n\|_p = \|f\|_p$.

(C) Property (iv) implies properties (ii) and (iii), and implies that some subsequence has property (i). Indeed, strong convergence implies weak convergence in any normed linear space, since $|T(f_n) - T(f)| \leq \|T\|_* \cdot \|f_n - f\|$ for every $T \in X^*$; convergence of the norms follows from $|\|f_n\|_p - \|f\|_p| \leq \|f_n - f\|_p$; and the Riesz-Fischer Theorem of the preceding chapter states that if $\{f_n\} \rightarrow f$ in $L^p(E)$, then a

subsequence of $\{f_n\}$ converges pointwise a.e. on E to f .

Now consider the six pairs.

The pairs (i) and (iv), (ii) and (iv), (iii) and (iv). Each contains property (iv). By (C), the whole sequence then has properties (ii), (iii), (iv), and some subsequence has in addition property (i). Since properties (ii), (iii), (iv) are inherited by every subsequence (a subsequence of a strongly convergent sequence converges strongly to the same limit, and (ii), (iii) then follow from (C)), that subsequence possesses all four properties. So the answer is yes.

The pair (i) and (iii). By (A), property (i) and the boundedness of $\{f_n\}$ give property (ii). Property (ii) together with the assumed property (iii) gives property (iv) by (B). Thus the whole sequence possesses all four properties, and the answer is yes.

The pair (ii) and (iii). By (B) the whole sequence has property (iv), hence also (ii) and (iii); and by (C) a subsequence in addition has property (i). That subsequence possesses all four properties. The answer is yes.

The pair (i) and (ii). Here the answer is no. Note first that by (A) this pair carries no more information than property (i) alone. Let $E = [0, 1]$, let $f \equiv 0$, and for each natural number n define

$$f_n = n^{1/p} \cdot \chi_{(0, 1/n)}.$$

Each f_n belongs to $L^p[0, 1]$ and

$$\|f_n\|_p = \left[\int_0^{1/n} n \right]^{1/p} = 1 \text{ for all } n,$$

so $\{f_n\}$ is a bounded sequence in $L^p[0, 1]$. If $0 < x \leq 1$, then $f_n(x) = 0$ once $n > 1/x$, so $\{f_n\}$ converges to $f \equiv 0$ pointwise on $(0, 1]$ and therefore almost everywhere on $[0, 1]$: property (i) holds. By Theorem 12, $\{f_n\} \rightharpoonup f$ in $L^p[0, 1]$: property (ii) holds.

But $\|f\|_p = 0$ while $\|f_{n_k}\|_p = 1$ for every subsequence $\{f_{n_k}\}$, so no subsequence has property (iii); and since strong convergence would force convergence of the norms by (C), no subsequence has property (iv) either. Hence no subsequence possesses all four properties.

In summary: if $\{f_n\}$ possesses two of the four properties, then a subsequence possesses all four, except in the single case where the two properties are (i) and (ii).

Problem 8.18. Let X be a normed linear space and $\{f_n\} \rightharpoonup f$ in X . Suppose $\{\|f_n\|\}$ is unbounded. Show that, by possibly taking a subsequence and relabeling, we may suppose $\|f_n\| \geq \alpha_n = n \cdot 3^n$ for all n . Then show that, by possibly taking a further subsequence and relabeling, we may suppose $\{\|f_n\|/\alpha_n\} \rightarrow \alpha \in [1, \infty]$. Define $g_n = \alpha_n/\|f_n\| \cdot f_n$ for each n . Show that $\{g_n\}$ converges weakly and $\|g_n\| = n \cdot 3^n$ for all n .

Solution. Two elementary observations will be used. First, a subsequence of a weakly convergent sequence converges weakly to the same limit: if $\{f_n\} \rightharpoonup f$ in X and $\{f_{n_k}\}$ is a subsequence, then for each $T \in X^*$ the sequence $\{T(f_{n_k})\}$ is a subsequence of the convergent sequence of real numbers $\{T(f_n)\}$ and hence converges to the same limit $T(f)$. Second, since $\{\|f_n\|\}$ is unbounded, for every $M > 0$ the set $\{n : \|f_n\| > M\}$ is infinite: were it finite for some M , then $\|f_n\| \leq M'$ for all n , where M' is the maximum of M and the finitely many values $\|f_n\|$ with $\|f_n\| > M$, contradicting unboundedness. Step 1: arranging $\|f_n\| \geq \alpha_n = n \cdot 3^n$.

We select indices inductively. Using the second observation with $M = 1 \cdot 3^1$, choose n_1 with $\|f_{n_1}\| \geq 1 \cdot 3^1$. Having chosen $n_1 < n_2 < \cdots < n_{k-1}$, use the second observation with $M = k \cdot 3^k$: infinitely many indices n satisfy $\|f_n\| > k \cdot 3^k$, so one of them exceeds n_{k-1} ; call it n_k . This produces a strictly increasing sequence of indices $\{n_k\}$ with

$$\|f_{n_k}\| \geq k \cdot 3^k = \alpha_k \text{ for all } k.$$

By the first observation, $\{f_{n_k}\} \rightharpoonup f$ in X . Relabeling this subsequence as $\{f_n\}$, we may and do suppose

$$\|f_n\| \geq \alpha_n = n \cdot 3^n \text{ for all } n.$$

In particular $\|f_n\| \geq 3 > 0$ for every n , so no f_n is the zero vector and the quotients below are defined.

Step 2: arranging $\{\|f_n\|/\alpha_n\} \rightarrow \alpha \in [1, \infty]$.

Set $\beta_n = \|f_n\|/\alpha_n$. By Step 1, $\beta_n \geq 1$ for all n . If $\{\beta_n\}$ already converges in the extended sense to some $\alpha \in [1, \infty]$, there is nothing to do.

In general it does not, and here one must be careful about what “relabeling” does. If we retain the indices $n_1 < n_2 < \dots$ and relabel f_{n_k} as the k th term, the ratio attached to the k th term of the new sequence is not $\beta_{n_k} = \|f_{n_k}\|/\alpha_{n_k}$ but rather $\|f_{n_k}\|/\alpha_k$; since $n_k \geq k$ and $\{\alpha_n\}$ is increasing, $\alpha_k \leq \alpha_{n_k}$, so relabeling can only increase the ratio. Thus one cannot simply apply the Bolzano-Weierstrass Theorem to $\{\beta_n\}$ and read off the conclusion: a finite limit for $\{\beta_{n_k}\}$ need not survive the reindexing. Nor can the finiteness of α be arranged in general. If, for instance, $\|f_n\| = 3^{n^2}$ for all n , then for any indices $n_1 < n_2 < \dots$ one has $n_k \geq k$ and hence

$$\frac{\|f_{n_k}\|}{\alpha_k} = \frac{3^{n_k^2}}{k \cdot 3^k} \geq \frac{3^{k^2}}{k \cdot 3^k} \rightarrow \infty,$$

so every relabeled subsequence has ratios tending to ∞ . This is why the value $\alpha = \infty$ must be allowed in the assertion.

What is always available is the following selection, and it suffices. By Step 1, $\|f_n\| \geq n \cdot 3^n$, so $\lim_{n \rightarrow \infty} \|f_n\| = \infty$. Hence, for each natural number k , the inequality $\|f_n\| \geq k \cdot \alpha_k$ holds for all sufficiently large n , since $k \cdot \alpha_k$ is a fixed real number. Choose inductively $n_1 < n_2 < \dots$ with

$$\|f_{n_k}\| \geq k \cdot \alpha_k \text{ for all } k.$$

By the first observation, $\{f_{n_k}\} \rightharpoonup f$ in X . Relabeling f_{n_k} as the k th term, the relabeled sequence satisfies $\|f_k\| \geq k \cdot \alpha_k \geq \alpha_k$, so the normalization of Step 1 persists, and

$$\frac{\|f_k\|}{\alpha_k} \geq k \rightarrow \infty,$$

so the relabeled ratios converge to $\alpha = \infty \in [1, \infty]$. Thus, after this further passage to a subsequence and relabeling, we may suppose both

$$\|f_n\| \geq \alpha_n \text{ for all } n \quad \text{and} \quad \lim_{n \rightarrow \infty} \frac{\|f_n\|}{\alpha_n} = \alpha \in [1, \infty].$$

Step 3: the sequence $\{g_n\}$.

Define $c_n = \alpha_n/\|f_n\|$ and $g_n = c_n \cdot f_n$. Since $\|f_n\| > 0$, c_n is a well-defined positive real number, and by the homogeneity of the norm,

$$\|g_n\| = c_n \|f_n\| = \frac{\alpha_n}{\|f_n\|} \cdot \|f_n\| = \alpha_n = n \cdot 3^n \text{ for all } n.$$

It remains to show that $\{g_n\}$ converges weakly in X . By Step 2, c_n is the reciprocal of $\|f_n\|/\alpha_n$, and this last quantity converges to $\alpha \in [1, \infty]$. Hence

$$\lim_{n \rightarrow \infty} c_n = c, \quad \text{where } c = 1/\alpha \in (0, 1] \text{ if } \alpha < \infty \text{ and } c = 0 \text{ if } \alpha = \infty.$$

(If $\alpha = \infty$, then $\beta_n \rightarrow \infty$ and so $c_n = 1/\beta_n \rightarrow 0$; if $\alpha \in [1, \infty)$, then $\alpha \geq 1 > 0$ and $c_n \rightarrow 1/\alpha$ by the quotient rule for limits of real sequences.)

Now let T belong to X^* . By the linearity of T ,

$$T(g_n) = T(c_n f_n) = c_n \cdot T(f_n).$$

Since $\{T(f_n)\}$ converges to the real number $T(f)$ and $\{c_n\}$ converges to the real number c , the product rule for limits of real sequences gives

$$\lim_{n \rightarrow \infty} T(g_n) = c \cdot T(f) = T(c \cdot f),$$

the last equality again by linearity of T . As $T \in X^*$ was arbitrary, $\{g_n\} \rightharpoonup c \cdot f$ in X , where $c \cdot f$ is the vector f/α if $\alpha < \infty$ and is the zero vector if $\alpha = \infty$. Thus $\{g_n\}$ converges weakly in X and $\|g_n\| = n \cdot 3^n$ for all n .

This is precisely the justification of the phrase “without loss of generality (see Problem 18), by possibly taking scalar multiples of a subsequence” in the proof of Theorem 7: to derive a contradiction from the assumption that a weakly convergent sequence in $L^p(E)$ has unbounded norms, one may replace the sequence by $\{g_n\}$, which is a sequence of scalar multiples of a subsequence, still converges weakly, and satisfies the normalization (18), namely $\|g_n\| = n \cdot 3^n$ for all n .

Problem 8.19. For $1 \leq p < \infty$, let $\{\zeta_n\}$ be a bounded sequence in ℓ^p and ζ belong to ℓ^p . Show that $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^p if and only if it converges componentwise, that is, for each index k ,

$$\lim_{n \rightarrow \infty} \zeta_n^k = \zeta^k \quad \text{where } \zeta_n = \langle \zeta_n^1, \zeta_n^2, \dots \rangle \text{ and } \zeta = \langle \zeta^1, \zeta^2, \dots \rangle.$$

Solution. Throughout, q denotes the conjugate of p . By Problem 7 of this chapter (the Riesz Representation Theorem for ℓ^p), for $1 \leq p < \infty$ every bounded linear functional T on ℓ^p is of the form

$$T(\xi) = \sum_{k=1}^{\infty} \eta^k \xi^k \text{ for all } \xi \in \ell^p,$$

for a unique $\eta = (\eta^1, \eta^2, \dots)$ in ℓ^q , and $\|T\|_* = \|\eta\|_q$. Thus $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^p if and only if

$$\lim_{n \rightarrow \infty} \sum_{k=1}^{\infty} \eta^k \zeta_n^k = \sum_{k=1}^{\infty} \eta^k \zeta^k \text{ for every } \eta \in \ell^q.$$

We refer to this displayed condition as the pairing criterion.

Weak convergence implies componentwise convergence, for every p with $1 \leq p < \infty$. Fix an index k and define $T_k(\xi) = \xi^k$ for $\xi \in \ell^p$. Then T_k is linear, and

$$|T_k(\xi)| = |\xi^k| \leq \left[\sum_{j=1}^{\infty} |\xi^j|^p \right]^{1/p} = \|\xi\|_p,$$

so T_k is a bounded linear functional on ℓ^p . (No representation theorem is needed for this direction: T_k is manifestly bounded.) If $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^p , then by the definition of weak convergence $\lim_{n \rightarrow \infty} T_k(\zeta_n) = T_k(\zeta)$, that is, $\lim_{n \rightarrow \infty} \zeta_n^k = \zeta^k$. Since k was arbitrary, $\{\zeta_n\}$ converges componentwise to ζ .

Componentwise convergence implies weak convergence, when $1 < p < \infty$. Assume now $p > 1$, so that $q < \infty$. Since $\{\zeta_n\}$ is bounded in ℓ^p and $\zeta \in \ell^p$, the number

$$M = \sup_n \|\zeta_n - \zeta\|_p \leq \sup_n \|\zeta_n\|_p + \|\zeta\|_p$$

is finite. Let $\eta \in \ell^q$ and let $\epsilon > 0$. Since $\sum_{k=1}^{\infty} |\eta^k|^q < \infty$, the tail of this convergent series is small: choose a natural number N for which

$$\left[\sum_{k=N+1}^{\infty} |\eta^k|^q \right]^{1/q} < \epsilon.$$

For each n , by the linearity of the (absolutely convergent) series and the triangle inequality,

$$\left| \sum_{k=1}^{\infty} \eta^k \zeta_n^k - \sum_{k=1}^{\infty} \eta^k \zeta^k \right| \leq \sum_{k=1}^N |\eta^k| |\zeta_n^k - \zeta^k| + \left| \sum_{k=N+1}^{\infty} \eta^k (\zeta_n^k - \zeta^k) \right|.$$

Hölder's Inequality for series – the counting-measure form of Theorem 1 of the preceding chapter, proved by the identical argument from Young's Inequality – applied to the sequences $\langle 0, \dots, 0, \eta^{N+1}, \eta^{N+2}, \dots \rangle$ in ℓ^q and $\zeta_n - \zeta$ in ℓ^p , bounds the second term:

$$\left| \sum_{k=N+1}^{\infty} \eta^k (\zeta_n^k - \zeta^k) \right| \leq \left[\sum_{k=N+1}^{\infty} |\eta^k|^q \right]^{1/q} \cdot \|\zeta_n - \zeta\|_p \leq \epsilon M.$$

The first term is a sum of the fixed finite number N of terms, each of which tends to 0 as $n \rightarrow \infty$ by componentwise convergence; hence it tends to 0. Consequently

$$\limsup_{n \rightarrow \infty} \left| \sum_{k=1}^{\infty} \eta^k \zeta_n^k - \sum_{k=1}^{\infty} \eta^k \zeta^k \right| \leq \epsilon M.$$

Since $\epsilon > 0$ was arbitrary and M is a fixed finite number, the limit is 0. Thus the pairing criterion holds and $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^p .

(This second half is the ℓ^p analogue of Proposition 9, proved above directly so that no transfer of that proposition from $L^p(E)$ to the counting measure is needed: the family $\mathcal{F} = \{e_k\}_{k \geq 1}$, where e_k has k th component 1 and all other components 0, has as its linear span the finitely supported sequences, and this span is dense in ℓ^q when $q < \infty$. Componentwise convergence is exactly the statement that $\lim_n \langle \zeta_n, e_k \rangle = \langle \zeta, e_k \rangle$ for each k .)

A remark on the case $p = 1$. The implication just proved genuinely requires $p > 1$, and the statement of the problem is not correct at $p = 1$: only the first half survives. For $p = 1$ the conjugate exponent is $q = \infty$, the tail estimate above is unavailable, and the linear span of $\{e_k\}$ is not dense in ℓ^∞ . Indeed, let $\zeta_n = e_n$ and $\zeta = 0$. Then $\|e_n\|_1 = 1$, so $\{\zeta_n\}$ is bounded in ℓ^1 , and for each fixed k we have $e_n^k = 0$ as soon as $n > k$, so $\{\zeta_n\}$ converges componentwise to $\zeta = 0$. But $\eta = (1, 1, 1, \dots)$ belongs to ℓ^∞ and

$$\sum_{k=1}^{\infty} \eta^k \zeta_n^k = 1 \text{ for all } n, \quad \text{while} \quad \sum_{k=1}^{\infty} \eta^k \zeta^k = 0,$$

so $\{\zeta_n\}$ does not converge weakly to ζ in ℓ^1 . This is the assertion of Problem 21.

Problem 8.20. Let $1 \leq p_1 < p_2 < \infty$, $\{f_n\}$ be a sequence in $L^{p_2}[0, 1]$ and f belong to $L^{p_2}[0, 1]$. What is the relationship between $\{f_n\} \rightharpoonup f$ in $L^{p_2}[0, 1]$ and $\{f_n\} \rightharpoonup f$ in $L^{p_1}[0, 1]$?

Solution. The answer: weak convergence in $L^{p_2}[0, 1]$ implies weak convergence in $L^{p_1}[0, 1]$; the converse implication is false in general, but it does hold under the additional hypothesis that $\{f_n\}$ is bounded in $L^{p_2}[0, 1]$.

Let q_1 and q_2 be the conjugates of p_1 and p_2 . Since $1 \leq p_1 < p_2 < \infty$ we have $1 < q_2 < q_1 \leq \infty$. Since $[0, 1]$ has finite measure, Corollary 3 of the preceding chapter tells us that

$$L^{p_2}[0, 1] \subseteq L^{p_1}[0, 1] \quad \text{and} \quad L^{q_1}[0, 1] \subseteq L^{q_2}[0, 1],$$

with $\|h\|_{p_1} \leq \|h\|_{p_2}$ and $\|h\|_{q_2} \leq \|h\|_{q_1}$, since $m([0, 1]) = 1$ makes the constant c in that corollary equal to 1. (For $q_1 = \infty$ the second inclusion is the case $p_2 = \infty$ of that corollary.) In particular, the functions f_n and f all belong to $L^{p_1}[0, 1]$, so the second mode of convergence is at least meaningful.

Weak convergence in L^{p_2} implies weak convergence in L^{p_1} . Suppose $\{f_n\} \rightharpoonup f$ in $L^{p_2}[0, 1]$. By Proposition 6 this means

$$\lim_{n \rightarrow \infty} \int_0^1 g \cdot f_n = \int_0^1 g \cdot f \text{ for all } g \in L^{q_2}[0, 1].$$

Let g belong to $L^{q_1}[0, 1]$. By the inclusion above, g belongs to $L^{q_2}[0, 1]$, so the displayed limit holds for this g . Since $g \in L^{q_1}[0, 1]$ was arbitrary, Proposition 6, applied now with the exponent p_1 , gives $\{f_n\} \rightharpoonup f$ in $L^{p_1}[0, 1]$.

The converse fails in general. Let $\theta = \frac{1}{2}(1/p_1 + 1/p_2)$, so that $1/p_2 < \theta < 1/p_1$, and for each natural number n define

$$f_n = n^\theta \cdot \chi_{(0,1/n)} \text{ on } [0, 1].$$

Each f_n is a bounded measurable function on $[0, 1]$ and so belongs to $L^{p_2}[0, 1]$. For any r with $1 \leq r < \infty$,

$$\|f_n\|_r = \left[n^{\theta r} \cdot \frac{1}{n} \right]^{1/r} = n^{\theta - 1/r}.$$

Take $f \equiv 0$. Since $\theta - 1/p_1 < 0$ we get $\|f_n - f\|_{p_1} = n^{\theta - 1/p_1} \rightarrow 0$, so $\{f_n\}$ converges strongly, and hence weakly, to $f \equiv 0$ in $L^{p_1}[0, 1]$. On the other hand $\theta - 1/p_2 > 0$, so

$$\|f_n\|_{p_2} = n^{\theta - 1/p_2} \rightarrow \infty,$$

and $\{f_n\}$ is unbounded in $L^{p_2}[0, 1]$. By Theorem 7, a sequence that converges weakly in $L^{p_2}[0, 1]$ is bounded in $L^{p_2}[0, 1]$. Therefore $\{f_n\}$ does not converge weakly in $L^{p_2}[0, 1]$ to f , nor indeed to any function whatsoever. So weak convergence in $L^{p_1}[0, 1]$ does not imply weak convergence in $L^{p_2}[0, 1]$. The converse holds if $\{f_n\}$ is bounded in $L^{p_2}[0, 1]$. Suppose $\{f_n\} \rightharpoonup f$ in $L^{p_1}[0, 1]$ and $\{f_n\}$ is bounded in $L^{p_2}[0, 1]$. Let A be a measurable subset of $[0, 1]$. Since $[0, 1]$ has finite measure, χ_A belongs to $L^r[0, 1]$ for every r with $1 \leq r \leq \infty$, and in particular $\chi_A \in L^{q_1}[0, 1]$. Hence, by Proposition 6 applied with the exponent p_1 ,

$$\lim_{n \rightarrow \infty} \int_A f_n = \lim_{n \rightarrow \infty} \int_0^1 \chi_A \cdot f_n = \int_0^1 \chi_A \cdot f = \int_A f.$$

Since $\{f_n\}$ is bounded in $L^{p_2}[0, 1]$, f belongs to $L^{p_2}[0, 1]$, and $1 < p_2 < \infty$, Theorem 10 tells us that this last property is equivalent to $\{f_n\} \rightharpoonup f$ in $L^{p_2}[0, 1]$.

Summarizing: weak convergence in the larger exponent is the stronger statement; it implies weak convergence in every smaller exponent, and the two are equivalent exactly when one supplements weak convergence in $L^{p_1}[0, 1]$ with boundedness in $L^{p_2}[0, 1]$, which by Theorem 7 is in any case a necessary condition for weak convergence in $L^{p_2}[0, 1]$.

Problem 8.21. For $1 \leq p < \infty$ and each index n , let $e_n \in \ell^p$ have n th component 1 and other components vanish. Show that if $p > 1$, then $\{e_n\}$ converges weakly to 0 in ℓ^p , but no subsequence converges strongly to 0. Show that $\{e_n\}$ does not converge weakly in ℓ^1 .

Solution. For every p with $1 \leq p < \infty$ we have

$$\|e_n\|_p = \left[\sum_{k=1}^{\infty} |e_n^k|^p \right]^{1/p} = 1 \text{ for all } n,$$

so $\{e_n\}$ is a sequence of unit vectors, and in particular is bounded in ℓ^p .

Weak convergence to 0 when $p > 1$. Let q be the conjugate of p ; since $p > 1$, $q < \infty$. By Problem 7 of this chapter (the Riesz Representation Theorem for ℓ^p), every bounded linear functional T on ℓ^p has the form

$$T(\xi) = \sum_{k=1}^{\infty} \eta^k \xi^k \text{ for all } \xi \in \ell^p,$$

for some $\eta \in \ell^q$. For such a T ,

$$T(e_n) = \sum_{k=1}^{\infty} \eta^k e_n^k = \eta^n.$$

Since $\eta \in \ell^q$ with $q < \infty$, the series $\sum_{k=1}^{\infty} |\eta^k|^q$ converges, and therefore its terms tend to 0; hence $|\eta^n|^q \rightarrow 0$ and so $\eta^n \rightarrow 0$. Thus

$$\lim_{n \rightarrow \infty} T(e_n) = 0 = T(0) \text{ for every } T \in (\ell^p)^*,$$

that is, $\{e_n\} \rightharpoonup 0$ in ℓ^p . (Alternatively: $\{e_n\}$ is bounded in ℓ^p and converges componentwise to 0, since for each fixed k we have $e_n^k = 0$ whenever $n \neq k$; now apply Problem 19.) No subsequence converges strongly to 0. For any subsequence $\{e_{n_k}\}$ we have

$$\|e_{n_k} - 0\|_p = \|e_{n_k}\|_p = 1 \text{ for all } k,$$

so $\{\|e_{n_k} - 0\|_p\}$ does not converge to 0. Hence no subsequence of $\{e_n\}$ converges strongly to 0 in ℓ^p . (This is consistent with the Radon-Riesz Theorem: $\{e_n\} \rightharpoonup 0$ while $\lim_n \|e_n\|_p = 1 \neq 0 = \|0\|_p$, so the norms do not converge to the norm of the weak limit, and strong convergence must fail. Equivalently, by Corollary 13, a subsequence converges strongly to the weak limit 0 if and only if $\|0\|_p = \liminf \|e_n\|_p$, and here the left side is 0 while the right side is 1.)

Failure of weak convergence in ℓ^1 . Suppose, to get a contradiction, that $\{e_n\} \rightharpoonup \zeta$ in ℓ^1 for some $\zeta = (\zeta^1, \zeta^2, \dots)$ in ℓ^1 .

First we identify ζ . Fix an index k and define $T_k(\xi) = \xi^k$ for $\xi \in \ell^1$. This is a linear functional, and $|T_k(\xi)| = |\xi^k| \leq \sum_{j=1}^{\infty} |\xi^j| = \|\xi\|_1$, so T_k is bounded on ℓ^1 . Weak convergence gives

$$\zeta^k = T_k(\zeta) = \lim_{n \rightarrow \infty} T_k(e_n) = \lim_{n \rightarrow \infty} e_n^k = 0,$$

because $e_n^k = 0$ for all $n \neq k$. Since k was arbitrary, $\zeta = 0$.

Next we contradict this. Integration against the bounded sequence $\eta = \langle 1, 1, 1, \dots \rangle$ gives the functional

$$T(\xi) = \sum_{k=1}^{\infty} \xi^k \text{ for } \xi \in \ell^1.$$

The series converges absolutely for each $\xi \in \ell^1$, T is linear, and $|T(\xi)| \leq \sum_{k=1}^{\infty} |\xi^k| = \|\xi\|_1$, so T is a bounded linear functional on ℓ^1 . But

$$T(e_n) = 1 \text{ for all } n, \quad \text{while} \quad T(\zeta) = T(0) = 0,$$

so $\{T(e_n)\}$ does not converge to $T(\zeta)$. This contradicts the weak convergence of $\{e_n\}$ to ζ .

Therefore $\{e_n\}$ does not converge weakly in ℓ^1 . Notice that the argument needed no representation theorem for $(\ell^1)^*$: the two explicit bounded functionals T_k and T suffice. Notice also the contrast with the case $p > 1$: there $\{e_n\}$ is a bounded sequence with no strongly convergent subsequence, yet it does converge weakly, whereas in ℓ^1 even weak convergence fails.

8.4 Problems 8.22–8.28

Problem 8.22. State and prove the Radon-Riesz Theorem in ℓ^2 .

Solution. Statement. Let $\{\zeta_n\}$ be a sequence in ℓ^2 and let ζ belong to ℓ^2 . Suppose $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^2 . Then $\{\zeta_n\} \rightarrow \zeta$ strongly in ℓ^2 if and only if

$$\lim_{n \rightarrow \infty} \|\zeta_n\|_2 = \|\zeta\|_2.$$

Here, for $\eta = (\eta^1, \eta^2, \dots)$ in ℓ^2 we write $\|\eta\|_2 = (\sum_{k=1}^{\infty} |\eta^k|^2)^{1/2}$, and for ξ, η in ℓ^2 we write $\langle \xi, \eta \rangle = \sum_{k=1}^{\infty} \xi^k \eta^k$; this series converges absolutely by the Cauchy-Schwarz (Hoelder) Inequality, and $|\langle \xi, \eta \rangle| \leq \|\xi\|_2 \|\eta\|_2$.

Preliminary: a description of weak convergence in ℓ^2 . By the Riesz Representation Theorem for the dual of ℓ^p , $1 \leq p < \infty$ (Problem 7 of this chapter), applied with $p = 2$, whose conjugate is $q = 2$: a functional T belongs to $(\ell^2)^*$ if and only if there is a unique η in ℓ^2 for which

$$T(\xi) = \sum_{k=1}^{\infty} \eta^k \xi^k = \langle \xi, \eta \rangle \quad \text{for all } \xi \in \ell^2,$$

and moreover $\|T\|_* = \|\eta\|_2$. Therefore, by the definition of weak convergence in a normed linear space, $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^2 if and only if

$$\lim_{n \rightarrow \infty} \langle \zeta_n, \eta \rangle = \langle \zeta, \eta \rangle \quad \text{for all } \eta \in \ell^2. \quad (*)$$

Proof of the theorem. First suppose $\{\zeta_n\} \rightarrow \zeta$ strongly, that is, $\lim_{n \rightarrow \infty} \|\zeta_n - \zeta\|_2 = 0$. In any linear space normed by $\|\cdot\|$ the triangle inequality gives

$$|\|\xi\| - \|\eta\|| \leq \|\xi - \eta\| \quad \text{for all } \xi, \eta,$$

and hence $|\|\zeta_n\|_2 - \|\zeta\|_2| \leq \|\zeta_n - \zeta\|_2 \rightarrow 0$. Thus $\lim_{n \rightarrow \infty} \|\zeta_n\|_2 = \|\zeta\|_2$. Observe that this half uses neither the weak convergence hypothesis nor any special property of ℓ^2 .

Conversely, assume $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^2 and $\lim_{n \rightarrow \infty} \|\zeta_n\|_2 = \|\zeta\|_2$. Since each $\zeta_n - \zeta$ belongs to ℓ^2 , we may expand the square of its norm: for each n ,

$$\begin{aligned} \|\zeta_n - \zeta\|_2^2 &= \sum_{k=1}^{\infty} (\zeta_n^k - \zeta^k)^2 \\ &= \sum_{k=1}^{\infty} \left[(\zeta_n^k)^2 - 2\zeta_n^k \zeta^k + (\zeta^k)^2 \right] \\ &= \|\zeta_n\|_2^2 - 2\langle \zeta_n, \zeta \rangle + \|\zeta\|_2^2. \end{aligned}$$

The regrouping of the three series is legitimate because each of the three separately converges absolutely: $\sum_k (\zeta_n^k)^2$ and $\sum_k (\zeta^k)^2$ converge since $\zeta_n, \zeta \in \ell^2$, and $\sum_k |\zeta_n^k \zeta^k| \leq \|\zeta_n\|_2 \|\zeta\|_2 < \infty$ by the Cauchy-Schwarz Inequality.

Now ζ itself belongs to ℓ^2 , so we may take $\eta = \zeta$ in $(*)$ to conclude

$$\lim_{n \rightarrow \infty} \langle \zeta_n, \zeta \rangle = \langle \zeta, \zeta \rangle = \|\zeta\|_2^2.$$

Together with the assumed convergence of the norms, $\lim_{n \rightarrow \infty} \|\zeta_n\|_2^2 = \|\zeta\|_2^2$, we infer that

$$\lim_{n \rightarrow \infty} \|\zeta_n - \zeta\|_2^2 = \|\zeta\|_2^2 - 2\|\zeta\|_2^2 + \|\zeta\|_2^2 = 0.$$

Therefore $\{\zeta_n\} \rightarrow \zeta$ strongly in ℓ^2 . This completes the proof.

Remark. This is exactly the argument the text gives for the Radon-Riesz Theorem in $L^2(E)$, with integration replaced by summation, that is, with Lebesgue measure replaced by counting measure on the natural numbers; the identity $(a - b)^2 = a^2 - 2ab + b^2$ is what makes the case $p = 2$ so simple.

A companion corollary. Just as Corollary 13 follows from the Radon-Riesz Theorem in $L^p(E)$, we get: if $\{\zeta_n\} \rightharpoonup \zeta$ in ℓ^2 , then a subsequence of $\{\zeta_n\}$ converges strongly to ζ in ℓ^2 if and only if $\|\zeta\|_2 = \liminf \|\zeta_n\|_2$. Indeed, if $\|\zeta\|_2 = \liminf \|\zeta_n\|_2$, choose a subsequence $\{\zeta_{n_k}\}$ with $\lim_{k \rightarrow \infty} \|\zeta_{n_k}\|_2 = \|\zeta\|_2$; this subsequence still converges weakly to ζ , so by the theorem just proved it converges strongly to ζ . Conversely, if some subsequence converges strongly to ζ , then along it the norms converge to $\|\zeta\|_2$, so $\liminf \|\zeta_n\|_2 \leq \|\zeta\|_2$; the reverse inequality $\|\zeta\|_2 \leq \liminf \|\zeta_n\|_2$ holds for any weakly convergent sequence. Indeed, this is trivial if $\zeta = 0$; and if $\zeta \neq 0$, then for each n the Cauchy-Schwarz Inequality gives $\langle \zeta_n, \zeta \rangle \leq \|\zeta_n\|_2 \|\zeta\|_2$, so passing to the limit inferior (which preserves termwise inequalities) yields $\|\zeta\|_2^2 = \lim_{n \rightarrow \infty} \langle \zeta_n, \zeta \rangle \leq \liminf \|\zeta_n\|_2 \cdot \|\zeta\|_2$, and division by $\|\zeta\|_2 > 0$ gives the claim.

Problem 8.23. Let $[a, b]$ be a closed, bounded interval. Suppose $\{f_n\} \rightharpoonup f$ in $C[a, b]$. Show that $\{f_n\}$ converges pointwise on $[a, b]$ to f .

Solution. Throughout, $C[a, b]$ is normed by the maximum norm,

$$\|g\|_{\max} = \max_{x \in [a, b]} |g(x)|,$$

which is defined and finite for every g in $C[a, b]$ by the Extreme Value Theorem.

Fix a point x_0 in $[a, b]$ and define the evaluation functional T_{x_0} on $C[a, b]$ by

$$T_{x_0}(g) = g(x_0) \quad \text{for all } g \in C[a, b].$$

Step 1: T_{x_0} is a bounded linear functional on $C[a, b]$. Linearity is immediate from the definition of the linear structure on $C[a, b]$: for g, h in $C[a, b]$ and real α, β , the function $\alpha g + \beta h$ is evaluated pointwise, so

$$T_{x_0}(\alpha g + \beta h) = (\alpha g + \beta h)(x_0) = \alpha g(x_0) + \beta h(x_0) = \alpha T_{x_0}(g) + \beta T_{x_0}(h).$$

For boundedness, observe that for every g in $C[a, b]$,

$$|T_{x_0}(g)| = |g(x_0)| \leq \max_{x \in [a, b]} |g(x)| = \|g\|_{\max},$$

since x_0 is one of the points over which the maximum is taken. Hence T_{x_0} is bounded and $\|T_{x_0}\|_* \leq 1$. In fact $\|T_{x_0}\|_* = 1$: the constant function $g \equiv 1$ belongs to $C[a, b]$, has $\|g\|_{\max} = 1$, and $T_{x_0}(g) = 1$. (This is the content of Problem 9 of this chapter.) Therefore T_{x_0} belongs to the dual space $(C[a, b])^*$. *Step 2: apply the definition of weak convergence.* By hypothesis $\{f_n\} \rightharpoonup f$ in $C[a, b]$, which by definition means

$$\lim_{n \rightarrow \infty} T(f_n) = T(f) \quad \text{for every } T \in (C[a, b])^*.$$

By Step 1 the functional T_{x_0} is a legitimate choice of T , and therefore

$$\lim_{n \rightarrow \infty} f_n(x_0) = \lim_{n \rightarrow \infty} T_{x_0}(f_n) = T_{x_0}(f) = f(x_0).$$

Since x_0 was an arbitrary point of $[a, b]$, the sequence $\{f_n\}$ converges to f pointwise on all of $[a, b]$.

Remark. The converse implication is false: pointwise convergence in $C[a, b]$ does not imply weak convergence. On $[0, 1]$, for each natural number n let f_n be the continuous function that vanishes outside the interval $(0, 1/n)$, is linear on $[0, 1/(2n)]$ and on $[1/(2n), 1/n]$, and takes the value n at $x = 1/(2n)$. For each x in $(0, 1]$ we have $f_n(x) = 0$ once $n > 1/x$, and $f_n(0) = 0$ for every n ; hence $\{f_n\}$ converges pointwise on $[0, 1]$ to $f \equiv 0$. But $T(g) = \int_0^1 g$ defines a bounded linear functional on $C[0, 1]$, since $|T(g)| \leq \|g\|_{\max}$, and $T(f_n)$ is the area of a triangle of base $1/n$ and height n , namely

$$T(f_n) = \frac{1}{2} \cdot \frac{1}{n} \cdot n = \frac{1}{2} \quad \text{for all } n,$$

which does not converge to $T(f) = 0$. So $\{f_n\}$ does not converge weakly to f in $C[0, 1]$.

Problem 8.24. Let $[a, b]$ be a closed, bounded interval. Suppose $\{f_n\} \rightharpoonup f$ in $L^\infty[a, b]$. Show that

$$\lim_{n \rightarrow \infty} \int_a^x f_n = \int_a^x f \quad \text{for all } x \in [a, b].$$

Solution. First note that all of the integrals in question are defined and finite. Indeed, $[a, b]$ has finite measure, so if h belongs to $L^\infty[a, b]$ then h is measurable and $|h| \leq \|h\|_\infty$ almost everywhere on $[a, b]$, whence

$$\int_a^b |h| \leq \|h\|_\infty \cdot (b - a) < \infty,$$

so h belongs to $L^1[a, b]$ and $\int_a^x h$ is a finite real number for each x in $[a, b]$.

Step 1: integration against an L^1 function is a bounded linear functional on L^∞ . Let g belong to $L^1[a, b]$ and define T_g on $L^\infty[a, b]$ by

$$T_g(h) = \int_a^b g \cdot h \quad \text{for all } h \in L^\infty[a, b].$$

This is well defined: $g \cdot h$ is measurable, and $|g \cdot h| \leq \|h\|_\infty \cdot |g|$ almost everywhere on $[a, b]$, so by the

monotonicity of integration $g \cdot h$ is integrable over $[a, b]$ and

$$|T_g(h)| \leq \int_a^b |g \cdot h| \leq \|g\|_1 \cdot \|h\|_\infty.$$

Linearity of T_g follows from the linearity of integration. Hence T_g is a bounded linear functional on $L^\infty[a, b]$ with $\|T_g\|_* \leq \|g\|_1$; that is, T_g belongs to $(L^\infty[a, b])^*$. (This is precisely the observation made in Section 8.1 preceding the problems: each g in $L^1[a, b]$ induces such a functional, although not every bounded linear functional on $L^\infty[a, b]$ arises this way. Note that this direction is Hölder's Inequality with $p = \infty$, $q = 1$, and it is all we need; we do not need any representation theorem for the dual of L^∞ .)

Step 2: choose the right g . Fix x in $[a, b]$ and let

$$g = \chi_{[a, x]},$$

the characteristic function of the interval $[a, x]$ (interpreted as $\chi_{\{a\}}$, hence as the zero function in L^1 , when $x = a$). Then g is measurable and

$$\int_a^b |g| = \int_a^b \chi_{[a, x]} = x - a < \infty,$$

so g belongs to $L^1[a, b]$. Moreover, for every h in $L^\infty[a, b]$,

$$T_g(h) = \int_a^b \chi_{[a, x]} \cdot h = \int_a^x h.$$

Step 3: apply weak convergence. By hypothesis $\{f_n\} \rightharpoonup f$ in $L^\infty[a, b]$, which by the definition of weak convergence in a normed linear space means that

$$\lim_{n \rightarrow \infty} T(f_n) = T(f) \quad \text{for every } T \in (L^\infty[a, b])^*.$$

By Steps 1 and 2, $T_g = T_{\chi_{[a, x]}}$ is such a functional. Therefore

$$\lim_{n \rightarrow \infty} \int_a^x f_n = \lim_{n \rightarrow \infty} T_g(f_n) = T_g(f) = \int_a^x f.$$

Since x was an arbitrary point of $[a, b]$, this holds for all x in $[a, b]$, as required.

Remark. The same argument, verbatim, shows more: $\lim_{n \rightarrow \infty} \int_A f_n = \int_A f$ for every measurable subset A of $[a, b]$, since χ_A belongs to $L^1[a, b]$. By linearity it then follows that $\lim_{n \rightarrow \infty} \int_a^b \varphi \cdot f_n = \int_a^b \varphi \cdot f$ for every simple function φ on $[a, b]$. One would like to pass from the simple functions to all of $L^1[a, b]$ by density, as in Proposition 9 of this chapter; that passage requires in addition that $\{\|f_n\|_\infty\}$ be bounded, and we do not assert that here, since the boundedness of a weakly convergent sequence in a general normed linear space is the Uniform Boundedness Principle, which is not available at this point in the book. What we have proved above uses only the single functional $T_{\chi_{[a, x]}}$ and needs no such input.

Problem 8.25. Let X be a normed linear space. Suppose that for each $f \in X$ there is bounded linear functional $T \in X^*$ for which $T(f) = \|f\|$ and $\|T\|_* = 1$.

- (i) Prove that if $\{f_n\}$ converges weakly in X to both f_1 and f_2 , then $f_1 = f_2$.
- (ii) Prove that if $\{f_n\} \rightharpoonup f$ in X , then $\|f\| \leq \liminf \|f_n\|$.

Solution. Recall the definition: $\{f_n\} \rightharpoonup f$ in X means that $\lim_{n \rightarrow \infty} T(f_n) = T(f)$ for every T in X^* . Recall also that for T in X^* ,

$$|T(h)| \leq \|T\|_* \cdot \|h\| \quad \text{for all } h \in X. \quad (\dagger)$$

(By the Hahn-Banach Theorem, proved in Section 2 of Chapter 14, the hypothesis imposed on X holds in every normed linear space; for $X = L^p(E)$ with $1 \leq p < \infty$ it is realized concretely by the conjugate

function, as the Remark at the end of Section 8.2 records in display (27). If $X = \{0\}$ both assertions are vacuous, so we assume $X \neq \{0\}$, which is what makes the normalization $\|T\|_* = 1$ possible.)

(i) *Uniqueness of the weak limit.* Suppose $\{f_n\} \rightharpoonup f_1$ and $\{f_n\} \rightharpoonup f_2$. Consider the vector

$$h = f_1 - f_2,$$

which belongs to X since X is a linear space. By hypothesis there is a bounded linear functional T in X^* for which

$$T(h) = \|h\| \quad \text{and} \quad \|T\|_* = 1.$$

Apply the definition of weak convergence twice to this single functional T . Since $\{f_n\} \rightharpoonup f_1$,

$$\lim_{n \rightarrow \infty} T(f_n) = T(f_1);$$

since $\{f_n\} \rightharpoonup f_2$,

$$\lim_{n \rightarrow \infty} T(f_n) = T(f_2).$$

A sequence of real numbers has at most one limit, so $T(f_1) = T(f_2)$. By the linearity of T ,

$$\|h\| = T(h) = T(f_1 - f_2) = T(f_1) - T(f_2) = 0.$$

A norm vanishes only at the zero vector, so $h = 0$, that is, $f_1 = f_2$. Thus a sequence in X can converge weakly to at most one member of X .

(ii) *Weak lower semicontinuity of the norm.* Suppose $\{f_n\} \rightharpoonup f$ in X . By hypothesis there is T in X^* with

$$T(f) = \|f\| \quad \text{and} \quad \|T\|_* = 1.$$

For each index n we infer from (†) that

$$T(f_n) \leq |T(f_n)| \leq \|T\|_* \cdot \|f_n\| = \|f_n\|.$$

Since $\{f_n\} \rightharpoonup f$, the sequence of real numbers $\{T(f_n)\}$ converges to $T(f)$; a convergent sequence of real numbers has limit inferior equal to its limit, so

$$\|f\| = T(f) = \lim_{n \rightarrow \infty} T(f_n) = \liminf_{n \rightarrow \infty} T(f_n).$$

Finally, the limit inferior is monotone with respect to the termwise inequality $T(f_n) \leq \|f_n\|$, and therefore

$$\|f\| = \liminf_{n \rightarrow \infty} T(f_n) \leq \liminf_{n \rightarrow \infty} \|f_n\|.$$

(If $\{\|f_n\|\}$ is unbounded the right-hand side may be $+\infty$, in which case the inequality is trivially true.) This is the desired inequality.

Remark. These are the abstract versions of two facts proved concretely for $L^p(E)$ in Section 8.2: the uniqueness of weak sequential limits in $L^p(E)$, established just after Proposition 6 using the conjugate function of $f_1 - f_2$, and the right-hand inequality of (17) in Theorem 7. Comparing the two arguments makes plain that the only property of the conjugate function used there is the pair of identities (27), $T(f) = \|f\|_p$ and $\|T\|_* = 1$.

Problem 8.26. (Uniform Boundedness Principle) Let E be a measurable set, $1 \leq p < \infty$, and q the conjugate of p . Suppose $\{f_n\}$ is a sequence in $L^p(E)$ such that for each $g \in L^q(E)$, the sequence $\{\int_E g \cdot f_n\}$ is bounded. Show that $\{f_n\}$ is bounded in $L^p(E)$.

Solution. Recall from Theorem 1 of Chapter 7 that for f in $L^p(E)$ with $f \neq 0$ the **conjugate function**

$$f^* = \|f\|_p^{1-p} \operatorname{sgn}(f) |f|^{p-1}$$

belongs to $L^q(E)$ and satisfies

$$\int_E f^* \cdot f = \|f\|_p \quad \text{and} \quad \|f^*\|_q = 1. \quad (1)$$

We also use Hoelder's Inequality: $|\int_E h \cdot f| \leq \|h\|_q \cdot \|f\|_p$ for $h \in L^q(E)$, $f \in L^p(E)$.

The proof is by contradiction, and is the gliding-hump construction used in the proof of Theorem 7; there weak convergence entered only through the fact that a convergent sequence of real numbers is bounded, and that is exactly what is assumed here.

Step 1: normalization. Assume, contrary to what is to be proved, that $\{\|f_n\|_p\}$ is unbounded. Observe first that then, for every $M \geq 0$ and every index N , there is an index $n > N$ with $\|f_n\|_p \geq M$: otherwise the terms beyond N would all be bounded by M , and, there being only finitely many terms with index at most N , the whole sequence of norms would be bounded. Hence we may choose inductively indices $n_1 < n_2 < \dots$ with $\|f_{n_k}\|_p \geq k \cdot 3^k$ for each k . For each k set

$$c_k = \frac{k \cdot 3^k}{\|f_{n_k}\|_p} \in (0, 1] \quad \text{and} \quad h_k = c_k \cdot f_{n_k}.$$

Then h_k belongs to $L^p(E)$ and $\|h_k\|_p = k \cdot 3^k$. Moreover the hypothesis passes to $\{h_k\}$: if g belongs to $L^q(E)$ and M is a bound for $\{|\int_E g \cdot f_n|\}$, then since $0 < c_k \leq 1$,

$$\left| \int_E g \cdot h_k \right| = c_k \left| \int_E g \cdot f_{n_k} \right| \leq M \quad \text{for all } k.$$

So it suffices to derive a contradiction from the existence of a sequence $\{h_n\}$ in $L^p(E)$ with

$$\|h_n\|_p = n \cdot 3^n \quad \text{for all } n, \quad (2)$$

for which $\{\int_E g \cdot h_n\}$ is bounded for every g in $L^q(E)$. (This normalization is Problem 18 of this chapter, carried out here directly.) Note each $h_n \neq 0$, so each conjugate function $(h_n)^*$ is defined.

Step 2: choice of signs. We select inductively real numbers $\{\epsilon_k\}$ with $\epsilon_k = \pm 1/3^k$. Put $\epsilon_1 = 1/3$. Suppose $\epsilon_1, \dots, \epsilon_{n-1}$ have been chosen, and set

$$A_n = \int_E \left[\sum_{k=1}^{n-1} \epsilon_k (h_k)^* \right] \cdot h_n$$

(with $A_1 = 0$). Define

$$\epsilon_n = \frac{1}{3^n} \quad \text{if } A_n \geq 0, \quad \epsilon_n = -\frac{1}{3^n} \quad \text{if } A_n < 0.$$

Each integral above is finite, since $\sum_{k=1}^{n-1} \epsilon_k (h_k)^*$ belongs to $L^q(E)$ and Hoelder's Inequality applies. With this choice, using (1) and (2),

$$\int_E \left[\sum_{k=1}^n \epsilon_k (h_k)^* \right] \cdot h_n = A_n + \epsilon_n \int_E (h_n)^* \cdot h_n = A_n + \epsilon_n \|h_n\|_p.$$

If $A_n \geq 0$ then $\epsilon_n > 0$ and the right-hand side is at least $\|h_n\|_p/3^n$; if $A_n < 0$ then $\epsilon_n < 0$ and the right-hand side is at most $-\|h_n\|_p/3^n$. In either case the two terms have the same sign, and therefore

$$\left| \int_E \left[\sum_{k=1}^n \epsilon_k (h_k)^* \right] \cdot h_n \right| \geq \frac{1}{3^n} \|h_n\|_p = \frac{n \cdot 3^n}{3^n} = n \quad \text{for all } n. \quad (3)$$

Also, by (1), $\|\epsilon_k (h_k)^*\|_q = |\epsilon_k| \cdot \|(h_k)^*\|_q = 1/3^k$ for every k .

Step 3: construction of g . Since $\sum_{k=1}^{\infty} \|\epsilon_k (h_k)^*\|_q = \sum_{k=1}^{\infty} 1/3^k = 1/2 < \infty$, the partial sums of the series $\sum_{k=1}^{\infty} \epsilon_k (h_k)^*$ form a Cauchy sequence in $L^q(E)$: for $m < n$,

$$\left\| \sum_{k=m+1}^n \epsilon_k (h_k)^* \right\|_q \leq \sum_{k=m+1}^n \frac{1}{3^k} \leq \frac{1}{2 \cdot 3^m}.$$

The space $L^q(E)$ is complete: for $1 \leq q < \infty$ this is the Riesz-Fischer Theorem of Chapter 7, while for $q = \infty$ (the case $p = 1$) it is Problem 33 of Chapter 7. Hence there is a function g in $L^q(E)$ with

$$g = \sum_{k=1}^{\infty} \epsilon_k(h_k)^*,$$

the series converging in $L^q(E)$, and for each n ,

$$\left\| g - \sum_{k=1}^n \epsilon_k(h_k)^* \right\|_q = \left\| \sum_{k=n+1}^{\infty} \epsilon_k(h_k)^* \right\|_q \leq \sum_{k=n+1}^{\infty} \frac{1}{3^k} = \frac{1}{2 \cdot 3^n}. \quad (4)$$

Step 4: the contradiction. Fix a natural number n . Write $g = \sum_{k=1}^n \epsilon_k(h_k)^* + r_n$, where $r_n = g - \sum_{k=1}^n \epsilon_k(h_k)^*$. By the triangle inequality, (3), Hoelder's Inequality, (4) and (2),

$$\begin{aligned} \left| \int_E g \cdot h_n \right| &\geq \left| \int_E \left[\sum_{k=1}^n \epsilon_k(h_k)^* \right] \cdot h_n \right| - \left| \int_E r_n \cdot h_n \right| \\ &\geq n - \|r_n\|_q \cdot \|h_n\|_p \\ &\geq n - \frac{1}{2 \cdot 3^n} \cdot n \cdot 3^n \\ &= n - \frac{n}{2} = \frac{n}{2}. \end{aligned}$$

Thus $\{\int_E g \cdot h_n\}$ is unbounded. But g belongs to $L^q(E)$, so by the hypothesis inherited in Step 1 this sequence must be bounded. This contradiction shows the assumption of Step 1 is false.

Therefore $\{\|f_n\|_p\}$ is bounded, that is, $\{f_n\}$ is a bounded sequence in $L^p(E)$.

Remark. Theorem 7 is the special case of this result in which $\{f_n\} \rightarrow f$ in $L^p(E)$: then for each g in $L^q(E)$ the sequence $\{\int_E g \cdot f_n\}$ converges, by Proposition 6, and a convergent sequence of real numbers is bounded. The name of this problem records that it is the L^p instance of the general Uniform Boundedness Principle for a family of bounded linear functionals on a Banach space, whose usual proof runs through the Baire Category Theorem; here the concrete structure of $L^q(E)$ supplies the sliding function g by hand.

Problem 8.27. Let $[a, b]$ be a nondegenerate closed, bounded interval. In the Banach space $C[a, b]$, normed by the maximum norm, find a bounded sequence that fails to have any strongly convergent subsequence.

Solution. Since $[a, b]$ is nondegenerate, $a < b$. Write $\ell = b - a > 0$. For each natural number n define

$$\alpha_n = a + \frac{\ell}{2^{n+1}}, \quad \beta_n = a + \frac{\ell}{2^n}, \quad m_n = \frac{\alpha_n + \beta_n}{2},$$

so that

$$a < \alpha_n < m_n < \beta_n \leq b \quad \text{and} \quad \beta_n - \alpha_n = \frac{\ell}{2^{n+1}} > 0.$$

The open intervals $(\alpha_n, \beta_n) = (a + \ell/2^{n+1}, a + \ell/2^n)$, $n = 1, 2, \dots$, are pairwise disjoint subintervals of $(a, b]$, since the sequence $\{a + \ell/2^n\}$ is strictly decreasing.

Define the “tent” functions

$$f_n(x) = \max \left\{ 0, 1 - \frac{2|x - m_n|}{\beta_n - \alpha_n} \right\} \quad \text{for } x \in [a, b].$$

The sequence lies in $C[a, b]$ and is bounded. Each f_n is continuous on $[a, b]$, being the maximum of the two continuous functions $x \mapsto 0$ and $x \mapsto 1 - 2|x - m_n|/(\beta_n - \alpha_n)$. Directly from the definition, $0 \leq f_n \leq 1$ on $[a, b]$, while $f_n(m_n) = 1$. Hence

$$\|f_n\|_{\max} = 1 \quad \text{for all } n,$$

so $\{f_n\}$ is a bounded sequence in $C[a, b]$.

Observe also that f_n vanishes outside (α_n, β_n) : if $|x - m_n| \geq (\beta_n - \alpha_n)/2$, that is, if $x \notin (\alpha_n, \beta_n)$, then $1 - 2|x - m_n|/(\beta_n - \alpha_n) \leq 0$ and so $f_n(x) = 0$.

No subsequence converges strongly. Let m and n be distinct natural numbers. Since the intervals (α_n, β_n) and (α_m, β_m) are disjoint and m_n belongs to (α_n, β_n) , the point m_n lies outside (α_m, β_m) , so $f_m(m_n) = 0$. Therefore

$$\|f_n - f_m\|_{\max} \geq |f_n(m_n) - f_m(m_n)| = |1 - 0| = 1.$$

Now suppose some subsequence $\{f_{n_k}\}$ converged strongly in $C[a, b]$, say to f . Then $\{f_{n_k}\}$ would be a Cauchy sequence in the maximum norm, since for all j, k ,

$$\|f_{n_j} - f_{n_k}\|_{\max} \leq \|f_{n_j} - f\|_{\max} + \|f - f_{n_k}\|_{\max} \rightarrow 0.$$

In particular there would be an index K with $\|f_{n_j} - f_{n_k}\|_{\max} < 1$ for all $j, k \geq K$. But the indices n_K and n_{K+1} are distinct, so by the estimate above $\|f_{n_K} - f_{n_{K+1}}\|_{\max} \geq 1$. This contradiction shows that no subsequence of $\{f_n\}$ converges strongly in $C[a, b]$.

Thus $\{f_n\}$ is a bounded sequence in $C[a, b]$ with no strongly convergent subsequence; the closed unit ball of $C[a, b]$ is not sequentially compact. This illustrates the failure, in the infinite dimensional space $C[a, b]$, of the Bolzano-Weierstrass property enjoyed by each Euclidean space $\mathbb{R}^n$, and it is the analogue for $C[a, b]$ of the Rademacher function example given at the start of Section 8.2 for $L^p[0, 1]$.

Remark. Other choices are available, for instance $f_n(x) = \sin\left(\frac{n\pi(x-a)}{b-a}\right)$, but for those one must still do work to bound $\|f_n - f_m\|_{\max}$ away from 0. The disjointly supported tents make the separation $\|f_n - f_m\|_{\max} \geq 1$ immediate, with no computation.

Problem 8.28. For $1 \leq p \leq \infty$, find a bounded sequence in ℓ^p that fails to have any strongly convergent subsequence.

Solution. For each natural number n let e_n be the sequence whose n th component is 1 and whose other components are 0, that is,

$$e_n = (\underbrace{0, \dots, 0}_{n-1}, 1, 0, 0, \dots), \quad e_n^k = \begin{cases} 1 & \text{if } k = n, \\ 0 & \text{if } k \neq n. \end{cases}$$

We claim that $\{e_n\}$ is a bounded sequence in ℓ^p , for every p with $1 \leq p \leq \infty$, that possesses no strongly convergent subsequence.

Membership and boundedness. If $1 \leq p < \infty$, then

$$\|e_n\|_p = \left(\sum_{k=1}^{\infty} |e_n^k|^p \right)^{1/p} = (1)^{1/p} = 1,$$

since exactly one term of the series is nonzero and it equals 1. If $p = \infty$, then

$$\|e_n\|_{\infty} = \sup_k |e_n^k| = 1.$$

In every case e_n belongs to ℓ^p and $\|e_n\|_p = 1$, so $\{e_n\}$ is a bounded sequence in ℓ^p .

Separation of the terms. Let $m \neq n$. The sequence $e_n - e_m$ has n th component 1, m th component -1 , and all other components 0. Hence, for $1 \leq p < \infty$,

$$\|e_n - e_m\|_p = (|1|^p + |-1|^p)^{1/p} = 2^{1/p} \geq 1,$$

and for $p = \infty$,

$$\|e_n - e_m\|_{\infty} = \max\{|1|, |-1|\} = 1.$$

So in every case

$$\|e_n - e_m\|_p \geq 1 \quad \text{whenever } m \neq n. \quad (*)$$

No subsequence converges strongly. Suppose, to the contrary, that some subsequence $\{e_{n_k}\}$ converged strongly in ℓ^p to some ζ in ℓ^p . A strongly convergent sequence in a normed linear space is Cauchy: given $\epsilon = 1/2$ there would be an index K such that $\|e_{n_k} - \zeta\|_p < 1/4$ for all $k \geq K$, and then for all $j, k \geq K$,

$$\|e_{n_j} - e_{n_k}\|_p \leq \|e_{n_j} - \zeta\|_p + \|\zeta - e_{n_k}\|_p < \frac{1}{4} + \frac{1}{4} = \frac{1}{2}.$$

Taking $j = K$ and $k = K + 1$, the indices n_K and n_{K+1} are distinct because the subsequence indices are strictly increasing, so $(*)$ gives $\|e_{n_K} - e_{n_{K+1}}\|_p \geq 1 > 1/2$. This contradiction shows that no subsequence of $\{e_n\}$ converges strongly in ℓ^p .

Therefore, for every p with $1 \leq p \leq \infty$, the sequence $\{e_n\}$ is bounded in ℓ^p but has no strongly convergent subsequence.

Remark. The contrast with weak convergence is instructive, and is the content of Problem 21 of this chapter: for $1 < p < \infty$ the same sequence $\{e_n\}$ does converge weakly to 0 in ℓ^p . Indeed, by the Riesz Representation Theorem for the dual of ℓ^p (Problem 7 of this chapter) every T in $(\ell^p)^*$ is of the form $T(\xi) = \sum_k \eta^k \xi^k$ for a single η in ℓ^q , and $T(e_n) = \eta^n \rightarrow 0$ because $\sum_k |\eta^k|^q < \infty$ forces the terms of a convergent series to tend to 0. In ℓ^1 , by contrast, $\{e_n\}$ does not converge weakly to 0: the dual of ℓ^1 contains the functional $T(\xi) = \sum_k \xi^k$ induced by the bounded sequence $\eta \equiv 1$ in ℓ^∞ , and $T(e_n) = 1$ for every n . So strong and weak convergence genuinely differ here, and no weakly convergent subsequence can be upgraded to a strongly convergent one.

8.5 Problems 8.29–8.35

Problem 8.29. Let E be a measurable set that contains a nondegenerate interval. Show that there is a bounded sequence in $L^1(E)$ that fails to have a weakly convergent subsequence. Exhibit a measurable set E for which every bounded sequence in $L^1(E)$ has a weakly convergent subsequence.

Solution. Throughout we use the definition of weak convergence in $L^1(E)$: a sequence $\{f_n\}$ in $L^1(E)$ converges weakly to f in $L^1(E)$ provided

$$\lim_{n \rightarrow \infty} \int_E f_n \cdot g = \int_E f \cdot g \quad \text{for all } g \in L^\infty(E),$$

since $L^\infty(E)$ is the conjugate space of $p = 1$. We will repeatedly use the following remark: if $h \in L^1(E)$, $A \subseteq E$ is measurable, and we set $g = \chi_A \cdot \text{sgn}(h)$, where $\text{sgn}(h)(x)$ equals 1 if $h(x) > 0$, equals -1 if $h(x) < 0$, and equals 0 otherwise, then g is measurable and $|g| \leq 1$, so $g \in L^\infty(E)$, and $\int_E h \cdot g = \int_A |h|$. Part 1: a bounded sequence with no weakly convergent subsequence.

Let $[a, b] \subseteq E$ with $a < b$. This is the construction of the Example of this section, transplanted to $[a, b]$. For each natural number n put

$$I_n = \left[a, a + \frac{b-a}{n} \right], \quad f_n = \frac{n}{b-a} \cdot \chi_{I_n} \quad \text{on } E,$$

that is, f_n vanishes on $E \setminus I_n$. Each f_n is measurable and $\|f_n\|_1 = \int_E |f_n| = \frac{n}{b-a} \cdot m(I_n) = 1$, so $\{f_n\}$ is a bounded sequence in $L^1(E)$.

Suppose, to get a contradiction, that a subsequence $\{f_{n_k}\}$ converges weakly in $L^1(E)$ to some $f \in L^1(E)$.

First, $f = 0$ almost everywhere on $A = E \setminus [a, b]$. Indeed, take $g = \chi_A \cdot \text{sgn}(f) \in L^\infty(E)$. Every f_{n_k} vanishes on A , so $\int_E f_{n_k} \cdot g = 0$ for every k , and therefore

$$\int_A |f| = \int_E f \cdot g = \lim_{k \rightarrow \infty} \int_E f_{n_k} \cdot g = 0.$$

By Proposition 9 of Chapter 4, a nonnegative integrable function with zero integral vanishes almost everywhere, so $f = 0$ a.e. on A .

Second, $f = 0$ almost everywhere on $[a, b]$. Fix a natural number $j \geq 2$ and set $J_j = [a + (b - a)/j, b]$ and $g_j = \chi_{J_j} \cdot \text{sgn}(f) \in L^\infty(E)$. If $n_k > j$ then $a + (b - a)/n_k < a + (b - a)/j$, so $I_{n_k} \cap J_j = \emptyset$ and hence $\int_E f_{n_k} \cdot g_j = 0$. Letting $k \rightarrow \infty$ gives $\int_{J_j} |f| = \int_E f \cdot g_j = 0$, so $f = 0$ a.e. on J_j . Since $(a, b] = \bigcup_{j \geq 2} J_j$ is a countable union and a countable union of sets of measure zero has measure zero, $f = 0$ a.e. on $(a, b]$, hence a.e. on $[a, b]$.

Therefore $f = 0$ almost everywhere on E , and so $\int_E f = 0$. On the other hand $\chi_E \in L^\infty(E)$, so weak convergence applied to $g = \chi_E$ gives

$$0 = \int_E f = \lim_{k \rightarrow \infty} \int_E f_{n_k} = \lim_{k \rightarrow \infty} 1 = 1,$$

a contradiction. Hence no subsequence of $\{f_n\}$ converges weakly in $L^1(E)$.

Part 2: a set E for which every bounded sequence in $L^1(E)$ has a weakly convergent subsequence.

Take E to be any set of measure zero, for instance $E = \emptyset$ or $E = \{0\}$. Then every measurable function on E vanishes almost everywhere on E , so $L^1(E)$ consists of the single element 0 and $\int_E f \cdot g = 0$ for all $f \in L^1(E)$, $g \in L^\infty(E)$. Consequently every sequence in $L^1(E)$ converges weakly to 0; in particular every bounded sequence has a weakly convergent subsequence.

This is in fact the only kind of example, and it is worth recording why. Suppose $m(E) > 0$. We produce a bounded sequence in $L^1(E)$ with no weakly convergent subsequence, which shows that Part 1 has nothing to do with E containing an interval. Choose a natural number N with $m(E \cap [-N, N]) > 0$ and set $E_0 = E \cap [-N, N]$, so $0 < m(E_0) < \infty$. Define $\varphi(t) = m(E_0 \cap [-N, t])$ for $t \in [-N, N]$. Then φ is nondecreasing and satisfies $|\varphi(t) - \varphi(s)| \leq |t - s|$ by the monotonicity and countable additivity of measure, so φ is continuous; moreover $\varphi(-N) = 0$ and $\varphi(N) = m(E_0) > 0$. Let $t_* = \sup\{t \in [-N, N] : \varphi(t) = 0\}$. By continuity $\varphi(t_*) = 0$, so $t_* < N$, and $\varphi(t) > 0$ for every $t > t_*$. For each natural number n let $\delta_n = \min\{1/n, (N - t_*)/2\} > 0$ and

$$B_n = E_0 \cap (t_*, t_* + \delta_n], \quad m(B_n) = \varphi(t_* + \delta_n) - \varphi(t_*) = \varphi(t_* + \delta_n) > 0.$$

The sequence $\{\delta_n\}$ is nonincreasing, so $\{B_n\}$ is a descending sequence of measurable subsets of E of positive finite measure, and $\bigcap_n B_n \subseteq \bigcap_n (t_*, t_* + \delta_n) = \emptyset$ because $\delta_n \rightarrow 0$. Define $f_n = \chi_{B_n}/m(B_n)$ on E ; then $\|f_n\|_1 = 1$.

Suppose a subsequence $\{f_{n_k}\}$ converged weakly to $f \in L^1(E)$. Fix a natural number m . For every k with $n_k \geq m$ we have $B_{n_k} \subseteq B_m$, so f_{n_k} vanishes on $E \setminus B_m$; testing against $g = \chi_{E \setminus B_m} \cdot \text{sgn}(f) \in L^\infty(E)$ gives $\int_{E \setminus B_m} |f| = 0$ and hence $f = 0$ a.e. on $E \setminus B_m$. Since $\bigcap_m B_m = \emptyset$ we have $E = \bigcup_{m=1}^\infty (E \setminus B_m)$, and a countable union of sets of measure zero has measure zero, so $f = 0$ a.e. on E . Testing against χ_E then yields $0 = \int_E f = \lim_k \int_E f_{n_k} = 1$, a contradiction. Thus for every E with $m(E) > 0$ there is a bounded sequence in $L^1(E)$ with no weakly convergent subsequence, and the sets E asked for in the second part of the problem are exactly the sets of measure zero.

Problem 8.30. Let X be a normed linear space, $\{T_n\}$ be a sequence in X^* , and T belong to X^* . Show that $\{T_n\} \rightarrow T$ with respect to the $\|\cdot\|_*$ norm if and only if

$$\lim_{n \rightarrow \infty} T_n(f) = T(f) \quad \text{uniformly on } \{f \in X \mid \|f\| \leq 1\}.$$

Solution. Write $B = \{f \in X \mid \|f\| \leq 1\}$ for the closed unit ball of X . Recall that for a bounded linear functional S on X , the norm $\|S\|_*$ is defined as the infimum of the numbers $M \geq 0$ for which

$$|S(f)| \leq M \cdot \|f\| \quad \text{for all } f \in X,$$

and that this inequality holds for $M = \|S\|_*$ itself.

Lemma. For every $S \in X^*$,

$$\|S\|_* = \sup\{|S(f)| : f \in B\}.$$

Indeed, let s denote the supremum on the right; it is finite because $|S(f)| \leq \|S\|_* \cdot \|f\| \leq \|S\|_*$ for $f \in B$, and this same inequality shows $s \leq \|S\|_*$. Conversely, $|S(f)| \leq s \cdot \|f\|$ for every $f \in X$: this

is clear for $f = 0$ since $S(0) = 0$ by linearity, and if $f \neq 0$ then $f/\|f\|$ belongs to B , so that by the homogeneity of S ,

$$\frac{|S(f)|}{\|f\|} = \left| S\left(\frac{f}{\|f\|}\right) \right| \leq s.$$

Thus s is one of the numbers M occurring in the definition of $\|S\|_*$, and therefore $\|S\|_* \leq s$. Hence $\|S\|_* = s$, proving the lemma.

Since X^* is a linear space, $T_n - T$ belongs to X^* for every n , and the lemma applied to $S = T_n - T$ gives

$$\|T_n - T\|_* = \sup_{f \in B} |T_n(f) - T(f)|.$$

Call this identity the norm formula.

Suppose first that $\{T_n\} \rightarrow T$ with respect to $\|\cdot\|_*$. Let $\epsilon > 0$. Choose an index N for which $\|T_n - T\|_* < \epsilon$ whenever $n \geq N$. Then for every $n \geq N$ and every $f \in B$,

$$|T_n(f) - T(f)| \leq \|T_n - T\|_* \cdot \|f\| \leq \|T_n - T\|_* < \epsilon.$$

The index N was chosen independently of $f \in B$, so $\{T_n(f)\} \rightarrow T(f)$ uniformly on B .

Conversely, suppose $\{T_n(f)\} \rightarrow T(f)$ uniformly on B . Let $\epsilon > 0$. Choose an index N for which

$$|T_n(f) - T(f)| < \epsilon/2 \quad \text{for all } n \geq N \text{ and all } f \in B.$$

Taking the supremum over $f \in B$ and using the norm formula, for $n \geq N$ we get $\|T_n - T\|_* \leq \epsilon/2 < \epsilon$. Since $\epsilon > 0$ was arbitrary, $\lim_{n \rightarrow \infty} \|T_n - T\|_* = 0$, that is, $\{T_n\} \rightarrow T$ in the $\|\cdot\|_*$ norm.

Thus convergence in the dual norm is precisely uniform convergence of the values on the closed unit ball of X .

Problem 8.31. Is the sequence defined in the last example of this section uniformly integrable?

Solution. The sequence in question is the one from the Example preceding the definition of weak sequential compactness: for $I = [0, 1]$ and each natural number n ,

$$I_n = [0, 1/n], \quad f_n = n \cdot \chi_{I_n}.$$

The answer is no: $\{f_n\}$ is not uniformly integrable over $[0, 1]$.

Recall the definition from Chapter 4: a family $\mathcal{F}$ of measurable functions on E is uniformly integrable over E provided for each $\epsilon > 0$ there is a $\delta > 0$ such that for each $f \in \mathcal{F}$, if $A \subseteq E$ is measurable and $m(A) < \delta$, then $\int_A |f| < \epsilon$.

Take the challenge $\epsilon = 1/2$ and let $\delta > 0$ be arbitrary. Choose a natural number n with $1/n < \delta$ and set $A = I_n = [0, 1/n]$. Then A is a measurable subset of $[0, 1]$ with $m(A) = 1/n < \delta$, while

$$\int_A |f_n| = \int_0^{1/n} n \, dx = n \cdot \frac{1}{n} = 1 > \frac{1}{2}.$$

Thus no $\delta > 0$ responds to the $\epsilon = 1/2$ challenge, and $\{f_n\}$ fails to be uniformly integrable. The point is that the whole of the mass of f_n , which has total integral 1 for every n , sits on a set of measure $1/n$; uniform integrability forbids exactly this concentration of mass on sets of small measure.

Two independent confirmations are worth recording.

First, $\{f_n\} \rightarrow 0$ pointwise on $(0, 1]$, hence a.e. on $[0, 1]$: given $x \in (0, 1]$, we have $f_n(x) = 0$ as soon as $n > 1/x$. But

$$\lim_{n \rightarrow \infty} \int_0^1 f_n = 1 \neq 0 = \int_0^1 0.$$

Since $[0, 1]$ has finite measure, were $\{f_n\}$ uniformly integrable the Vitali Convergence Theorem of Chapter 4 would force these two limits to agree. Hence $\{f_n\}$ is not uniformly integrable.

Second, the answer is exactly what is required for consistency with the Remark that closes this section: by the theorem of Dunford and Pettis quoted there, a bounded sequence in $L^1(E)$ that is uniformly

integrable possesses a weakly convergent subsequence. The Example shows that this bounded sequence in $L^1[0, 1]$ has no weakly convergent subsequence, so it cannot be uniformly integrable.

Problem 8.32. For $p = 1$, at what point does the proof of Theorem 14 fail?

Solution. Set $p = 1$, so that the conjugate exponent is $q = \infty$ and the space X appearing in the proof is $X = L^\infty(E)$. Run through the proof of Theorem 14 with these values, taking E to be a set of positive measure (for a null set there is nothing to prove, and indeed by Problem 29 the theorem is true for $p = 1$ exactly on the null sets).

The conclusions of the opening steps survive, though one citation must be repaired. Given a bounded sequence $\{f_n\}$ in $L^1(E)$, the functionals

$$T_n(g) = \int_E f_n \cdot g \quad \text{for } g \in X = L^\infty(E)$$

are still well defined, linear, and bounded, with $\|T_n\|_* = \|f_n\|_1$. The proof obtains this from Proposition 2 with p and q interchanged, and strictly speaking that invocation is already illegitimate: Proposition 2 assumes that the exponent of the space on which the functional is defined is finite, and here that exponent is $q = \infty$. The conclusion is nevertheless true, by a direct argument that does not use Proposition 2. Hölder's Inequality gives $|\int_E f_n \cdot g| \leq \|f_n\|_1 \cdot \|g\|_\infty$, so T_n is bounded with $\|T_n\|_* \leq \|f_n\|_1$; and $g = \text{sgn}(f_n)$ is measurable with $\|g\|_\infty \leq 1$ and $T_n(g) = \int_E |f_n| = \|f_n\|_1$, so $\|T_n\|_* = \|f_n\|_1$. Hence $\{T_n\}$ is still a bounded sequence in X^* . This first gap is therefore only apparent; it is a defect of citation, not of substance.

The first substantive failure occurs at the very next sentence, the invocation of separability. The proof asserts that $X = L^q(E)$ is separable, citing Theorem 11 of Chapter 7 (printed in the proof as Theorem 11 of Chapter 6) and explicitly restricting to $1 < q < \infty$ at that step. That theorem guarantees the separability of $L^q(E)$ only for $1 \leq q < \infty$, and for $q = \infty$ the hypothesis is simply false. This is recorded in the Example of Section 7.4, which shows that $L^\infty[a, b]$ is not separable; we recall the argument. If $[a, b] \subseteq E$ is a nondegenerate interval, then

$$\|\chi_{[a, x_1]} - \chi_{[a, x_2]}\|_\infty = 1 \quad \text{whenever } a \leq x_1 < x_2 \leq b,$$

so $\{\chi_{[a, x]}\}_{x \in (a, b]}$ is an uncountable family of functions in $L^\infty(E)$ any two of which are at distance 1; a countable set cannot be dense, since the balls of radius $1/2$ about the members of such a family are disjoint and each would have to contain a point of the dense set. Hence $L^\infty(E)$ is not separable and Helley's Theorem, whose hypothesis is precisely the separability of X , does not apply. The failure is genuine at the level of Helley's proof as well: that proof selects, by a diagonal argument, a subsequence for which $\{T_{n_k}(f_j)\}$ converges at each member of a countable dense set $\{f_j\}$, and then uses the density of $\{f_j\}$ together with the uniform bound to conclude that $\{T_{n_k}(f)\}$ is Cauchy for every $f \in X$. With no countable dense set available, the diagonal argument controls the subsequence at only countably many elements of $L^\infty(E)$ and yields no information at the remaining ones.

There is a second, independent failure further on. Even if one were handed a subsequence $\{T_{n_k}\}$ and a $T \in X^*$ with $\lim_k T_{n_k}(g) = T(g)$ for all $g \in L^\infty(E)$, the proof next invokes the Riesz Representation Theorem with p and q interchanged in order to produce $f \in L^1(E)$ with

$$T(g) = \int_E f \cdot g \quad \text{for all } g \in L^\infty(E).$$

This is a representation theorem for the dual of $L^\infty(E)$, and the Riesz Representation Theorem of Section 8.1 is established only for the dual of $L^r(E)$ with $1 \leq r < \infty$; it is not available for $r = \infty$. It is moreover false, as the Remark closing Section 8.1 already warns: there are bounded linear functionals on $L^\infty[a, b]$ that are not given by integration against a function in $L^1[a, b]$, the dual of L^∞ being described instead by the theorem of Kantorovitch proved in Section 3 of Chapter 19. Here is the argument. Granting the Hahn-Banach Theorem of Chapter 14, extend the functional $g \mapsto g(0)$, defined and of norm 1 on the subspace $C[0, 1]$ of $L^\infty[0, 1]$, to a bounded linear functional Λ on all of $L^\infty[0, 1]$. If

$\Lambda(g) = \int_0^1 f \cdot g$ for some $f \in L^1[0, 1]$, choose continuous g_n with $0 \leq g_n \leq 1$, $g_n(0) = 1$, and $g_n = 0$ off $[0, 1/n]$; then $\Lambda(g_n) = 1$ for all n , while $|\int_0^1 f g_n| \leq \int_0^{1/n} |f| \rightarrow 0$ by the continuity of integration. This contradiction shows that no such f exists.

Finally, neither of these two failures can be repaired, because the conclusion itself is false for $p = 1$: the Example of this section exhibits a bounded sequence in $L^1[0, 1]$ with no weakly convergent subsequence. In summary: the proof breaks down at the appeal to the separability of $X = L^q(E)$, and again at the appeal to the Riesz Representation Theorem for the dual of $L^q(E)$, both of which require $q < \infty$, that is, $p > 1$.

Problem 8.33. Show that in ℓ^p , $1 \leq p < \infty$, every bounded sequence in ℓ^p has a weakly convergent subsequence.

Solution. We prove the assertion for $1 < p < \infty$, which is the range in which it is true, and then show by an explicit counterexample that the case $p = 1$ must be excluded from the statement.

Weak convergence in a normed linear space X means, by the definition of Section 8.2, that $\lim_n T(x^{(n)}) = T(x)$ for every $T \in X^*$. So before anything else we must know what the bounded linear functionals on ℓ^p are. We prove this from scratch, since the Riesz Representation Theorem of Section 8.1 is stated for $L^p(E)$ with E a measurable set of real numbers and is not directly applicable to the sequence spaces.

Duality Lemma. Let $1 \leq p < \infty$ and let q be the conjugate of p . For each $g = \{g_j\} \in \ell^q$ the formula

$$T_g(x) = \sum_{j=1}^{\infty} x_j \cdot g_j \quad \text{for } x = \{x_j\} \in \ell^p$$

defines a bounded linear functional on ℓ^p with $\|T_g\|_* = \|g\|_q$, and every $T \in (\ell^p)^*$ is of this form.

Proof. Hölder's Inequality for series gives $\sum_j |x_j g_j| \leq \|x\|_p \cdot \|g\|_q$, so the series defining $T_g(x)$ converges absolutely, T_g is properly defined, it is linear by the linearity of summation, and $\|T_g\|_* \leq \|g\|_q$.

Conversely, let $T \in (\ell^p)^*$ and put $g_j = T(e_j)$, where e_j is the sequence with j -th term 1 and all other terms 0. We first show $g = \{g_j\} \in \ell^q$ with $\|g\|_q \leq \|T\|_*$. Fix a natural number N and set $S_N = \sum_{j \leq N} |g_j|^q$; we may assume $S_N > 0$. Suppose first $p > 1$, so $1 < q < \infty$. Define x by $x_j = |g_j|^{q-1} \operatorname{sgn}(g_j)$ for $j \leq N$ and $x_j = 0$ for $j > N$. Then x has finite support, so $x = \sum_{j \leq N} x_j e_j$ and, by the linearity of T , $T(x) = \sum_{j \leq N} x_j g_j = S_N$. Since $(q-1)p = q$, we have $\|x\|_p = S_N^{1/p}$, and therefore

$$S_N = T(x) \leq \|T\|_* \cdot \|x\|_p = \|T\|_* \cdot S_N^{1/p},$$

whence $S_N^{1/q} = S_N^{1-1/p} \leq \|T\|_*$. If instead $p = 1$, so $q = \infty$, then for each j the choice $x = \operatorname{sgn}(g_j) e_j$ has $\|x\|_1 = 1$ and $T(x) = |g_j|$, so $|g_j| \leq \|T\|_*$. In either case $\|g\|_q \leq \|T\|_*$, so $g \in \ell^q$ and T_g is defined. Finally, T and T_g are bounded linear functionals on ℓ^p that agree on every finitely supported sequence, by the linearity of both. The finitely supported sequences are dense in ℓ^p : for $x \in \ell^p$, the truncation y_N agreeing with x in the first N places and vanishing thereafter satisfies $\|x - y_N\|_p^p = \sum_{j > N} |x_j|^p$, which tends to 0 as $N \rightarrow \infty$ because $p < \infty$ and $\sum_j |x_j|^p$ converges. Two bounded linear functionals that agree on a dense subset of X are equal, since each is continuous. Hence $T = T_g$, and taking $x = g^* = \|g\|_q^{1-q} \operatorname{sgn}(g) |g|^{q-1}$ in the case $q < \infty$, respectively $x = \operatorname{sgn}(g_j) e_j$ with $|g_j|$ near $\|g\|_\infty$ in the case $q = \infty$, gives the reverse inequality $\|T_g\|_* \geq \|g\|_q$. This proves the lemma.

Consequently, if q is the conjugate of p , then $\{x^{(n)}\} \rightarrow x$ weakly in ℓ^p if and only if

$$\lim_{n \rightarrow \infty} \sum_{j=1}^{\infty} x_j^{(n)} \cdot g_j = \sum_{j=1}^{\infty} x_j \cdot g_j \quad \text{for every } g = \{g_j\} \in \ell^q.$$

The case $1 < p < \infty$. Let $\{x^{(n)}\}$ be a sequence in ℓ^p with $\|x^{(n)}\|_p \leq M$ for all n , where $M \geq 0$.

Step 1: a coordinatewise convergent subsequence. For every index j and every n ,

$$|x_j^{(n)}| \leq \left(\sum_{i=1}^{\infty} |x_i^{(n)}|^p \right)^{1/p} = \|x^{(n)}\|_p \leq M,$$

so each coordinate sequence is a bounded sequence of real numbers. We now run the diagonal argument used in the proof of Helley's Theorem. Since $\{x_1^{(n)}\}_n$ is bounded, the Bolzano-Weierstrass Theorem provides a strictly increasing sequence of natural numbers $\{s(1, n)\}$ and a number a_1 with $\lim_n x_1^{(s(1, n))} = a_1$. Since $\{x_2^{(s(1, n))}\}_n$ is bounded, there is a subsequence $\{s(2, n)\}$ of $\{s(1, n)\}$ and a number a_2 with $\lim_n x_2^{(s(2, n))} = a_2$. Continuing inductively we obtain, for each j , a strictly increasing sequence $\{s(j, n)\}_n$ that is a subsequence of $\{s(j-1, n)\}_n$, and a number a_j , with $\lim_n x_j^{(s(j, n))} = a_j$. Set $n_k = s(k, k)$. Then $\{n_k\}$ is strictly increasing, and for each fixed j the tail $\{n_k\}_{k \geq j}$ is a subsequence of $\{s(j, n)\}_n$; therefore

$$\lim_{k \rightarrow \infty} x_j^{(n_k)} = a_j \quad \text{for every index } j.$$

Step 2: the limit belongs to ℓ^p . Fix a natural number N . Since the sum is finite, we may pass to the limit termwise:

$$\sum_{j=1}^N |a_j|^p = \lim_{k \rightarrow \infty} \sum_{j=1}^N |x_j^{(n_k)}|^p \leq \limsup_{k \rightarrow \infty} \|x^{(n_k)}\|_p^p \leq M^p.$$

The partial sums of the nonnegative series $\sum_j |a_j|^p$ are thus bounded by M^p , so $a = \{a_j\}$ belongs to ℓ^p and $\|a\|_p \leq M$. By Minkowski's Inequality, $\|x^{(n_k)} - a\|_p \leq 2M$ for every k .

Step 3: $\{x^{(n_k)}\}$ converges weakly to a . Let $g \in \ell^q$ and let $\epsilon > 0$. Since $\sum_j |g_j|^q < \infty$, its tails tend to zero, so we may choose N with

$$\left(\sum_{j>N} |g_j|^q \right)^{1/q} < \frac{\epsilon}{2(2M+1)}.$$

By Hölder's Inequality applied to the tail,

$$\left| \sum_{j>N} (x_j^{(n_k)} - a_j) g_j \right| \leq \|x^{(n_k)} - a\|_p \cdot \left(\sum_{j>N} |g_j|^q \right)^{1/q} \leq 2M \cdot \frac{\epsilon}{2(2M+1)} < \frac{\epsilon}{2}$$

for every k . On the other hand $\sum_{j \leq N} (x_j^{(n_k)} - a_j) g_j$ is a sum of N terms, each of which tends to 0 as $k \rightarrow \infty$ by Step 1; choose K so that this finite sum has absolute value less than $\epsilon/2$ for all $k \geq K$. Then for $k \geq K$,

$$\left| \sum_{j=1}^{\infty} x_j^{(n_k)} g_j - \sum_{j=1}^{\infty} a_j g_j \right| \leq \left| \sum_{j \leq N} (x_j^{(n_k)} - a_j) g_j \right| + \left| \sum_{j>N} (x_j^{(n_k)} - a_j) g_j \right| < \epsilon.$$

Since $\epsilon > 0$ and $g \in \ell^q$ were arbitrary, $\{x^{(n_k)}\}$ converges weakly in ℓ^p to $a \in \ell^p$. This proves the assertion for $1 < p < \infty$.

The case $p = 1$. Here the argument above breaks down at Step 3: the conjugate exponent is $q = \infty$, and for $g \in \ell^\infty$ the quantity $\sup_{j>N} |g_j|$ need not be small, so the tail cannot be controlled. Steps 1 and 2 survive verbatim and produce a subsequence converging coordinatewise to some $a \in \ell^1$, but this subsequence need not converge weakly, and no other subsequence need do so either. Indeed, the assertion is false for $p = 1$.

To see this, let e_n denote the sequence whose n -th term is 1 and whose other terms are 0. Then $\|e_n\|_1 = 1$, so $\{e_n\}$ is a bounded sequence in ℓ^1 . Let $\{e_{n_k}\}$ be any subsequence. Define $g = \{g_j\}$ by

$$g_j = \begin{cases} (-1)^k & \text{if } j = n_k \text{ for some } k, \\ 0 & \text{otherwise.} \end{cases}$$

This is well defined because $\{n_k\}$ is strictly increasing, and $\|g\|_\infty = 1$, so $g \in \ell^\infty$, the conjugate space of ℓ^1 . But

$$\sum_{j=1}^{\infty} (e_{n_k})_j \cdot g_j = g_{n_k} = (-1)^k,$$

and this sequence of real numbers does not converge. Hence $\{e_{n_k}\}$ does not converge weakly in ℓ^1 to any element of ℓ^1 . Since the subsequence was arbitrary, the bounded sequence $\{e_n\}$ in ℓ^1 has no weakly convergent subsequence, and the hypothesis $1 \leq p < \infty$ in the statement of the problem must be replaced by $1 < p < \infty$. This is exactly parallel to Theorem 14 and to the Example of this section, where the same restriction on p appears for the same reason: the conjugate space must be separable, and ℓ^∞ is not.

Problem 8.34. Let $\{f_n\}$ be a sequence of functions on $[0, 1]$, each of which is of bounded variation and for which $\{TV(f_n)\}$ is bounded. Show that there is a subsequence $\{f_{n_k}\}$ with the property that for each continuous function g on $[0, 1]$, the sequence of integrals $\left\{\int_0^1 g(x) df_{n_k}(x)\right\}$ is Cauchy.

Solution. (The printed statement carries a stray dx after the Stieltjes differential $df_{n_k}(x)$; the integral intended is the Riemann-Stieltjes integral $\int_0^1 g(x) df_{n_k}(x)$, and that is what we treat.)

Let $M \geq 0$ be such that $TV(f_n) \leq M$ for all n ; such an M exists because $\{TV(f_n)\}$ is assumed to be a bounded sequence of numbers, and each $TV(f_n)$ is finite since f_n is of bounded variation.

Take $X = C[0, 1]$, the linear space of continuous real-valued functions on $[0, 1]$ normed by the maximum norm $\|g\|_{\max} = \max_{0 \leq x \leq 1} |g(x)|$.

Step 1: the functionals. For each natural number n define

$$T_n(g) = \int_0^1 g(x) df_n(x) \quad \text{for } g \in C[0, 1],$$

the integral being taken in the sense of Riemann-Stieltjes. By the second example of Section 8.1, since f_n is of bounded variation on $[0, 1]$ this integral is properly defined for every continuous g , the functional T_n is linear, and

$$|T_n(g)| \leq TV(f_n) \cdot \|g\|_{\max} \leq M \cdot \|g\|_{\max} \quad \text{for all } g \in C[0, 1].$$

The estimate is immediate from the definition of the Riemann-Stieltjes integral as a limit of sums: for any partition $0 = x_0 < x_1 < \cdots < x_m = 1$ and any choice of points $\xi_i \in [x_{i-1}, x_i]$,

$$\left| \sum_{i=1}^m g(\xi_i) [f_n(x_i) - f_n(x_{i-1})] \right| \leq \|g\|_{\max} \sum_{i=1}^m |f_n(x_i) - f_n(x_{i-1})| \leq \|g\|_{\max} \cdot TV(f_n).$$

Hence each T_n belongs to X^* and $\{T_n\}$ satisfies the boundedness hypothesis (28) of Helley's Theorem with the single constant M .

Step 2: $C[0, 1]$ is separable. Let $\mathcal{P}$ be the collection of polynomials with rational coefficients, restricted to $[0, 1]$. Since for each degree d the set of $(d+1)$ -tuples of rationals is countable and a countable union of countable sets is countable, $\mathcal{P}$ is countable. Let $g \in C[0, 1]$ and $\epsilon > 0$. By the Weierstrass Approximation Theorem there is a polynomial $p(x) = \sum_{j=0}^d c_j x^j$ with $\|g - p\|_{\max} < \epsilon/2$. Choose rationals r_j with $|c_j - r_j| < \epsilon/(2(d+1))$ and set $\tilde{p}(x) = \sum_{j=0}^d r_j x^j$, a member of $\mathcal{P}$. Since $0 \leq x^j \leq 1$ on $[0, 1]$,

$$\|p - \tilde{p}\|_{\max} \leq \sum_{j=0}^d |c_j - r_j| < \frac{\epsilon}{2},$$

and therefore $\|g - \tilde{p}\|_{\max} < \epsilon$. Thus $\mathcal{P}$ is a countable dense subset of $C[0, 1]$, so $C[0, 1]$ is a separable normed linear space.

Step 3: apply Helley's Theorem. The space $X = C[0, 1]$ is a separable normed linear space and $\{T_n\}$ is a sequence in X^* with $|T_n(g)| \leq M \cdot \|g\|_{\max}$ for all $g \in X$ and all n . By Helley's Theorem there is a subsequence $\{T_{n_k}\}$ of $\{T_n\}$ and a $T \in X^*$ for which

$$\lim_{k \rightarrow \infty} T_{n_k}(g) = T(g) \quad \text{for all } g \in C[0, 1].$$

Step 4: conclusion. Fix a continuous function g on $[0, 1]$. By Step 3 the sequence of real numbers

$$\left\{ \int_0^1 g(x) df_{n_k}(x) \right\}_{k=1}^{\infty} = \{T_{n_k}(g)\}_{k=1}^{\infty}$$

converges, and every convergent sequence of real numbers is Cauchy. Hence this sequence of integrals is Cauchy, and the single subsequence $\{f_{n_k}\}$ furnished by Helley's Theorem works simultaneously for every continuous g , as required.

We remark that more is true. The limit functional T is a bounded linear functional on $C[0, 1]$, and according to the Remark closing Section 8.1, the theorem of Riesz proved in Chapter 21 tells us that every bounded linear functional on $C[a, b]$ is given by Lebesgue-Stieltjes integration against a function of bounded variation. So there is in fact a function f of bounded variation on $[0, 1]$ with $\lim_k \int_0^1 g(x) df_{n_k}(x) = \int_0^1 g(x) df(x)$ for every continuous g on $[0, 1]$; this is the classical Helley selection principle. The exercise as posed asks only for the Cauchy property, which does not need this identification of the limit.

Problem 8.35. Let X be a normed linear space and $\{T_n\}$ a sequence in X^* for which there is an $M \geq 0$ such that $\|T_n\|_* \leq M$ for all n . Let $\mathcal{S}$ be a dense subset of X such that $\{T_n(g)\}$ is Cauchy for all $g \in \mathcal{S}$.

- (i) Show that $\{T_n(g)\}$ is Cauchy for all $g \in X$.
- (ii) Define $T(g) = \lim_{n \rightarrow \infty} T_n(g)$ for all $g \in X$. Show that T is linear. Then show that T is bounded.

Solution. This is the final step of the proof of Helley's Theorem, isolated and proved in general.

Throughout we use two standing facts. First, since $\|T_n\|_*$ is the norm of the bounded linear functional T_n , the defining inequality holds with $M_n = \|T_n\|_*$, so

$$|T_n(h)| \leq \|T_n\|_* \cdot \|h\| \leq M \cdot \|h\| \quad \text{for all } h \in X \text{ and all } n.$$

Second, $\mathcal{S}$ being dense in X means that for each $g \in X$ and each $\eta > 0$ there is an $h \in \mathcal{S}$ with $\|g - h\| < \eta$.

Part (i). Let $g \in X$ and let $\epsilon > 0$. Choose $h \in \mathcal{S}$ with

$$\|g - h\| < \frac{\epsilon}{3(M+1)},$$

which is possible by the density of $\mathcal{S}$; note $M+1 > 0$, so the right-hand side is a legitimate positive number even if $M = 0$. Since $\{T_n(h)\}$ is Cauchy, there is an index N for which

$$|T_n(h) - T_m(h)| < \frac{\epsilon}{3} \quad \text{for all } n, m \geq N.$$

Let $n, m \geq N$. Using the linearity of T_n and T_m and the estimates above,

$$\begin{aligned} |T_n(g) - T_m(g)| &\leq |T_n(g) - T_n(h)| + |T_n(h) - T_m(h)| + |T_m(h) - T_m(g)| \\ &= |T_n(g - h)| + |T_n(h) - T_m(h)| + |T_m(h - g)| \\ &\leq M \cdot \|g - h\| + \frac{\epsilon}{3} + M \cdot \|g - h\| \\ &< \frac{2M}{3(M+1)} \cdot \epsilon + \frac{\epsilon}{3} \\ &\leq \frac{2\epsilon}{3} + \frac{\epsilon}{3} = \epsilon, \end{aligned}$$

where in the last line we used $M/(M+1) \leq 1$. Since $\epsilon > 0$ was arbitrary, $\{T_n(g)\}$ is a Cauchy sequence of real numbers, for every $g \in X$.

Part (ii). The real numbers are complete, so by part (i) the limit

$$T(g) = \lim_{n \rightarrow \infty} T_n(g)$$

exists as a real number for every $g \in X$; thus T is a properly defined real-valued function on X . T is linear. Let $g, h \in X$ and let α, β be real numbers. Each T_n is linear, so for every n ,

$$T_n(\alpha g + \beta h) = \alpha T_n(g) + \beta T_n(h).$$

The sequences $\{T_n(g)\}$ and $\{T_n(h)\}$ converge to $T(g)$ and $T(h)$ respectively, so by the linearity of limits of convergent sequences of real numbers, the right-hand side converges to $\alpha T(g) + \beta T(h)$. The left-hand side converges to $T(\alpha g + \beta h)$, again by part (i) applied to the vector $\alpha g + \beta h \in X$. Limits of convergent real sequences are unique, and therefore

$$T(\alpha g + \beta h) = \alpha T(g) + \beta T(h).$$

Hence T is linear.

T is bounded. Let $g \in X$. For every n we have $|T_n(g)| \leq M \cdot \|g\|$. Since $\{T_n(g)\} \rightarrow T(g)$ and the absolute value function is continuous, $\{|T_n(g)|\} \rightarrow |T(g)|$, and a limit of a convergent sequence of real numbers each of which is at most $M \cdot \|g\|$ is itself at most $M \cdot \|g\|$. Therefore

$$|T(g)| = \lim_{n \rightarrow \infty} |T_n(g)| \leq M \cdot \|g\| \quad \text{for all } g \in X.$$

Thus T is a bounded linear functional on X , that is, T belongs to X^* , and moreover $\|T\|_* \leq M$ since $\|T\|_*$ is the infimum of the constants for which such an inequality holds.

8.6 Problems 8.36–8.42

Problem 8.36. Show that the conclusion of Helley's Theorem is not true for $X = L^\infty[0, 1]$.

Solution. Helley's Theorem asserts that if X is a **separable** normed linear space and $\{T_n\}$ is a sequence in X^* for which $|T_n(f)| \leq M \cdot \|f\|$ for all f in X and all n , then some subsequence $\{T_{n_k}\}$ converges pointwise on X to some T in X^* . We exhibit a uniformly bounded sequence of bounded linear functionals on $X = L^\infty[0, 1]$ no subsequence of which converges pointwise on all of X . (Separability is exactly what fails here: $L^\infty[0, 1]$ is not separable.)

For each natural number n define $T_n: L^\infty[0, 1] \rightarrow \mathbb{R}$ by

$$T_n(f) = n \int_0^{1/n} f.$$

Each T_n is linear by the linearity of integration, and since $|f| \leq \|f\|_\infty$ a.e. on $[0, 1]$,

$$|T_n(f)| \leq n \int_0^{1/n} |f| \leq n \cdot \frac{1}{n} \cdot \|f\|_\infty = \|f\|_\infty.$$

Thus each T_n belongs to X^* and the sequence $\{T_n\}$ satisfies the boundedness hypothesis (28) of Helley's Theorem with $M = 1$.

We claim no subsequence of $\{T_n\}$ converges pointwise on X . Let $\{T_{n_k}\}$ be any subsequence. Since $n_1 < n_2 < \dots$ is strictly increasing, we may select indices $k_1 < k_2 < \dots$ inductively so that, writing $m_j = n_{k_j}$,

$$m_{j+1} \geq j \cdot m_j \quad \text{for all } j \geq 1;$$

this is possible because $n_k \rightarrow \infty$. In particular $m_j/m_{j+1} \leq 1/j$ for all $j \geq 1$.

Define f on $[0, 1]$ by

$$f = \sum_{j=1}^{\infty} (-1)^j \chi_{A_j}, \quad A_j = \left(\frac{1}{m_{j+1}}, \frac{1}{m_j} \right],$$

and $f = 0$ on $(1/m_1, 1]$ and at 0. The intervals A_j are pairwise disjoint, so f is a well-defined measurable function with $|f| \leq 1$; hence $f \in L^\infty[0, 1]$ and $\|f\|_\infty \leq 1$.

Fix j . Since $(0, 1/m_j] = A_j \cup (0, 1/m_{j+1}]$ and this union is disjoint,

$$T_{m_j}(f) = m_j \int_{A_j} f + m_j \int_0^{1/m_{j+1}} f = (-1)^j m_j \left(\frac{1}{m_j} - \frac{1}{m_{j+1}} \right) + m_j \int_0^{1/m_{j+1}} f.$$

The first term equals $(-1)^j (1 - m_j/m_{j+1})$, and the second is bounded in absolute value by $m_j \cdot (1/m_{j+1}) \leq 1/j$. Since $m_j/m_{j+1} \leq 1/j$ as well, we obtain

$$|T_{m_j}(f) - (-1)^j| \leq \frac{1}{j} + \frac{1}{j} = \frac{2}{j}.$$

Therefore $T_{m_{2i}}(f) \rightarrow 1$ and $T_{m_{2i+1}}(f) \rightarrow -1$ as $i \rightarrow \infty$, so the sequence of real numbers $\{T_{m_j}(f)\}$ does not converge.

But $\{T_{m_j}\}$ is a subsequence of $\{T_{n_k}\}$. If $\{T_{n_k}(f)\}$ converged, every one of its subsequences would converge to the same limit, which is false. Hence $\{T_{n_k}(f)\}$ fails to converge, so $\{T_{n_k}\}$ does not converge pointwise on X .

Since the subsequence $\{T_{n_k}\}$ was arbitrary, no subsequence of $\{T_n\}$ converges pointwise on $L^\infty[0, 1]$, and the conclusion of Helly's Theorem fails for $X = L^\infty[0, 1]$.

Problem 8.37. Let E have finite measure and $1 \leq p < \infty$. Suppose $\{f_n\}$ is a bounded sequence in $L^p(E)$ and f belongs to $L^p(E)$. If one of the following properties holds, determine, for each of the other properties, if a subsequence has that other property. The cases $p = 1$ and $p > 1$ should be considered.

- (i) $\{f_n\} \rightarrow f$ in $L^p(E)$.
- (ii) $\{f_n\} \rightharpoonup f$ in $L^p(E)$.
- (iii) $\{f_n\} \rightarrow f$ pointwise a.e. on E .
- (iv) $\{f_n\} \rightarrow f$ in measure.

Solution. Throughout, $m(E) < \infty$, q is the conjugate of p , and $M \geq 0$ is a bound with $\|f_n\|_p \leq M$ for all n . We treat the twelve implications; the answers are collected at the end.

Two counterexamples. Take $E = [0, 1]$ and $f \equiv 0$.

The moving spike. Let $g_n = n^{1/p} \chi_{(0, 1/n)}$. Then $\|g_n\|_p = 1$ for all n , so $\{g_n\}$ is bounded in $L^p[0, 1]$, and $g_n(x) \rightarrow 0$ for every $x \in (0, 1]$, so $\{g_n\} \rightarrow 0$ pointwise a.e.; by Proposition 3 of Chapter 5 it also converges to 0 in measure. No subsequence converges to 0 in L^p , since $\|g_{n_k}\|_p = 1$ for every k . When $p = 1$, $g_n = n \chi_{(0, 1/n)}$ and $\int_0^1 g_n \cdot 1 = 1$ for all n , while $\int_0^1 0 \cdot 1 = 0$; as the constant function 1 lies in $L^\infty[0, 1] = L^q[0, 1]$, Proposition 6 shows that no subsequence of $\{g_n\}$ converges weakly to 0 in $L^1[0, 1]$.

The Rademacher functions. Let $r_n(x) = 1$ if $[2^n x]$ is even and $r_n(x) = -1$ otherwise; equivalently r_n is +1 on the even dyadic intervals $[k2^{-n}, (k+1)2^{-n})$ and -1 on the odd ones. Then $|r_n| = 1$, so $\|r_n\|_p = 1$ and $\{r_n\}$ is bounded in $L^p[0, 1]$.

We claim $\{r_n\} \rightharpoonup 0$ in $L^p[0, 1]$ for every $p \in [1, \infty)$. By Proposition 6 it suffices to show that $\int_0^1 r_n h \rightarrow 0$ for every $h \in L^q[0, 1]$. First observe that

$$0 \leq \int_0^x r_n \leq 2^{-n} \quad \text{for all } x \in [0, 1],$$

because on each interval $[2j \cdot 2^{-n}, (2j+2) \cdot 2^{-n}]$ the function r_n equals +1 on the first half and -1 on the second, so $t \mapsto \int_0^t r_n$ rises from 0 to 2^{-n} and falls back to 0. Consequently $\left| \int_c^d r_n \right| \leq 2^{-n}$ for every subinterval $[c, d]$ of $[0, 1]$, and therefore $\int_0^1 r_n \psi \rightarrow 0$ for every step function ψ on $[0, 1]$, such a ψ being a finite linear combination of characteristic functions of intervals.

Now let $h \in L^q[0, 1]$ and $\varepsilon > 0$. Since $[0, 1]$ has finite measure, h belongs to $L^1[0, 1]$, and by Proposition 10 of Chapter 7 the step functions are dense in $L^1[0, 1]$; choose a step function ψ with $\|h - \psi\|_1 < \varepsilon$. Since $|r_n| \leq 1$,

$$\left| \int_0^1 r_n h \right| \leq \int_0^1 |h - \psi| + \left| \int_0^1 r_n \psi \right| < \varepsilon + \left| \int_0^1 r_n \psi \right|.$$

Letting $n \rightarrow \infty$ gives $\limsup_{n \rightarrow \infty} \left| \int_0^1 r_n h \right| \leq \varepsilon$, and as $\varepsilon > 0$ was arbitrary, $\int_0^1 r_n h \rightarrow 0$. Hence $\{r_n\} \rightarrow 0$ in $L^p[0, 1]$ for every $p \in [1, \infty)$.

On the other hand no subsequence of $\{r_n\}$ has any of the properties (i), (iii), (iv) with limit 0. Indeed $\|r_{n_k}\|_p = 1$ for all k , so no subsequence converges to 0 in L^p . If some subsequence converged to 0 pointwise a.e., then, since $|r_{n_k}| \leq 1$ and the constant 1 is integrable over $[0, 1]$, the Dominated Convergence Theorem applied to $|r_{n_k}|^p$ would give $\|r_{n_k}\|_p \rightarrow 0$, a contradiction. If some subsequence converged to 0 in measure, then by Theorem 4 of Chapter 5 (Riesz) a further subsequence would converge to 0 pointwise a.e., which we just excluded.

(i) implies (ii), (iii) up to a subsequence, and (iv), for all $p \in [1, \infty)$. Suppose $\{f_n\} \rightarrow f$ in $L^p(E)$. For $h \in L^q(E)$, Hölder's Inequality gives $|\int_E (f_n - f)h| \leq \|f_n - f\|_p \|h\|_q \rightarrow 0$, so by Proposition 6, $\{f_n\} \rightarrow f$: (ii) holds for the whole sequence. By the Riesz–Fischer Theorem there is a subsequence of $\{f_n\}$ that converges to f pointwise a.e. on E , so (iii) holds for a subsequence. (Not for the whole sequence: the functions $\chi_{[0,1/2]}, \chi_{[1/2,1]}, \chi_{[0,1/4]}, \chi_{[1/4,1/2]}, \dots$ converge to 0 in $L^p[0, 1]$ but at no point.) Finally, for $\eta > 0$, Chebychev's Inequality applied to $|f_n - f|^p$ gives

$$m\{x \in E : |f_n(x) - f(x)| \geq \eta\} \leq \frac{1}{\eta^p} \int_E |f_n - f|^p \rightarrow 0,$$

so $\{f_n\} \rightarrow f$ in measure: (iv) holds for the whole sequence.

(iii) implies (iv), for all p . This is Proposition 3 of Chapter 5, which requires only that $m(E) < \infty$.

(iv) implies (iii) up to a subsequence, for all p . This is Theorem 4 of Chapter 5 (Riesz).

(iii) implies (ii), and (iv) implies (ii), when $p > 1$; both fail when $p = 1$. Assume $p > 1$, so $1 \leq q < \infty$, and assume (iii). Let $h \in L^q(E)$ and $\varepsilon > 0$. Since $|h|^q$ is integrable over E , by the continuity of integration there is a $\delta > 0$ such that $\int_A |h|^q < \varepsilon^q$ whenever $A \subseteq E$ is measurable with $m(A) < \delta$. Since $m(E) < \infty$ and $\{f_n\} \rightarrow f$ pointwise a.e. on E , Egoroff's Theorem provides a measurable $F \subseteq E$ with $m(E \setminus F) < \delta$ on which $\{f_n\} \rightarrow f$ uniformly. By Hölder's Inequality, $\int_F |h| \leq \|h\|_q m(E)^{1/p} < \infty$, so

$$\left| \int_F (f_n - f)h \right| \leq \left(\sup_F |f_n - f| \right) \int_F |h| \rightarrow 0.$$

Also, by Hölder's Inequality and Minkowski's Inequality,

$$\left| \int_{E \setminus F} (f_n - f)h \right| \leq \|f_n - f\|_p \left(\int_{E \setminus F} |h|^q \right)^{1/q} \leq (M + \|f\|_p) \varepsilon.$$

Hence $\limsup_n \left| \int_E (f_n - f)h \right| \leq (M + \|f\|_p) \varepsilon$ for every $\varepsilon > 0$, so $\int_E f_n h \rightarrow \int_E f h$. By Proposition 6, $\{f_n\} \rightarrow f$ in $L^p(E)$: the whole sequence converges weakly.

If instead (iv) holds and $p > 1$, apply the preceding to subsequences: every subsequence of $\{f_n\}$ still converges to f in measure, hence by Theorem 4 of Chapter 5 has a further subsequence converging to f pointwise a.e., which by the paragraph above converges weakly to f . Thus for each $h \in L^q(E)$ every subsequence of the real sequence $\{\int_E f_n h\}$ has a further subsequence converging to $\int_E f h$, so the whole sequence $\{\int_E f_n h\}$ converges to $\int_E f h$, and $\{f_n\} \rightarrow f$.

For $p = 1$ both implications fail, even for subsequences: the moving spike $g_n = n\chi_{(0,1/n)}$ is bounded in $L^1[0, 1]$, converges to 0 pointwise a.e. and in measure, yet no subsequence converges weakly to 0 in $L^1[0, 1]$.

Nothing implies (i) except (i), for any p . The moving spike $\{g_n\}$ satisfies (ii) when $p > 1$ (by the paragraph above), and satisfies (iii) and (iv) for every $p \in [1, \infty)$, but no subsequence converges to 0 in L^p . For $p = 1$ the Rademacher sequence $\{r_n\}$ satisfies (ii) with no subsequence satisfying (i). So (ii), (iii), (iv) each fail to yield (i) along a subsequence.

(ii) implies neither (iii) nor (iv) along a subsequence, for any $p \in [1, \infty)$. The Rademacher sequence $\{r_n\}$ is bounded in $L^p[0, 1]$ and converges weakly to 0, but as shown above no subsequence converges to 0 pointwise a.e. or in measure (or in L^p).

Summary. Write “yes” if the second property holds for a suitable subsequence and “no” otherwise.

- (i) $\Rightarrow$ (ii): yes (whole sequence), all p . (i) $\Rightarrow$ (iii): yes (subsequence), all p . (i) $\Rightarrow$ (iv): yes (whole sequence), all p .

- (ii) $\Rightarrow$ (i): no, all p . (ii) $\Rightarrow$ (iii): no, all p . (ii) $\Rightarrow$ (iv): no, all p .
- (iii) $\Rightarrow$ (i): no, all p . (iii) $\Rightarrow$ (ii): yes (whole sequence) if $p > 1$; no if $p = 1$. (iii) $\Rightarrow$ (iv): yes (whole sequence), all p .
- (iv) $\Rightarrow$ (i): no, all p . (iv) $\Rightarrow$ (ii): yes (whole sequence) if $p > 1$; no if $p = 1$. (iv) $\Rightarrow$ (iii): yes (subsequence), all p .

The boundedness of $\{f_n\}$ in $L^p(E)$ is used only in the implications (iii) $\Rightarrow$ (ii) and (iv) $\Rightarrow$ (ii); by Theorem 7 it is automatic under (i) and (ii).

Problem 8.38. For $1 < p < \infty$ and each index n , let $e_n \in \ell^p$ have n th component 1 and other components 0. Show that $\{e_n\}$ converges weakly to 0 in ℓ^p , but no subsequence converges strongly to 0. Find a subsequence whose arithmetic means converge strongly to 0 in ℓ^p .

Solution. Let q be the conjugate of p , so $1 < q < \infty$ and $(q-1)p = q$.

Weak convergence. By definition, $\{e_n\} \rightarrow 0$ in ℓ^p means $T(e_n) \rightarrow 0$ for every bounded linear functional T on ℓ^p . So let T belong to $(\ell^p)^*$ and put $y_n = T(e_n)$. We show $\sum_{n=1}^{\infty} |y_n|^q < \infty$, which forces $y_n \rightarrow 0$. Fix a natural number N and define

$$x = \sum_{n=1}^N \operatorname{sgn}(y_n) |y_n|^{q-1} e_n,$$

a vector with only finitely many nonzero components, so $x \in \ell^p$. Since $(q-1)p = q$,

$$\|x\|_p = \left(\sum_{n=1}^N |y_n|^{(q-1)p} \right)^{1/p} = \left(\sum_{n=1}^N |y_n|^q \right)^{1/p}.$$

By linearity, $T(x) = \sum_{n=1}^N \operatorname{sgn}(y_n) |y_n|^{q-1} y_n = \sum_{n=1}^N |y_n|^q$. Hence, writing $S_N = \sum_{n=1}^N |y_n|^q$,

$$S_N = T(x) \leq \|T\|_* \cdot \|x\|_p = \|T\|_* \cdot S_N^{1/p}.$$

If $S_N > 0$, dividing by $S_N^{1/p}$ gives $S_N^{1-1/p} = S_N^{1/q} \leq \|T\|_*$; this also holds trivially if $S_N = 0$. Thus $S_N \leq \|T\|_*^q$ for every N , so $\sum_{n=1}^{\infty} |y_n|^q \leq \|T\|_*^q < \infty$. The terms of a convergent series tend to 0, so $T(e_n) = y_n \rightarrow 0 = T(0)$. Since $T \in (\ell^p)^*$ was arbitrary, $\{e_n\} \rightarrow 0$ in ℓ^p .

No subsequence converges strongly. For every n , $\|e_n\|_p = 1$. Hence for any subsequence $\{e_{n_k}\}$ we have $\|e_{n_k} - 0\|_p = 1$ for all k , so $\{e_{n_k}\}$ does not converge strongly to 0. (This is the promised illustration that weak convergence is strictly weaker than strong convergence: the sequence $\{e_n\}$ lies on the unit sphere of ℓ^p and converges weakly to a point of norm 0.)

Arithmetic means. In fact the arithmetic means of the full sequence $\{e_n\}$ converge strongly to 0, so we may take the subsequence to be $\{e_n\}$ itself; more generally, this works for every subsequence. Let $\{e_{n_k}\}$ be any subsequence and set

$$\sigma_k = \frac{e_{n_1} + e_{n_2} + \cdots + e_{n_k}}{k}.$$

Since $n_1 < n_2 < \cdots$, the vectors $e_{n_1}, \dots, e_{n_k}$ have disjoint supports, so σ_k has exactly k nonzero components, each equal to $1/k$. Therefore

$$\|\sigma_k\|_p = \left(k \cdot \frac{1}{k^p} \right)^{1/p} = (k^{1-p})^{1/p} = k^{(1-p)/p} = \frac{1}{k^{1-1/p}}.$$

Because $p > 1$ we have $1 - 1/p > 0$, so $\|\sigma_k\|_p \rightarrow 0$ as $k \rightarrow \infty$; that is, the arithmetic means converge strongly to 0 in ℓ^p .

This is exactly the conclusion of the Banach–Saks Theorem in this example. Note that the computation fails for $p = 1$: there $\|\sigma_k\|_1 = 1$ for all k , and indeed $\{e_n\}$ does not converge weakly to 0 in ℓ^1 , since the bounded linear functional $x \mapsto \sum_n x_n$ (represented by the element $(1, 1, 1, \dots)$ of ℓ^∞) takes the value 1 at every e_n .

Problem 8.39. Show that if a sequence of real numbers $\{a_n\}$ converges to a , then the sequence of arithmetic means also converges to a .

Solution. For each natural number n define the n th arithmetic mean

$$\sigma_n = \frac{a_1 + a_2 + \cdots + a_n}{n}.$$

We must show $\sigma_n \rightarrow a$.

Replacing a_n by $a_n - a$ replaces σ_n by $\sigma_n - a$, since

$$\frac{(a_1 - a) + \cdots + (a_n - a)}{n} = \sigma_n - a.$$

Hence there is no loss of generality in assuming $a = 0$, and we must show $\sigma_n \rightarrow 0$.

Since $\{a_n\}$ converges, it is bounded: choose $M \geq 0$ with $|a_n| \leq M$ for all n .

Let $\varepsilon > 0$. Since $a_n \rightarrow 0$, there is a natural number N such that

$$|a_n| < \frac{\varepsilon}{2} \quad \text{for all } n > N.$$

For $n > N$ split the sum at N :

$$|\sigma_n| = \left| \frac{1}{n} \sum_{k=1}^n a_k \right| \leq \frac{1}{n} \sum_{k=1}^N |a_k| + \frac{1}{n} \sum_{k=N+1}^n |a_k| \leq \frac{NM}{n} + \frac{n-N}{n} \cdot \frac{\varepsilon}{2} \leq \frac{NM}{n} + \frac{\varepsilon}{2}.$$

Here N and M are fixed, so $NM/n \rightarrow 0$ as $n \rightarrow \infty$. Choose a natural number $N' > N$ with $NM/n < \varepsilon/2$ for all $n > N'$, that is, $N' \geq 2NM/\varepsilon$. Then for all $n > N'$,

$$|\sigma_n| < \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon.$$

Since $\varepsilon > 0$ was arbitrary, $\sigma_n \rightarrow 0$. In the general case, $\sigma_n \rightarrow a$.

The converse is false: for $a_n = (-1)^n$ the arithmetic means converge to 0 while $\{a_n\}$ diverges. So the passage to arithmetic means is a genuine strengthening of the summability of a sequence, which is precisely why it is useful in the Banach–Saks Theorem.

Problem 8.40. State and prove the Banach–Saks Theorem in ℓ^2 .

Solution. Statement. Let $\{x_n\}$ be a sequence in ℓ^2 that converges weakly in ℓ^2 to x . Then there is a subsequence $\{x_{n_k}\}$ for which the sequence of arithmetic means converges strongly to x in ℓ^2 , that is,

$$\lim_{k \rightarrow \infty} \left\| \frac{x_{n_1} + x_{n_2} + \cdots + x_{n_k}}{k} - x \right\|_2 = 0.$$

For $u = \{u_n\}$ and $v = \{v_n\}$ in ℓ^2 write $\langle u, v \rangle = \sum_{n=1}^{\infty} u_n v_n$; by the Cauchy–Schwarz (Hölder) Inequality this series converges absolutely and $|\langle u, v \rangle| \leq \|u\|_2 \|v\|_2$, and $\langle u, u \rangle = \|u\|_2^2$.

A preliminary lemma: every $T \in (\ell^2)^*$ has the form $T(u) = \langle u, y \rangle$ for some $y \in \ell^2$. Let $e_n \in \ell^2$ have n th component 1 and the others 0, and set $y_n = T(e_n)$. Exactly as in Problem 38 (with $p = q = 2$), for each N the vector $w = \sum_{n=1}^N y_n e_n$ satisfies $T(w) = \sum_{n=1}^N y_n^2$ and $\|w\|_2 = \left(\sum_{n=1}^N y_n^2 \right)^{1/2}$, whence

$\left(\sum_{n=1}^N y_n^2 \right)^{1/2} \leq \|T\|_*$. Letting $N \rightarrow \infty$ shows $y = \{y_n\} \in \ell^2$. The functionals T and $u \mapsto \langle u, y \rangle$ are both bounded and linear on ℓ^2 and agree on each e_n , hence on the linear span of $\{e_n\}$, which is the set of vectors with finitely many nonzero components. That span is dense in ℓ^2 , since for $u \in \ell^2$ the truncations $\sum_{n \leq N} u_n e_n$ satisfy $\|u - \sum_{n \leq N} u_n e_n\|_2^2 = \sum_{n > N} u_n^2 \rightarrow 0$. Two continuous functions agreeing on a dense subset agree everywhere, so $T(u) = \langle u, y \rangle$ for all $u \in \ell^2$.

Consequently, $\{x_n\} \rightharpoonup x$ in ℓ^2 if and only if $\langle x_n, y \rangle \rightarrow \langle x, y \rangle$ for every $y \in \ell^2$.

Proof of the theorem. Replacing each x_n by $x_n - x$ replaces the arithmetic means by their translates by $-x$, so we may assume $x = 0$; thus $\langle x_n, y \rangle \rightarrow 0$ for every $y \in \ell^2$, and we must produce a subsequence whose arithmetic means converge strongly to 0.

Boundedness of $\{x_n\}$. The book's proof invokes Theorem 7 at this point; here is the ℓ^2 analogue, proved in full. For each n define $T_n(u) = \langle u, x_n \rangle$ for $u \in \ell^2$. By the Cauchy-Schwarz Inequality $|T_n(u)| \leq \|u\|_2 \|x_n\|_2$, while $T_n(x_n) = \|x_n\|_2^2$; hence $T_n \in (\ell^2)^*$ and $\|T_n\|_* = \|x_n\|_2$. By the preliminary lemma, weak convergence of $\{x_n\}$ to 0 says exactly that $T_n(u) = \langle u, x_n \rangle \rightarrow 0$ for each $u \in \ell^2$; in particular $\sup_n |T_n(u)| < \infty$ for each $u \in \ell^2$.

Suppose, to get a contradiction, that $\{\|T_n\|_*\}$ is unbounded. We use the following elementary observation: for a bounded linear functional T on a normed linear space, any point z , and any $r > 0$,

$$\sup \{|T(w)| : \|w - z\| \leq r\} \geq r \|T\|_*,$$

since for $\|u\| \leq r$ we have $\max \{|T(z+u)|, |T(z-u)|\} \geq \frac{1}{2} (|T(z+u)| + |T(z-u)|) \geq |T(u)|$, and $\sup_{\|u\| \leq r} |T(u)| = r \|T\|_*$.

Choose indices $k_1 < k_2 < \dots$ with $\|T_{k_j}\|_* \geq 4^j$. Put $z_0 = 0$ and choose inductively, using the observation with $r = 3^{-j}$ and the fact that $2/3 < 1$, points $z_j \in \ell^2$ with

$$\|z_j - z_{j-1}\|_2 \leq 3^{-j} \quad \text{and} \quad |T_{k_j}(z_j)| \geq \frac{2}{3} \cdot 3^{-j} \|T_{k_j}\|_*.$$

Write $d_j = z_j - z_{j-1}$, so $\sum_j \|d_j\|_2 \leq \sum_j 3^{-j} < \infty$. For each coordinate i we have $|d_j(i)| \leq \|d_j\|_2$, so the series $z(i) = \sum_{j \geq 1} d_j(i)$ converges absolutely; and for every N and every m , Minkowski's Inequality for

finite sums gives $\left(\sum_{i \leq N} \left| \sum_{j \leq m} d_j(i) \right|^2 \right)^{1/2} \leq \sum_{j \geq 1} \|d_j\|_2$, so letting $m \rightarrow \infty$ and then $N \rightarrow \infty$ shows $z = \{z(i)\} \in \ell^2$. The same estimate applied to the tail $\sum_{j > m} d_j$ gives $\|z - z_m\|_2 \leq \sum_{j > m} 3^{-j} = \frac{1}{2} \cdot 3^{-m}$. Therefore, for every j ,

$$|T_{k_j}(z)| \geq |T_{k_j}(z_j)| - \|T_{k_j}\|_* \|z - z_j\|_2 \geq \left(\frac{2}{3} - \frac{1}{2} \right) 3^{-j} \|T_{k_j}\|_* \geq \frac{1}{6} \left(\frac{4}{3} \right)^j,$$

which is unbounded in j . This contradicts $\sup_n |T_n(z)| < \infty$. Hence $\sup_n \|x_n\|_2 = \sup_n \|T_n\|_* < \infty$, and we may choose $M \geq 0$ with

$$\|x_n\|_2^2 \leq M \quad \text{for all } n.$$

(The argument just given is the Uniform Boundedness Principle; Problem 26 of this chapter is its L^p counterpart.)

We choose the subsequence inductively so that the partial sums

$$s_k = x_{n_1} + x_{n_2} + \dots + x_{n_k}$$

satisfy

$$\|s_k\|_2^2 \leq (2 + M)k \quad \text{for all } k. \quad (*)$$

Set $n_1 = 1$. Then $\|s_1\|_2^2 = \|x_1\|_2^2 \leq M \leq (2 + M) \cdot 1$, so $(*)$ holds for $k = 1$.

Suppose $n_1 < n_2 < \dots < n_k$ have been chosen with $(*)$ holding for that k . The vector s_k belongs to ℓ^2 , so by weak convergence $\langle s_k, x_n \rangle \rightarrow 0$ as $n \rightarrow \infty$. Hence we may choose a natural number $n_{k+1} > n_k$ with

$$|\langle s_k, x_{n_{k+1}} \rangle| \leq 1.$$

Since $s_{k+1} = s_k + x_{n_{k+1}}$, expanding the inner product gives

$$\|s_{k+1}\|_2^2 = \|s_k\|_2^2 + 2\langle s_k, x_{n_{k+1}} \rangle + \|x_{n_{k+1}}\|_2^2 \leq (2 + M)k + 2 + M = (2 + M)(k + 1),$$

so $(*)$ holds for $k + 1$. This completes the induction and produces a subsequence $\{x_{n_k}\}$ satisfying $(*)$ for every k .

Finally, for each k ,

$$\left\| \frac{x_{n_1} + x_{n_2} + \cdots + x_{n_k}}{k} \right\|_2^2 = \frac{\|s_k\|_2^2}{k^2} \leq \frac{(2+M)k}{k^2} = \frac{2+M}{k},$$

which tends to 0 as $k \rightarrow \infty$. Therefore the arithmetic means of $\{x_{n_k}\}$ converge strongly to 0 in ℓ^2 , and in the general case to x . ■

Remark. Combining this with Problem 33 (every bounded sequence in ℓ^p , $1 \leq p < \infty$, has a weakly convergent subsequence) yields: every bounded sequence in ℓ^2 has a subsequence whose arithmetic means converge strongly in ℓ^2 . Problem 38 exhibits the theorem in action: the sequence $\{e_n\}$ converges weakly but not strongly to 0, yet its arithmetic means converge strongly to 0.

Problem 8.41. Let E be a measurable set and $1 \leq p < \infty$. Let T be a continuous linear functional on $L^p[a, b]$ and $K = \{f \in L^p(E) \mid \|f\|_p \leq 1\}$. Find a function $f_0 \in K$ for which

$$T(f_0) \geq T(f) \quad \text{for all } f \text{ in } K.$$

Solution. Here T is a continuous, that is bounded, linear functional on $L^p(E)$ and K is the closed unit ball of $L^p(E)$. We give the answer for $1 < p < \infty$, first by an appeal to Theorem 17 and then by an explicit formula, and we then show that for $p = 1$ a maximizer need not exist, so that the hypothesis must be read as $1 < p < \infty$.

Existence by Theorem 17 ($1 < p < \infty$). As observed in the second Example of this section, $K = \{f \in L^p(E) \mid \|f\|_p \leq 1\}$ is a closed, bounded, convex subset of $L^p(E)$: it is bounded by definition; it is convex by Minkowski's Inequality, since for $f, g \in K$ and $\lambda \in [0, 1]$, $\|\lambda f + (1-\lambda)g\|_p \leq \lambda\|f\|_p + (1-\lambda)\|g\|_p \leq 1$; and it is closed because $\|\|f_n\|_p - \|f\|_p\| \leq \|f_n - f\|_p$, so the norms of a strongly convergent sequence converge to the norm of the limit. The functional $-T$ is linear, hence convex (equality holds in the convexity inequality), and it is continuous since T is bounded: $|-T(f_n) - (-T)(f)| \leq \|T\|_* \|f_n - f\|_p$. Therefore Theorem 17 applies to $C = K$ and the continuous convex functional $-T$: there is $f_0 \in K$ with $-T(f_0) \leq -T(f)$ for all $f \in K$, that is,

$$T(f_0) \geq T(f) \quad \text{for all } f \in K.$$

An explicit maximizer ($1 < p < \infty$). Let q be the conjugate of p , so $1 < q < \infty$. By the Riesz Representation Theorem for the Dual of $L^p(E)$ there is a function $g \in L^q(E)$ with

$$T(f) = \int_E f \cdot g \quad \text{for all } f \in L^p(E), \quad \|T\|_* = \|g\|_q.$$

If $g = 0$ a.e. on E , then T is identically 0 and $f_0 = 0$ works. Otherwise $\|g\|_q > 0$, and we set

$$f_0 = \frac{\operatorname{sgn}(g) |g|^{q-1}}{\|g\|_q^{q-1}},$$

where $\operatorname{sgn}(g)$ is 1 where $g > 0$, -1 where $g < 0$, and 0 where $g = 0$. This is a measurable function, and since $(q-1)p = q$,

$$\int_E |f_0|^p = \frac{1}{\|g\|_q^{(q-1)p}} \int_E |g|^{(q-1)p} = \frac{1}{\|g\|_q^q} \int_E |g|^q = 1.$$

So $f_0 \in L^p(E)$ with $\|f_0\|_p = 1$, hence $f_0 \in K$. Moreover $f_0 \cdot g = |g|^q / \|g\|_q^{q-1}$, so

$$T(f_0) = \frac{1}{\|g\|_q^{q-1}} \int_E |g|^q = \frac{\|g\|_q^q}{\|g\|_q^{q-1}} = \|g\|_q = \|T\|_*.$$

On the other hand, for any $f \in K$, $T(f) \leq |T(f)| \leq \|T\|_* \|f\|_p \leq \|T\|_*$. Therefore

$$T(f_0) = \|T\|_* \geq T(f) \quad \text{for all } f \in K,$$

which is the required conclusion, and it identifies the maximum value of T on K as $\|T\|_*$.

The case $p = 1$. Here $q = \infty$, and the maximum need not be attained. Take $E = [0, 1]$, $p = 1$, and $T(f) = \int_0^1 xf(x) dx$, integration against $g(x) = x \in L^\infty[0, 1]$; T is a bounded linear functional with $\|T\|_* = \|g\|_\infty = 1$. The value 1 is not attained on K : if $f \in L^1[0, 1]$ with $\|f\|_1 \leq 1$ and f is not zero a.e., then, since $1 - x > 0$ for all $x \in [0, 1]$ and $|f| > 0$ on a set of positive measure, $\int_0^1 (1 - x)|f(x)| dx > 0$, so

$$T(f) \leq \int_0^1 x|f(x)| dx = \int_0^1 |f| - \int_0^1 (1 - x)|f| < \int_0^1 |f| \leq 1,$$

while $T(0) = 0 < 1$. Thus $T(f) < 1$ for every $f \in K$. Yet the supremum is 1: for $f_n = n\chi_{[1-1/n, 1]}$ we have $\|f_n\|_1 = 1$ and

$$T(f_n) = n \int_{1-1/n}^1 x dx = \frac{n}{2} \left(1 - \left(1 - \frac{1}{n} \right)^2 \right) = 1 - \frac{1}{2n} \rightarrow 1.$$

So no $f_0 \in K$ maximizes T . This is consistent with Theorem 17, whose hypothesis is $1 < p < \infty$: it is exactly the weak sequential compactness of K furnished by Theorem 14, which fails in L^1 , that is lost. More precisely, when $p = 1$ and T is given by integration against $g \in L^\infty(E)$ with g not zero a.e., a maximizer exists if and only if the set $A = \{x \in E : |g(x)| = \|g\|_\infty\}$ has positive measure. If $m(A) > 0$, choose a measurable $B \subseteq A$ with $0 < m(B) < \infty$ and put $f_0 = \text{sgn}(g)\chi_B/m(B)$; then $\|f_0\|_1 = 1$ and $T(f_0) = \|g\|_\infty = \|T\|_*$. If $m(A) = 0$, then $\|g\|_\infty - |g| > 0$ a.e. on E , so for $f \in K$ that is not zero a.e. the set on which $|f| > 0$ has positive measure and hence $\int_E (\|g\|_\infty - |g|)|f| > 0$; therefore

$$T(f) \leq \int_E |g||f| = \|g\|_\infty \int_E |f| - \int_E (\|g\|_\infty - |g|)|f| < \|g\|_\infty \int_E |f| \leq \|T\|_*,$$

while $T(0) = 0 < \|T\|_*$. On the other hand $\sup_{f \in K} T(f) = \|T\|_*$: given $\varepsilon > 0$, the set $\{x \in E : |g(x)| > \|g\|_\infty - \varepsilon\}$ has positive measure, so it contains a measurable subset B with $0 < m(B) < \infty$, and $f = \text{sgn}(g)\chi_B/m(B)$ belongs to K with $T(f) = \frac{1}{m(B)} \int_B |g| \geq \|g\|_\infty - \varepsilon$. So the supremum is not attained and no maximizer exists.

Problem 8.42. (Nemytskii) Let E be a measurable set and p_1, p_2 belong to $[1, \infty)$. Suppose φ is a continuous real-valued function defined on $\mathbb{R}$ for which there are constants c_1 and c_2 such that $|\varphi(s)| \leq c_1 + c_2|s|^{p_1/p_2}$ for all real numbers s . Let $\{f_n\}$ be a sequence in $L^{p_1}(E)$. Show that

$$\text{if } \{f_n\} \rightarrow f \text{ in } L^{p_1}(E), \text{ then } \{\varphi \circ f_n\} \rightarrow \varphi \circ f \text{ in } L^{p_2}.$$

Solution. We may assume $c_1 \geq 0$ and $c_2 \geq 0$, since replacing c_1 and c_2 by their absolute values only weakens the growth bound. We also assume, as in Corollary 18 of this section, that E has finite measure, or else that $c_1 = 0$; the argument below is the same in the two cases.

Some such hypothesis is genuinely needed. For $f \equiv 0$ the growth bound gives only $|\varphi \circ f| \leq c_1$, and the constant function c_1 does not belong to $L^{p_2}(E)$ when $m(E) = \infty$ and $c_1 > 0$, so the conclusion need not even be meaningful. Worse, the asserted convergence can fail outright on a set of infinite measure. Take $E = \mathbb{R}$ and $p_1 = p_2 = 1$, and let $\varphi(s) = |s|^{1/2}$ for $|s| \leq 1$ and $\varphi(s) = 1$ for $|s| > 1$; then φ is continuous on $\mathbb{R}$ and $|\varphi(s)| \leq 1$ for all s , so the growth bound holds with $c_1 = 1$ and $c_2 = 0$. Put $f_n = n^{-2}\chi_{[0, n]}$ and $f \equiv 0$. Then $\|f_n - f\|_1 = n^{-2} \cdot n = 1/n \rightarrow 0$, so $\{f_n\} \rightarrow f$ in $L^1(\mathbb{R})$, while $\varphi \circ f_n = n^{-1}\chi_{[0, n]}$ and $\varphi \circ f \equiv 0$, so

$$\|\varphi \circ f_n - \varphi \circ f\|_1 = n^{-1} \cdot n = 1 \quad \text{for all } n.$$

We use repeatedly the elementary inequality: for $r \geq 1$ and $a, b \geq 0$,

$$(a + b)^r \leq (2 \max\{a, b\})^r = 2^r \max\{a^r, b^r\} \leq 2^r (a^r + b^r). \quad (1)$$

Step 1: $\varphi \circ h$ belongs to $L^{p_2}(E)$ for every $h \in L^{p_1}(E)$. Since φ is continuous and h is measurable and

finite a.e. on E , the composition $\varphi \circ h$ is measurable on E . By the growth bound and (1) with $r = p_2$,

$$|\varphi \circ h|^{p_2} \leq (c_1 + c_2|h|^{p_1/p_2})^{p_2} \leq 2^{p_2} (c_1^{p_2} + c_2^{p_2}|h|^{p_1}) \quad \text{a.e. on } E.$$

The right-hand side is integrable over E : $|h|^{p_1}$ is integrable since $h \in L^{p_1}(E)$, and the constant $c_1^{p_2}$ is integrable over E by our standing assumption. By the integral comparison test, $|\varphi \circ h|^{p_2}$ is integrable over E , that is, $\varphi \circ h \in L^{p_2}(E)$. In particular $\varphi \circ f$ and every $\varphi \circ f_n$ lie in $L^{p_2}(E)$, so the assertion is meaningful.

Step 2: reduction to a subsequence argument. Suppose, to get a contradiction, that $\{f_n\} \rightarrow f$ in $L^{p_1}(E)$ but $\{\varphi \circ f_n\}$ fails to converge to $\varphi \circ f$ in $L^{p_2}(E)$. Then there is an $\varepsilon > 0$ and a subsequence $\{f_{n_j}\}$ for which

$$\|\varphi \circ f_{n_j} - \varphi \circ f\|_{p_2} \geq \varepsilon \quad \text{for all } j. \quad (2)$$

Of course $\{f_{n_j}\} \rightarrow f$ in $L^{p_1}(E)$ as well. We will produce a further subsequence along which $\|\varphi \circ f_{n_j} - \varphi \circ f\|_{p_2} \rightarrow 0$, contradicting (2).

Step 3: a dominated, pointwise convergent further subsequence. Since $\{f_{n_j}\} \rightarrow f$ in $L^{p_1}(E)$, we may choose a subsequence, which we relabel $\{h_k\}$, that is rapidly Cauchy, that is,

$$\|h_{k+1} - h_k\|_{p_1} \leq 2^{-k} \quad \text{for all } k.$$

Define

$$g = |h_1| + \sum_{k=1}^{\infty} |h_{k+1} - h_k|,$$

the sum of a series of nonnegative measurable functions, so g is a nonnegative measurable function on E (possibly infinite at some points). Let $g_m = |h_1| + \sum_{k=1}^m |h_{k+1} - h_k|$. By Minkowski's Inequality,

$$\|g_m\|_{p_1} \leq \|h_1\|_{p_1} + \sum_{k=1}^m \|h_{k+1} - h_k\|_{p_1} \leq \|h_1\|_{p_1} + \sum_{k=1}^{\infty} 2^{-k} = \|h_1\|_{p_1} + 1.$$

Since $\{g_m^{p_1}\}$ is an increasing sequence of nonnegative measurable functions converging pointwise to g^{p_1} , the Monotone Convergence Theorem gives

$$\int_E g^{p_1} = \lim_{m \rightarrow \infty} \int_E g_m^{p_1} \leq (\|h_1\|_{p_1} + 1)^{p_1} < \infty.$$

Thus $g \in L^{p_1}(E)$; in particular $g < \infty$ a.e. on E . Consequently the series $h_1 + \sum_{k \geq 1} (h_{k+1} - h_k)$ converges absolutely at almost every point of E , and its m th partial sum is h_{m+1} . Hence $\{h_k\}$ converges pointwise a.e. on E to some measurable function h , and the triangle inequality gives

$$|h_k| \leq g_{k-1} \leq g \quad \text{a.e. on } E \text{ for all } k, \quad |h| \leq g \quad \text{a.e. on } E.$$

Moreover $\{h_k\} \rightarrow f$ in $L^{p_1}(E)$, being a subsequence of $\{f_{n_j}\}$. By the Riesz–Fischer Theorem some subsequence of $\{h_k\}$ converges to f pointwise a.e. on E ; since the whole sequence $\{h_k\}$ converges pointwise a.e. to h , we conclude $h = f$ a.e. on E . So, after modifying f on a set of measure zero (which changes neither $\|\cdot\|_{p_2}$ nor anything else),

$$\{h_k\} \rightarrow f \text{ pointwise a.e. on } E, \quad |h_k| \leq g \text{ and } |f| \leq g \text{ a.e. on } E.$$

Step 4: passing to the limit. Since φ is continuous on $\mathbb{R}$ and $h_k(x) \rightarrow f(x)$ for almost all $x \in E$,

$$\varphi(h_k(x)) \rightarrow \varphi(f(x)) \quad \text{for almost all } x \in E,$$

so $\{|\varphi \circ h_k - \varphi \circ f|^{p_2}\} \rightarrow 0$ pointwise a.e. on E . We dominate this sequence. By the growth bound and the estimates $|h_k| \leq g$, $|f| \leq g$ a.e.,

$$|\varphi \circ h_k| + |\varphi \circ f| \leq 2c_1 + 2c_2 g^{p_1/p_2} \quad \text{a.e. on } E \text{ for all } k,$$

and therefore, by (1) with $r = p_2$,

$$|\varphi \circ h_k - \varphi \circ f|^{p_2} \leq \left(2c_1 + 2c_2 g^{p_1/p_2}\right)^{p_2} \leq 2^{p_2} ((2c_1)^{p_2} + (2c_2)^{p_2} g^{p_1}) =: G \quad \text{a.e. on } E.$$

Exactly as in Step 1, G is integrable over E , since g^{p_1} is integrable and the constant $(2c_1)^{p_2}$ is integrable over E by our standing assumption. Thus the Lebesgue Dominated Convergence Theorem applies and yields

$$\lim_{k \rightarrow \infty} \int_E |\varphi \circ h_k - \varphi \circ f|^{p_2} = 0,$$

that is, $\|\varphi \circ h_k - \varphi \circ f\|_{p_2} \rightarrow 0$.

But $\{h_k\}$ is a subsequence of $\{f_{n_j}\}$, so this contradicts (2). Therefore no such ε and subsequence exist, and

$$\{\varphi \circ f_n\} \rightarrow \varphi \circ f \quad \text{in } L^{p_2}(E).$$

Remark. This is the assertion the book leaves as an exercise in the Example preceding Lemma 16, where E has finite measure, $1 < p < \infty$, φ is continuous and convex with $|\varphi(s)| \leq a + b|s|^p$, and $T(f) = \int_E \varphi \circ f$. Taking $p_1 = p$ and $p_2 = 1$ above, the growth bound reads $|\varphi(s)| \leq c_1 + c_2|s|^p$, and the conclusion is that $\{f_n\} \rightarrow f$ in $L^p(E)$ implies $\{\varphi \circ f_n\} \rightarrow \varphi \circ f$ in $L^1(E)$; hence $|T(f_n) - T(f)| \leq \int_E |\varphi \circ f_n - \varphi \circ f| \rightarrow 0$, so T is properly defined (Step 1) and continuous on $L^p(E)$. The map $f \mapsto \varphi \circ f$ is the Nemytskii operator associated with φ ; the content of the problem is that it carries $L^{p_1}(E)$ continuously into $L^{p_2}(E)$ under the stated growth condition.

8.7 Problems 8.43–8.45

Problem 8.43. (Beppo Levi) Let E be a measurable set, $1 \leq p < \infty$, and C a closed bounded convex subset of $L^p(E)$. Show that for any function $f_0 \in L^p(E)$, there is a function g_0 in C for which

$$\|g_0 - f_0\|_p \leq \|g - f_0\|_p \quad \text{for all } g \in C.$$

Solution. Assume, as is implicit in the assertion, that C is nonempty.

The case $1 < p < \infty$. Fix $f_0 \in L^p(E)$ and define the real-valued functional T on C by

$$T(g) = \|g - f_0\|_p \quad \text{for all } g \in C.$$

This is properly defined, since $g - f_0$ belongs to $L^p(E)$ whenever g does.

T is convex. Indeed, let g and h belong to C and $\lambda \in [0, 1]$. Then $\lambda g + (1 - \lambda)h$ belongs to C since C is convex, and

$$\lambda g + (1 - \lambda)h - f_0 = \lambda(g - f_0) + (1 - \lambda)(h - f_0),$$

so that, by the Minkowski Inequality,

$$T(\lambda g + (1 - \lambda)h) \leq \lambda\|g - f_0\|_p + (1 - \lambda)\|h - f_0\|_p = \lambda T(g) + (1 - \lambda)T(h).$$

T is continuous on C . Indeed, by the triangle inequality for the norm $\|\cdot\|_p$,

$$|T(g) - T(h)| = \left| \|g - f_0\|_p - \|h - f_0\|_p \right| \leq \|g - h\|_p \quad \text{for all } g, h \in C,$$

so if $\{g_n\}$ is a sequence in C converging strongly in $L^p(E)$ to $g \in C$, then $\{T(g_n)\} \rightarrow T(g)$.

Thus C is a closed, bounded, convex subset of $L^p(E)$ and T is a continuous convex functional on C . Since $1 < p < \infty$, Theorem 17 tells us that T takes on a minimum value on C : there is a function $g_0 \in C$ for which $T(g_0) \leq T(g)$ for all $g \in C$, that is,

$$\|g_0 - f_0\|_p \leq \|g - f_0\|_p \quad \text{for all } g \in C.$$

The case $p = 1$. For $p = 1$ the assertion is false, and the above proof genuinely breaks down: Theorem 17 rests on Theorem 14 (weak sequential compactness of bounded sequences), which fails in L^1 . Here

is a counterexample. Take $E = [0, 1]$, $f_0 \equiv 0$, and

$$C = \left\{ f \in L^1[0, 1] \mid \int_0^1 xf(x) dx = 1 \text{ and } \|f\|_1 \leq 3 \right\}.$$

C is nonempty: since $\int_{1/2}^1 x dx = 3/8$, the function $f = (8/3)\chi_{[1/2, 1]}$ belongs to C , as $\|f\|_1 = 4/3 \leq 3$. C is convex, being the intersection of the ball $\{\|f\|_1 \leq 3\}$ (convex by Minkowski's Inequality) with the set on which the linear functional $f \mapsto \int_0^1 xf$ takes the value 1.

C is closed: if $\{f_n\}$ is a sequence in C converging in $L^1[0, 1]$ to f , then

$$\left| \int_0^1 xf_n - \int_0^1 xf \right| \leq \int_0^1 |f_n - f| = \|f_n - f\|_1 \rightarrow 0,$$

so $\int_0^1 xf = 1$; and $\|f\|_1 = \lim \|f_n\|_1 \leq 3$. Of course C is bounded.

Now compute the distance from $f_0 = 0$ to C . For $f \in C$,

$$1 = \int_0^1 xf(x) dx \leq \int_0^1 x|f(x)| dx \leq \int_0^1 |f| = \|f\|_1,$$

so $\|f - f_0\|_1 \geq 1$ for all $f \in C$. On the other hand, for each natural number $n \geq 1$ set

$$a_n = \left(\int_{1-1/n}^1 x dx \right)^{-1} = \left(\frac{1}{n} - \frac{1}{2n^2} \right)^{-1}, \quad f_n = a_n \chi_{[1-1/n, 1]}.$$

Then $\int_0^1 xf_n = 1$ and

$$\|f_n\|_1 = \frac{a_n}{n} = \frac{1}{1 - 1/(2n)} \leq 2 \leq 3,$$

so $f_n \in C$, while $\|f_n - f_0\|_1 = 1/(1 - 1/(2n)) \rightarrow 1$. Hence

$$\inf_{f \in C} \|f - f_0\|_1 = 1.$$

This infimum is not attained. Suppose $f \in C$ had $\|f\|_1 = 1$. Then

$$0 = \|f\|_1 - \int_0^1 xf(x) dx = \int_0^1 (|f(x)| - xf(x)) dx \geq \int_0^1 (1-x)|f(x)| dx \geq 0,$$

since $|f| - xf \geq |f| - x|f| = (1-x)|f| \geq 0$ on $[0, 1]$. Therefore $(1-x)|f(x)| = 0$ for almost all $x \in [0, 1]$, and hence $f = 0$ almost everywhere on $[0, 1]$, so $f = 0$ in $L^1[0, 1]$. This contradicts $\int_0^1 xf = 1$. Thus no $g_0 \in C$ satisfies $\|g_0 - f_0\|_1 \leq \|g - f_0\|_1$ for all $g \in C$.

So the conclusion holds exactly for $1 < p < \infty$; the hypothesis in the statement should read $1 < p < \infty$, which is the range for which Theorem 17 is available.

Problem 8.44. (Banach-Saks) For a natural number n , define the function f_n on $[0, 1]$ by setting

$$f_n(x) = 1 \text{ for } k/2^n + 1/2^{2n+1} \leq x < (k+1)/2^n \text{ and } 0 \leq k \leq 2^n - 1,$$

and $f_n(x) = 1 - 2^{n+1}$ elsewhere on $[0, 1]$. Define $f \equiv 0$ on $[0, 1]$.

(i) Show that

$$\left| \int_0^x f_n \right| \leq 1/2^n \text{ for all } x \in [0, 1] \text{ and all } n,$$

and therefore

$$\lim_{n \rightarrow \infty} \int_0^x f_n = \int_0^x f \text{ for all } x \in [0, 1].$$

(ii) Define E to be the subset of $[0, 1]$ on which $f_n = 1$ for all n . Show that

$$\int_E f_n = m(E) > 0 \quad \text{for all } n.$$

- (iii) Show that $\|f_n\|_1 \leq 2$ for all n . Infer from part (ii) that $\{f_n\}$ is a bounded sequence in $L^1[0, 1]$ that does not converge weakly in $L^1[0, 1]$ to f . Does this and part (i) contradict Theorem 11?
- (iv) For $1 < p < \infty$, infer from part (ii) that $\{f_n\}$ is a sequence in $L^p[0, 1]$ that does not converge weakly in $L^p[0, 1]$ to f . Does this and part (i) contradict Theorem 11?

Solution. Throughout, fix a natural number n and write

$$I_k = [k/2^n, (k+1)/2^n), \quad J_k = [k/2^n, k/2^n + 1/2^{2n+1}) \subseteq I_k, \quad 0 \leq k \leq 2^n - 1.$$

The intervals I_k partition $[0, 1)$, each has length $1/2^n$, and each J_k has length $1/2^{2n+1}$. By definition $f_n = 1 - 2^{n+1}$ on J_k and $f_n = 1$ on $I_k \setminus J_k$. The single point $x = 1$ lies in no I_k , so it falls under the *elsewhere* clause and $f_n(1) = 1 - 2^{n+1}$. Accordingly put

$$B_n = \{1\} \cup \bigcup_{k=0}^{2^n-1} J_k, \quad A_n = [0, 1] \setminus B_n.$$

The J_k are disjoint and $\{1\}$ has measure zero, so

$$m(B_n) = 2^n \cdot \frac{1}{2^{2n+1}} = \frac{1}{2^{n+1}}, \quad m(A_n) = 1 - \frac{1}{2^{n+1}},$$

and $f_n = 1$ on A_n , $f_n = 1 - 2^{n+1}$ on B_n . Each f_n is a simple function, hence bounded and measurable, so it belongs to $L^p[0, 1]$ for every $1 \leq p \leq \infty$.

The key computation is that f_n has mean zero on each I_k :

$$\int_{I_k} f_n = 1 \cdot \left(\frac{1}{2^n} - \frac{1}{2^{2n+1}} \right) + (1 - 2^{n+1}) \cdot \frac{1}{2^{2n+1}} = \frac{1}{2^n} - \frac{2^{n+1}}{2^{2n+1}} = \frac{1}{2^n} - \frac{1}{2^n} = 0.$$

Call this identity (*). Note that $m(I_k) = 1/2^n$ and $m(J_k) = 1/2^{2n+1}$ were used, together with $f_n = 1$ on $I_k \setminus J_k$ and $f_n = 1 - 2^{n+1}$ on J_k .

(i) Let $x \in [0, 1]$. If $x = 1$, then by (*), $\int_0^1 f_n = \sum_{k=0}^{2^n-1} \int_{I_k} f_n = 0$, and the bound holds. Otherwise let k be the unique index with $x \in I_k$, and write $x = k/2^n + t$ with $0 \leq t < 1/2^n$. By (*) the integrals over $I_0, \dots, I_{k-1}$ all vanish, so

$$\int_0^x f_n = \int_{k/2^n}^{k/2^n+t} f_n =: \varphi(t).$$

If $0 \leq t \leq 1/2^{2n+1}$, the interval of integration lies in J_k , where $f_n = 1 - 2^{n+1}$, so

$$\varphi(t) = (1 - 2^{n+1})t,$$

which decreases from $\varphi(0) = 0$ to $\varphi(1/2^{2n+1}) = 1/2^{2n+1} - 1/2^n$. If $1/2^{2n+1} \leq t < 1/2^n$, then

$$\varphi(t) = \left(\frac{1}{2^{2n+1}} - \frac{1}{2^n} \right) + \left(t - \frac{1}{2^{2n+1}} \right),$$

since $f_n = 1$ on $I_k \setminus J_k$; this increases with t and its supremum, at $t = 1/2^n$, is 0. Hence φ takes values between $1/2^{2n+1} - 1/2^n$ and 0, so

$$\left| \int_0^x f_n \right| = |\varphi(t)| \leq \frac{1}{2^n} - \frac{1}{2^{2n+1}} \leq \frac{1}{2^n}.$$

Since $f \equiv 0$, $\int_0^x f = 0$ for every x , and since $1/2^n \rightarrow 0$,

$$\lim_{n \rightarrow \infty} \int_0^x f_n = 0 = \int_0^x f \quad \text{for all } x \in [0, 1].$$

(ii) Since $1 - 2^{n+1} \neq 1$, the set on which $f_n = 1$ is exactly A_n . Therefore

$$E = \bigcap_{n=1}^{\infty} A_n = [0, 1] \setminus \bigcup_{n=1}^{\infty} B_n,$$

which is measurable. By the countable subadditivity and monotonicity of Lebesgue measure,

$$m\left(\bigcup_{n=1}^{\infty} B_n\right) \leq \sum_{n=1}^{\infty} m(B_n) = \sum_{n=1}^{\infty} \frac{1}{2^{n+1}} = \frac{1}{2},$$

and hence

$$m(E) \geq 1 - \frac{1}{2} = \frac{1}{2} > 0.$$

Since $f_n \equiv 1$ on E ,

$$\int_E f_n = m(E) \geq \frac{1}{2} > 0 \text{ for all } n.$$

(iii) We compute the L^1 norm:

$$\|f_n\|_1 = \int_{A_n} |f_n| + \int_{B_n} |f_n| = \left(1 - \frac{1}{2^{n+1}}\right) + (2^{n+1} - 1) \cdot \frac{1}{2^{n+1}} = 2 - \frac{1}{2^n} \leq 2.$$

So $\{f_n\}$ is a bounded sequence in $L^1[0, 1]$.

The conjugate of $p = 1$ is $q = \infty$, and χ_E belongs to $L^\infty[0, 1]$. If $\{f_n\}$ converged weakly to $f \equiv 0$ in $L^1[0, 1]$, then, testing against χ_E ,

$$\lim_{n \rightarrow \infty} \int_0^1 f_n \cdot \chi_E = \int_0^1 f \cdot \chi_E = 0.$$

But by part (ii), $\int_0^1 f_n \cdot \chi_E = \int_E f_n = m(E) \geq 1/2$ for every n , so this limit is $m(E) > 0$, a contradiction. Hence $\{f_n\}$ does not converge weakly in $L^1[0, 1]$ to f .

This does not contradict Theorem 11, because Theorem 11 is stated only for $1 < p < \infty$. What parts (i) and (iii) do show is that the theorem genuinely fails at $p = 1$: here $\{f_n\}$ is a bounded sequence in $L^1[0, 1]$, $f \in L^1[0, 1]$, and $\lim_n \int_0^x f_n = \int_0^x f$ for every $x \in [0, 1]$, and yet $\{f_n\}$ does not converge weakly to f in $L^1[0, 1]$. The reason is the one recorded in the text after Theorem 11: the proof of Theorem 11 runs through Proposition 9 and requires the linear span of the characteristic functions of intervals, that is, the step functions, to be dense in $L^q[0, 1]$; for $q = \infty$ the step functions are not dense in $L^\infty[0, 1]$. This is exactly the remark the text makes immediately after Theorem 11, and the function χ_E above is a witness to it. Indeed, we claim that $\|\chi_E - \varphi\|_\infty \geq 1/2$ for every step function φ on $[0, 1]$. First observe that if I is an interval with $m(I \cap E) > 0$, then $m(I \setminus E) > 0$: choose n with $1/2^n < m(I)$, so that I contains some I_k in its entirety, hence contains J_k , and $J_k \subseteq B_n \subseteq [0, 1] \setminus E$ has positive measure. Now let φ be a step function, determined by a finite partition of $[0, 1]$ into intervals on each of which φ is constant. Since $m(E) \geq 1/2 > 0$, at least one partition interval I has $m(I \cap E) > 0$; by the observation, $m(I \setminus E) > 0$ as well. If c is the value of φ on I , then $\chi_E - \varphi$ equals $1 - c$ on a subset of I of positive measure and equals $-c$ on a subset of I of positive measure, so

$$\|\chi_E - \varphi\|_\infty \geq \max\{|1 - c|, |c|\} \geq \frac{1}{2},$$

which proves the claim.

(iv) Fix $1 < p < \infty$ and let $q = p/(p - 1)$ be its conjugate. Each f_n is bounded and measurable on a set of finite measure, so $\{f_n\}$ is a sequence in $L^p[0, 1]$, and $f \equiv 0$ belongs to $L^p[0, 1]$. Also χ_E belongs to $L^q[0, 1]$, since $m(E) < \infty$. Exactly as in part (iii), if $\{f_n\}$ converged weakly to f in $L^p[0, 1]$, then

$$0 = \int_0^1 f \cdot \chi_E = \lim_{n \rightarrow \infty} \int_0^1 f_n \cdot \chi_E = \lim_{n \rightarrow \infty} m(E) = m(E) \geq \frac{1}{2},$$

a contradiction. So $\{f_n\}$ does not converge weakly in $L^p[0, 1]$ to f .

Again there is no contradiction with Theorem 11, but now for a different reason: Theorem 11 assumes that $\{f_n\}$ is a *bounded* sequence in $L^p[0, 1]$, and for $p > 1$ this sequence is not bounded. Indeed,

$$\|f_n\|_p^p = \int_{A_n} 1 + \int_{B_n} (2^{n+1} - 1)^p = \left(1 - \frac{1}{2^{n+1}}\right) + \frac{(2^{n+1} - 1)^p}{2^{n+1}} \geq \frac{(2^{n+1} - 1)^p}{2^{n+1}}.$$

Since $2^{n+1} - 1 \geq 2^n$, we get $\|f_n\|_p^p \geq 2^{np}/2^{n+1} = 2^{n(p-1)-1}$, and hence

$$\|f_n\|_p \geq 2^{(n(p-1)-1)/p} \rightarrow \infty \text{ as } n \rightarrow \infty,$$

because $p > 1$. So the hypothesis of Theorem 11 fails, and the theorem says nothing about this sequence.

Problem 8.45. Find a sequence $\{g_n\}$ in $L^2[0, 1]$ that has no Cauchy subsequence. Use this subsequence and the denseness of the continuous functions in $L^2[0, 1]$ to find a sequence of continuous functions on $[0, 1]$ for which no subsequence converges in $L^2[0, 1]$ to a function in $L^2[0, 1]$.

Solution. *A sequence with no Cauchy subsequence.* For each natural number n let

$$J_n = (2^{-n}, 2^{-n+1}] \subseteq [0, 1], \quad g_n = 2^{n/2} \chi_{J_n}.$$

Each g_n is a bounded measurable function, so it belongs to $L^2[0, 1]$, and since $m(J_n) = 2^{-n}$,

$$\|g_n\|_2^2 = \int_0^1 2^n \chi_{J_n} = 2^n \cdot 2^{-n} = 1.$$

The intervals J_n are pairwise disjoint, so for $n \neq m$ the functions g_n and g_m have disjoint supports and therefore $g_n \cdot g_m = 0$ on $[0, 1]$. Consequently, for $n \neq m$,

$$\|g_n - g_m\|_2^2 = \int_0^1 (g_n^2 - 2g_n g_m + g_m^2) = \|g_n\|_2^2 + \|g_m\|_2^2 = 2,$$

that is, $\|g_n - g_m\|_2 = \sqrt{2}$ whenever $n \neq m$.

Now let $\{g_{n_k}\}$ be any subsequence. Since the indices n_k are distinct, $\|g_{n_j} - g_{n_k}\|_2 = \sqrt{2}$ for all $j \neq k$. Taking $\epsilon = 1$ in the definition of a Cauchy sequence, there is no index K beyond which all pairwise distances are less than 1. Hence no subsequence of $\{g_n\}$ is Cauchy in $L^2[0, 1]$; in particular, since a convergent sequence is Cauchy, no subsequence of $\{g_n\}$ converges in $L^2[0, 1]$.

Passing to continuous functions. By Theorem 12 of Chapter 7, $C_c(E)$ is dense in $L^p(E)$ for $1 \leq p < \infty$; taking $E = [0, 1]$ and $p = 2$, and noting that $[0, 1]$ is itself bounded so that $C_c[0, 1]$ is the whole space of continuous functions on $[0, 1]$, the continuous functions on $[0, 1]$ are dense in $L^2[0, 1]$. Hence for each natural number n we may choose a continuous function h_n on $[0, 1]$ for which

$$\|h_n - g_n\|_2 < \frac{1}{n}.$$

We claim that no subsequence of $\{h_n\}$ converges in $L^2[0, 1]$ to a function in $L^2[0, 1]$. Suppose, to the contrary, that $\{h_{n_k}\}$ converges in $L^2[0, 1]$ to some $h \in L^2[0, 1]$. A convergent sequence in a normed linear space is Cauchy (Proposition 4 of Chapter 7), so $\{h_{n_k}\}$ is Cauchy in $L^2[0, 1]$. But then, for all indices j and k , by the triangle inequality,

$$\|g_{n_j} - g_{n_k}\|_2 \leq \|g_{n_j} - h_{n_j}\|_2 + \|h_{n_j} - h_{n_k}\|_2 + \|h_{n_k} - g_{n_k}\|_2 < \frac{1}{n_j} + \|h_{n_j} - h_{n_k}\|_2 + \frac{1}{n_k}.$$

Given $\epsilon > 0$, choose K_1 so that $\|h_{n_j} - h_{n_k}\|_2 < \epsilon/3$ for $j, k \geq K_1$, and choose K_2 so that $1/n_k < \epsilon/3$ for $k \geq K_2$; this is possible since $n_k \geq k$. Then for $j, k \geq \max\{K_1, K_2\}$ we have $\|g_{n_j} - g_{n_k}\|_2 < \epsilon$. Thus $\{g_{n_k}\}$ would be a Cauchy subsequence of $\{g_n\}$, contradicting what was proved above. Therefore no subsequence of the sequence $\{h_n\}$ of continuous functions converges in $L^2[0, 1]$ to a function in $L^2[0, 1]$.

Remark. Observe that $\|h_n\|_2 \leq \|g_n\|_2 + \|h_n - g_n\|_2 < 1 + 1/n \leq 2$ for all n , so $\{h_n\}$ is a bounded sequence of continuous functions; replacing h_n by $h_n/2$ (which changes nothing, since a convergent subsequence of $\{h_n/2\}$ would give one of $\{h_n\}$) produces continuous functions with $\int_0^1 |h_n|^2 \leq 1$ for all n and with no subsequence converging in $L^2[0, 1]$. Thus the Bolzano-Weierstrass Theorem does not extend to bounded sets in $L^2[0, 1]$, even to bounded sets of continuous functions. Note also that, by the Riesz-Fischer Theorem, $L^2[0, 1]$ is complete, so for a sequence in $L^2[0, 1]$ convergence to a function in $L^2[0, 1]$ is equivalent to being Cauchy; this is why the absence of Cauchy subsequences is exactly the absence of convergent subsequences.

9.1 Problems 9.1–9.7

Problem 9.1. Show that two metrics ρ and τ on the same set X are equivalent if and only if there is a $c > 0$ such that for all $u, v \in X$,

$$\frac{1}{c} \tau(u, v) \leq \rho(u, v) \leq c \tau(u, v).$$

Solution. Recall the definition: ρ and τ are equivalent provided there are positive numbers c_1 and c_2 such that

$$c_1 \cdot \tau(x_1, x_2) \leq \rho(x_1, x_2) \leq c_2 \cdot \tau(x_1, x_2) \quad \text{for all } x_1, x_2 \in X.$$

Suppose first that ρ and τ are equivalent, and let $c_1, c_2 > 0$ be as in the definition. Define

$$c = \max \left\{ \frac{1}{c_1}, c_2 \right\}.$$

Then $c > 0$, since both $1/c_1$ and c_2 are positive. Moreover $c \geq c_2$, so for all $u, v \in X$,

$$\rho(u, v) \leq c_2 \tau(u, v) \leq c \tau(u, v),$$

where we used $\tau(u, v) \geq 0$. Also $c \geq 1/c_1$, and hence $1/c \leq c_1$; therefore, again using $\tau(u, v) \geq 0$,

$$\frac{1}{c} \tau(u, v) \leq c_1 \tau(u, v) \leq \rho(u, v).$$

Combining the two displays, $\frac{1}{c} \tau(u, v) \leq \rho(u, v) \leq c \tau(u, v)$ for all $u, v \in X$, which is the asserted inequality.

Conversely, suppose there is a $c > 0$ with

$$\frac{1}{c} \tau(u, v) \leq \rho(u, v) \leq c \tau(u, v) \quad \text{for all } u, v \in X.$$

Set $c_1 = 1/c$ and $c_2 = c$. Both are positive, and the displayed inequality is exactly

$$c_1 \cdot \tau(u, v) \leq \rho(u, v) \leq c_2 \cdot \tau(u, v) \quad \text{for all } u, v \in X,$$

so ρ and τ are equivalent.

It is worth recording the symmetry that this reformulation makes transparent: the condition $\frac{1}{c} \tau \leq \rho \leq c \tau$ is unchanged if the roles of ρ and τ are interchanged, since it is equivalent to $\frac{1}{c} \rho \leq \tau \leq c \rho$. Indeed, from $\rho \leq c \tau$ we get $\frac{1}{c} \rho \leq \tau$, and from $\frac{1}{c} \tau \leq \rho$ we get $\tau \leq c \rho$. Hence equivalence of metrics is a symmetric relation. It is also reflexive (take $c = 1$) and transitive: if $\frac{1}{c} \tau \leq \rho \leq c \tau$ and $\frac{1}{c'} \sigma \leq \tau \leq c' \sigma$, then

$$\frac{1}{cc'} \sigma \leq \frac{1}{c} \tau \leq \rho \leq c \tau \leq cc' \sigma,$$

so ρ and σ are equivalent with constant cc' . Thus equivalence of metrics is an equivalence relation on the set of metrics on X .

Problem 9.2. Show that the following define equivalent metrics on $\mathbb{R}^n$:

$$\rho^*(x, y) = |x_1 - y_1| + \cdots + |x_n - y_n|;$$

$$\rho^+(x, y) = \max\{|x_1 - y_1|, \dots, |x_n - y_n|\}.$$

Solution. Write $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ for points of $\mathbb{R}^n$.

Both are metrics. Each arises from a norm on the linear space $\mathbb{R}^n$ by the recipe $\rho(x, y) = \|x - y\|$ of

formula (1) of Section 9.1. Define

$$\|u\|_* = |u_1| + \cdots + |u_n|, \quad \|u\|_+ = \max\{|u_1|, \dots, |u_n|\}.$$

Both are nonnegative real-valued. Each vanishes exactly at $u = 0$: $\|u\|_* = 0$ forces every $|u_i| = 0$ since the $|u_i|$ are nonnegative and sum to 0, and $\|u\|_+ = 0$ forces $|u_i| \leq 0$, hence $u_i = 0$, for each i . Homogeneity is immediate from $|\alpha u_i| = |\alpha| |u_i|$: summing gives $\|\alpha u\|_* = |\alpha| \|u\|_*$, and taking maxima gives $\|\alpha u\|_+ = |\alpha| \|u\|_+$ (for $\alpha = 0$ both sides are 0). For the triangle inequality, the inequality $|u_i + v_i| \leq |u_i| + |v_i|$ for real numbers gives, upon summation over i , that $\|u + v\|_* \leq \|u\|_* + \|v\|_*$; and for each i ,

$$|u_i + v_i| \leq |u_i| + |v_i| \leq \|u\|_+ + \|v\|_+,$$

so taking the maximum over i on the left gives $\|u + v\|_+ \leq \|u\|_+ + \|v\|_+$. Thus $\|\cdot\|_*$ and $\|\cdot\|_+$ are norms, and, as observed in Section 9.1, the induced functions $\rho^*(x, y) = \|x - y\|_*$ and $\rho^+(x, y) = \|x - y\|_+$ are metrics: properties (i)-(iii) of a metric are immediate from the corresponding properties of the norm together with $\| - u \| = \| - 1 \| \|u\| = \|u\|$, and the triangle inequality (iv) for the metric is, as noted in the text, equivalent to the triangle inequality for the norm, via $x - y = (x - z) + (z - y)$.

Equivalence. Fix $x, y \in \mathbb{R}^n$ and put $t_i = |x_i - y_i| \geq 0$ for $1 \leq i \leq n$, so that

$$\rho^*(x, y) = t_1 + \cdots + t_n, \quad \rho^+(x, y) = \max\{t_1, \dots, t_n\}.$$

Choose an index k with $t_k = \max\{t_1, \dots, t_n\}$. Since every $t_i \geq 0$,

$$\rho^+(x, y) = t_k \leq t_1 + \cdots + t_n = \rho^*(x, y).$$

On the other hand, each $t_i \leq t_k$, so

$$\rho^*(x, y) = t_1 + \cdots + t_n \leq n t_k = n \cdot \rho^+(x, y).$$

Therefore

$$1 \cdot \rho^+(x, y) \leq \rho^*(x, y) \leq n \cdot \rho^+(x, y) \quad \text{for all } x, y \in \mathbb{R}^n,$$

which is precisely the definition of equivalence with $c_1 = 1$ and $c_2 = n$. (In the formulation of the preceding problem, one may take $c = n$, since $n \geq 1$ gives $\frac{1}{n}\rho^+ \leq \rho^+ \leq \rho^* \leq n\rho^+$.)

Problem 9.3. Find a metric on $\mathbb{R}^n$ that fails to be equivalent to either of those defined in the preceding problem.

Solution. Take ρ to be the discrete metric on $X = \mathbb{R}^n$, described in Section 9.1:

$$\rho(x, y) = \begin{cases} 0, & x = y, \\ 1, & x \neq y. \end{cases}$$

ρ is a metric. Clearly $\rho(x, y) \geq 0$, $\rho(x, y) = 0$ if and only if $x = y$, and $\rho(x, y) = \rho(y, x)$, since the defining condition $x = y$ is symmetric in x and y . For the triangle inequality, let $x, y, z \in \mathbb{R}^n$. If $x = y$ then $\rho(x, y) = 0 \leq \rho(x, z) + \rho(z, y)$ because ρ is nonnegative. If $x \neq y$, then z cannot equal both x and y ; hence at least one of $\rho(x, z)$, $\rho(z, y)$ equals 1, and therefore

$$\rho(x, y) = 1 \leq \rho(x, z) + \rho(z, y).$$

Next, ρ is not equivalent to ρ^* . Suppose it were. Then there would be a $c_1 > 0$ with

$$c_1 \cdot \rho^*(x, y) \leq \rho(x, y) \leq 1 \quad \text{for all } x, y \in \mathbb{R}^n,$$

the final inequality because ρ takes only the values 0 and 1. Thus $\rho^*(x, y) \leq 1/c_1$ for all x, y ; that is, ρ^* is a bounded function on $\mathbb{R}^n \times \mathbb{R}^n$. But ρ^* is unbounded: taking $x = 0$ and $y_t = (t, 0, \dots, 0)$ for $t > 0$ gives

$$\rho^*(0, y_t) = |t - 0| + 0 + \cdots + 0 = t,$$

which exceeds $1/c_1$ once $t > 1/c_1$. This contradiction shows ρ and ρ^* are not equivalent.

ρ is not equivalent to ρ^+ . The same argument applies verbatim, since $\rho^+(0, y_t) = \max\{t, 0, \dots, 0\} = t$ is likewise unbounded in t . Alternatively, invoke the preceding problem: ρ^* and ρ^+ are equivalent, and, as shown in Problem 1, equivalence of metrics is a transitive relation; so if ρ were equivalent to ρ^+ it would be equivalent to ρ^* , which we have just excluded.

The essential mechanism is that ρ is a bounded metric while ρ^* and ρ^+ are unbounded, and the inequality $c_1\rho^* \leq \rho$ required by equivalence transfers boundedness. Any bounded metric on $\mathbb{R}^n$ would do equally well; for instance $\sigma(x, y) = \min\{1, \rho^*(x, y)\}$ is a bounded metric, hence not equivalent to either ρ^* or ρ^+ . That σ is a metric is checked as follows: it is nonnegative, vanishes exactly when $\rho^*(x, y) = 0$, that is, when $x = y$, and is symmetric; for the triangle inequality, fix x, y, z and consider the two cases. If $\sigma(x, z) = 1$ or $\sigma(z, y) = 1$, then $\sigma(x, z) + \sigma(z, y) \geq 1 \geq \sigma(x, y)$. Otherwise $\sigma(x, z) = \rho^*(x, z)$ and $\sigma(z, y) = \rho^*(z, y)$, so

$$\sigma(x, y) \leq \rho^*(x, y) \leq \rho^*(x, z) + \rho^*(z, y) = \sigma(x, z) + \sigma(z, y).$$

Problem 9.4. For a closed, bounded interval $[a, b]$, consider the set $X = C[a, b]$ of continuous real-valued functions on $[a, b]$. Show that the metric induced by the maximum norm and that induced by the $L^1[a, b]$ norm are not equivalent.

Solution. Here $[a, b]$ is a nondegenerate interval, so $a < b$. Denote the two metrics on $X = C[a, b]$ by

$$\rho_{\max}(f, g) = \|f - g\|_{\max} = \max\{|f(x) - g(x)| : x \in [a, b]\}, \quad \rho_1(f, g) = \|f - g\|_1 = \int_a^b |f - g|.$$

Both are metrics on X : the maximum norm is a norm on $C[a, b]$ as recalled in Section 9.1, and the $L^1[a, b]$ norm restricted to $C[a, b]$ is a norm as well, since a continuous function on $[a, b]$ with $\int_a^b |h| = 0$ vanishes identically. (Indeed, if h is continuous and $h(x_0) \neq 0$ for some $x_0 \in [a, b]$, then by continuity $|h| > |h(x_0)|/2$ on a nondegenerate subinterval $I \subseteq [a, b]$ containing x_0 , whence by the monotonicity of integration $\int_a^b |h| \geq \frac{1}{2}|h(x_0)| \cdot \ell(I) > 0$.) The metrics they induce are then given by formula (1) of Section 9.1.

One of the two comparisons required for equivalence does hold: since $|f(x) - g(x)| \leq \|f - g\|_{\max}$ for every $x \in [a, b]$, monotonicity of the integral gives

$$\rho_1(f, g) = \int_a^b |f - g| \leq (b - a) \|f - g\|_{\max} = (b - a) \rho_{\max}(f, g).$$

We show that no inequality in the opposite direction is possible; that is, there is no $c > 0$ with $\rho_{\max}(f, g) \leq c\rho_1(f, g)$ for all $f, g \in X$. This suffices: by the preceding problems, if $\rho_{\max}$ and ρ_1 were equivalent then, in either order of the two metrics in the definition, there would be a $c > 0$ with $\frac{1}{c}\rho_1 \leq \rho_{\max} \leq c\rho_1$ throughout $X \times X$, and in particular $\rho_{\max} \leq c\rho_1$.

Choose a natural number N with $1/N < b - a$, and for each natural number $n \geq N$ define $f_n : [a, b] \rightarrow \mathbb{R}$ by

$$f_n(x) = \max\{0, 1 - n(x - a)\}.$$

Each f_n is continuous, being the maximum of two continuous functions, so $f_n \in X$. Explicitly, $f_n(x) = 1 - n(x - a)$ for $a \leq x \leq a + 1/n$ and $f_n(x) = 0$ for $a + 1/n \leq x \leq b$; note $a + 1/n \leq a + 1/N < b$, so this describes f_n on all of $[a, b]$.

Let $g \equiv 0$, the zero function, which belongs to X . Since $f_n(a) = 1$ and $0 \leq f_n \leq 1$ everywhere,

$$\rho_{\max}(f_n, g) = \max\{|f_n(x)| : x \in [a, b]\} = 1.$$

On the other hand, f_n vanishes on $[a + 1/n, b]$ and the region under its graph over $[a, a + 1/n]$ is a triangle of base $1/n$ and height 1, so

$$\rho_1(f_n, g) = \int_a^b |f_n| = \int_a^{a+1/n} (1 - n(x - a)) dx = \left[(x - a) - \frac{n}{2}(x - a)^2 \right]_a^{a+1/n} = \frac{1}{n} - \frac{1}{2n} = \frac{1}{2n}.$$

Now suppose, for the sake of contradiction, that the two metrics were equivalent. Then there would be a $c > 0$ with $\rho_{\max}(f, g) \leq c \rho_1(f, g)$ for all $f, g \in X$. Applying this to $f = f_n$ and $g \equiv 0$ gives

$$1 \leq c \cdot \frac{1}{2n} \quad \text{for every } n \geq N,$$

that is, $n \leq c/2$ for every $n \geq N$. This is false for n large, by the Archimedean property of $\mathbb{R}$. This contradiction shows that no such c exists, and hence the metric induced by the maximum norm and the metric induced by the $L^1[a, b]$ norm are not equivalent.

Informally: convergence in the L^1 metric does not control the size of a function at a single point, and the tall thin spikes f_n have maximum distance 1 from 0 while their L^1 distance from 0 tends to 0.

Problem 9.5. The Nikodym Metric. Let E be a Lebesgue measurable set of real numbers of finite measure, X the set of Lebesgue measurable subsets of E , and m Lebesgue measure. For $A, B \in X$, define $\rho(A, B) = m(A \Delta B)$, where $A \Delta B = [A \sim B] \cup [B \sim A]$, the symmetric difference of A and B . Show that this is a pseudometric on X . Define two measurable sets to be equivalent provided their symmetric difference has measure zero. Show that ρ induces a metric on the collection of equivalence classes. Finally, show that for $A, B \in X$,

$$\rho(A, B) = \int_E |\chi_A - \chi_B|,$$

where χ_A and χ_B are the characteristic functions of A and B , respectively.

Solution. Throughout, A, B, C denote members of X , that is, Lebesgue measurable subsets of E ; recall $m(E) < \infty$.

ρ is well defined and real-valued. Since the Lebesgue measurable sets form a σ -algebra, $A \sim B = A \cap B^c$ and $B \sim A$ are measurable, hence so is their union $A \Delta B$. Moreover $A \Delta B \subseteq E$, so by the monotonicity of measure $\rho(A, B) = m(A \Delta B) \leq m(E) < \infty$. Thus $\rho: X \times X \rightarrow \mathbb{R}$.

Property (i). $\rho(A, B) = m(A \Delta B) \geq 0$, since measure is nonnegative.

Property (ii) in the pseudometric form. If $A = B$ then $A \sim B = B \sim A = \emptyset$, so $A \Delta B = \emptyset$ and $\rho(A, A) = m(\emptyset) = 0$. The converse implication fails, which is why ρ is only a pseudometric: for $E = [0, 1]$, $A = [0, 1]$ and $B = (0, 1]$ we have $A \Delta B = \{0\}$, so $\rho(A, B) = 0$ although $A \neq B$.

Property (iii). The definition $A \Delta B = [A \sim B] \cup [B \sim A]$ is unchanged when A and B are interchanged, since union is commutative. Hence $A \Delta B = B \Delta A$ and $\rho(A, B) = \rho(B, A)$.

Property (iv), the triangle inequality. We claim that for all $A, B, C \in X$,

$$A \Delta B \subseteq [A \Delta C] \cup [C \Delta B].$$

Indeed, let $x \in A \Delta B$. Two cases. If $x \in A \sim B$, then $x \in A$ and $x \notin B$. Should $x \in C$, then $x \in C \sim B \subseteq C \Delta B$; should $x \notin C$, then $x \in A \sim C \subseteq A \Delta C$. Either way x lies in the right-hand side. If instead $x \in B \sim A$, the same argument with the roles of A and B interchanged, using $A \Delta C = C \Delta A$ and $C \Delta B = B \Delta C$, again places x in the right-hand side. This proves the claim.

Now by the monotonicity and the finite subadditivity of Lebesgue measure,

$$\rho(A, B) = m(A \Delta B) \leq m([A \Delta C] \cup [C \Delta B]) \leq m(A \Delta C) + m(C \Delta B) = \rho(A, C) + \rho(C, B).$$

Hence ρ satisfies (i), (iii), (iv) and $\rho(A, A) = 0$ for all A : it is a pseudometric on X .

The induced metric on equivalence classes. Define $A \cong B$ provided $m(A \Delta B) = 0$, i.e. provided $\rho(A, B) = 0$. This is exactly the relation described in Section 9.1 for a general pseudometric, and it is an equivalence relation. Reflexivity: $\rho(A, A) = 0$. Symmetry: ρ is symmetric. Transitivity: if $\rho(A, B) = 0$ and $\rho(B, C) = 0$, then by the triangle inequality and nonnegativity, $0 \leq \rho(A, C) \leq \rho(A, B) + \rho(B, C) = 0$, so $\rho(A, C) = 0$.

Let $X/\cong$ denote the collection of equivalence classes and, for classes $[A]$ and $[B]$, define

$$\tilde{\rho}([A], [B]) = \rho(A, B).$$

This is well defined, that is, independent of the representatives chosen. Suppose $A \cong A'$ and $B \cong B'$. Two applications of the triangle inequality give

$$\rho(A, B) \leq \rho(A, A') + \rho(A', B') + \rho(B', B) = 0 + \rho(A', B') + 0 = \rho(A', B'),$$

where we used $\rho(B', B) = \rho(B, B') = 0$; interchanging the roles of the primed and unprimed sets gives the reverse inequality, so $\rho(A, B) = \rho(A', B')$.

Finally, $\tilde{\rho}$ is a metric on $X/\cong$. Nonnegativity and symmetry are inherited from ρ , as is the triangle inequality:

$$\tilde{\rho}([A], [B]) = \rho(A, B) \leq \rho(A, C) + \rho(C, B) = \tilde{\rho}([A], [C]) + \tilde{\rho}([C], [B]).$$

And $\tilde{\rho}([A], [B]) = 0$ means $\rho(A, B) = 0$, which is precisely $A \cong B$, that is, $[A] = [B]$; conversely $[A] = [B]$ gives $\tilde{\rho}([A], [B]) = \rho(A, A) = 0$. So $\tilde{\rho}$ vanishes exactly on the diagonal, and $(X/\cong, \tilde{\rho})$ is a metric space.

The integral formula. Fix $A, B \in X$ and let $x \in E$. The number $\chi_A(x) - \chi_B(x)$ takes only the values $-1, 0, 1$, and it is nonzero precisely when exactly one of the statements $x \in A$, $x \in B$ holds. Explicitly: if $x \in A \cap B$ or $x \in E \sim [A \cup B]$, then $\chi_A(x) = \chi_B(x)$ and the difference is 0; if $x \in A \sim B$ the difference is 1; if $x \in B \sim A$ it is -1 . Since $A \Delta B$ is exactly the set of points lying in exactly one of A and B , we conclude

$$|\chi_A(x) - \chi_B(x)| = \chi_{A \Delta B}(x) \quad \text{for all } x \in E.$$

The function $\chi_{A \Delta B}$ is a nonnegative measurable simple function on E , bounded by 1, and E has finite measure, so it is integrable over E and its integral is the measure of the set on which it takes the value 1, namely

$$\int_E |\chi_A - \chi_B| = \int_E \chi_{A \Delta B} = m(A \Delta B) = \rho(A, B),$$

using $A \Delta B \subseteq E$. This is the asserted identity.

Problem 9.6. Show that for $a, b, c \geq 0$,

$$\text{if } a \leq b + c, \text{ then } \frac{a}{1+a} \leq \frac{b}{1+b} + \frac{c}{1+c}.$$

Solution. Define $\varphi: [0, \infty) \rightarrow \mathbb{R}$ by

$$\varphi(t) = \frac{t}{1+t} = 1 - \frac{1}{1+t}.$$

This is well defined since $1+t \geq 1 > 0$ for $t \geq 0$.

The function φ is increasing on $[0, \infty)$. Indeed, if $0 \leq s \leq t$, then

$$\varphi(t) - \varphi(s) = \frac{1}{1+s} - \frac{1}{1+t} = \frac{(1+t) - (1+s)}{(1+s)(1+t)} = \frac{t-s}{(1+s)(1+t)} \geq 0,$$

because the numerator is nonnegative and the denominator is positive.

Now let $a, b, c \geq 0$ with $a \leq b + c$. Since $b + c \geq 0$ as well, monotonicity of φ gives

$$\frac{a}{1+a} = \varphi(a) \leq \varphi(b+c) = \frac{b+c}{1+b+c} = \frac{b}{1+b+c} + \frac{c}{1+b+c}.$$

It remains to compare each of the last two terms with the corresponding term in the conclusion. Since $c \geq 0$, we have $1+b+c \geq 1+b > 0$, so

$$\frac{b}{1+b+c} \leq \frac{b}{1+b},$$

using $b \geq 0$ (a nonnegative numerator over a larger positive denominator gives a smaller quotient). Symmetrically, since $b \geq 0$ we have $1+b+c \geq 1+c > 0$ and $c \geq 0$, so

$$\frac{c}{1+b+c} \leq \frac{c}{1+c}.$$

Adding the last two inequalities and combining with the preceding display,

$$\frac{a}{1+a} \leq \frac{b}{1+b+c} + \frac{c}{1+b+c} \leq \frac{b}{1+b} + \frac{c}{1+c},$$

which is the asserted inequality.

Problem 9.7. Let E be a Lebesgue measurable set of real numbers that has finite measure and X the set of Lebesgue measurable real-valued functions on E . For $f, g \in X$, define

$$\rho(f, g) = \int_E \frac{|f - g|}{1 + |f - g|}.$$

Use the preceding problem to show that this is a pseudometric on X . Define two measurable functions to be equivalent provided they are equal a.e. on E . Show that ρ induces a metric on the collection of equivalence classes.

Solution. Throughout let $\varphi(t) = t/(1+t)$ for $t \geq 0$, the function studied in the preceding problem; it is increasing, $\varphi(0) = 0$, and $0 \leq \varphi(t) < 1$ for all $t \geq 0$, since $t < 1+t$.

ρ is well defined and real-valued. Let $f, g \in X$. Then $f - g$ is measurable, hence so is $|f - g|$. Extend φ to a continuous real-valued function on all of $\mathbb{R}$ by setting $\varphi(t) = t/(1+|t|)$; by Proposition 7 of Chapter 3, the composition

$$h_{f,g} = \varphi \circ |f - g| = \frac{|f - g|}{1 + |f - g|}$$

is measurable on E . It satisfies $0 \leq h_{f,g} < 1$ on E , so it is a bounded measurable function on the set E of finite measure, and hence, by Theorem 4 of Chapter 4, it is integrable over E . Thus $\rho(f, g) = \int_E h_{f,g}$ is a well-defined real number, and by the monotonicity of integration

$$0 \leq \rho(f, g) \leq m(E) < \infty.$$

Properties (i) and (iii). Nonnegativity was just noted. Symmetry is immediate, since $|f - g| = |g - f|$ pointwise on E , so $h_{f,g} = h_{g,f}$ and therefore $\rho(f, g) = \rho(g, f)$.

ρ vanishes on the diagonal. If $f = g$ on E , then $h_{f,g} \equiv \varphi(0) = 0$ and $\rho(f, f) = 0$. Note that ρ is only a pseudometric: if f and g differ on a set of measure zero but are not identical, then, as shown below, $\rho(f, g) = 0$ while $f \neq g$.

Property (iv), the triangle inequality. Let $f, g, k \in X$ and let $x \in E$. Put

$$a = |f(x) - k(x)|, \quad b = |f(x) - g(x)|, \quad c = |g(x) - k(x)|.$$

These are nonnegative real numbers, and the triangle inequality for absolute values gives $a \leq b + c$. Hence by the preceding problem,

$$\frac{|f(x) - k(x)|}{1 + |f(x) - k(x)|} \leq \frac{|f(x) - g(x)|}{1 + |f(x) - g(x)|} + \frac{|g(x) - k(x)|}{1 + |g(x) - k(x)|},$$

that is, $h_{f,k} \leq h_{f,g} + h_{g,k}$ pointwise on E . All three functions are integrable over E , so by the monotonicity and linearity of integration,

$$\rho(f, k) = \int_E h_{f,k} \leq \int_E (h_{f,g} + h_{g,k}) = \int_E h_{f,g} + \int_E h_{g,k} = \rho(f, g) + \rho(g, k).$$

Therefore ρ is a pseudometric on X .

Identification of the null pairs. We claim that for $f, g \in X$,

$$\rho(f, g) = 0 \quad \text{if and only if} \quad f = g \text{ a.e. on } E.$$

Indeed, $h_{f,g}$ is a nonnegative measurable function on E , so by Proposition 9 of Chapter 4, $\int_E h_{f,g} = 0$ if and only if $h_{f,g} = 0$ a.e. on E . (Proposition 9 concerns the integral of a nonnegative measurable

function as defined in Section 4.3; for our $h_{f,g}$, which is bounded, measurable, and vanishes outside the set E of finite measure, that supremum agrees with the integral of Section 4.2 used above. Indeed $h_{f,g}$ is itself one of the competitors h in the supremum (8), so the supremum is at least $\int_E h_{f,g}$, while every competitor $h \leq h_{f,g}$ has $\int_E h \leq \int_E h_{f,g}$ by the monotonicity of Theorem 5 of Chapter 4.) Now for a point $x \in E$, $h_{f,g}(x) = \varphi(|f(x) - g(x)|)$ vanishes if and only if $|f(x) - g(x)| = 0$, since $\varphi(t) = 0$ with $t \geq 0$ forces $t = 0$ (as $1 + t > 0$). So the set on which $h_{f,g}$ vanishes is exactly the set on which $f = g$, and $h_{f,g} = 0$ a.e. on E if and only if $f = g$ a.e. on E . This proves the claim, and in particular shows ρ genuinely is not a metric on X (take $E = [0, 1]$, $f \equiv 0$ and $g = \chi_{\{0\}}$).

The induced metric on equivalence classes. Define $f \cong g$ provided $f = g$ a.e. on E . This is an equivalence relation on X : reflexivity and symmetry are clear, and if $f = g$ a.e. and $g = k$ a.e., then the set where $f \neq k$ is contained in the union of the two sets of measure zero where $f \neq g$ and where $g \neq k$, hence has measure zero by the countable subadditivity and monotonicity of Lebesgue measure. By the claim just proved, $f \cong g$ if and only if $\rho(f, g) = 0$, so this is precisely the equivalence relation associated with the pseudometric ρ as described in Section 9.1.

For equivalence classes $[f], [g] \in X/\cong$, define

$$\tilde{\rho}([f], [g]) = \rho(f, g).$$

This does not depend on the representatives. Suppose $f \cong f'$ and $g \cong g'$; then $\rho(f, f') = \rho(g, g') = 0$, and two applications of the triangle inequality give

$$\rho(f, g) \leq \rho(f, f') + \rho(f', g') + \rho(g', g) = \rho(f', g'),$$

using symmetry for the last term; interchanging the primed and unprimed functions gives the reverse inequality, so $\rho(f, g) = \rho(f', g')$.

Finally, $\tilde{\rho}$ is a metric on $X/\cong$. It is nonnegative and symmetric, and satisfies the triangle inequality, all inherited directly from the corresponding properties of ρ :

$$\tilde{\rho}([f], [k]) = \rho(f, k) \leq \rho(f, g) + \rho(g, k) = \tilde{\rho}([f], [g]) + \tilde{\rho}([g], [k]).$$

Moreover $\tilde{\rho}([f], [g]) = 0$ if and only if $\rho(f, g) = 0$, which by the claim holds if and only if $f = g$ a.e. on E , that is, if and only if $[f] = [g]$. Hence $\tilde{\rho}$ separates distinct equivalence classes, and $(X/\cong, \tilde{\rho})$ is a metric space.

9.2 Problems 9.8–9.14

Problem 9.8. For $0 < p < 1$, show that

$$(a + b)^p \leq a^p + b^p \text{ for all } a, b \geq 0.$$

Solution. We first record an elementary inequality: if $0 < p < 1$ and $0 \leq t \leq 1$, then

$$t \leq t^p.$$

Indeed, this is clear for $t = 0$, while for $0 < t \leq 1$ we have $t^p/t = t^{p-1} = t^{-(1-p)} \geq 1$, since $0 < t \leq 1$ and $1 - p > 0$ force $t^{-(1-p)} \geq 1$; multiplying through by $t > 0$ gives $t^p \geq t$.

Now let $a, b \geq 0$. If $a = b = 0$ the asserted inequality reads $0 \leq 0$ and there is nothing to prove. So assume $a + b > 0$ and set

$$t = \frac{a}{a + b}, \quad 1 - t = \frac{b}{a + b},$$

so that both t and $1 - t$ lie in $[0, 1]$. By the inequality of the preceding paragraph applied to t and to $1 - t$,

$$1 = t + (1 - t) \leq t^p + (1 - t)^p = \frac{a^p}{(a + b)^p} + \frac{b^p}{(a + b)^p} = \frac{a^p + b^p}{(a + b)^p},$$

where we used that $(a/(a + b))^p = a^p/(a + b)^p$ and similarly for b . Multiplying both sides of this

inequality by the positive number $(a+b)^p$ yields

$$(a+b)^p \leq a^p + b^p.$$

This holds for all $a, b \geq 0$, as required.

We remark, for later use, that the function $t \mapsto t^p$ is increasing on $[0, \infty)$: if $0 \leq s \leq t$ then $s^p \leq t^p$. Indeed, if $s = 0$ this reads $0 \leq t^p$, which holds; and if $0 < s \leq t$, then $t/s \geq 1$, so $(t/s)^p \geq 1$ because $u \mapsto u^p = e^{p \log u}$ is increasing in u for $p > 0$ and equals 1 at $u = 1$, and multiplying $(t/s)^p \geq 1$ by $s^p > 0$ gives $t^p \geq s^p$. Combined with the inequality just proved, this gives the frequently used consequence that for $a, b, c \geq 0$,

$$\text{if } a \leq b + c, \text{ then } a^p \leq (b + c)^p \leq b^p + c^p.$$

Problem 9.9. For E a Lebesgue measurable set of real numbers, $0 < p < 1$, and g and h Lebesgue measurable functions on E that have integrable p th powers, define

$$\rho_p(h, g) = \int_E |g - h|^p.$$

Use the preceding problem to show that this is a pseudometric on the collection of Lebesgue measurable functions on E that have integrable p th powers. Define two such functions to be equivalent provided they are equal a.e. on E . Show that $\rho_p(\cdot, \cdot)$ induces a metric on the collection of equivalence classes.

Solution. Let X denote the collection of Lebesgue measurable real-valued functions f on E for which $|f|^p$ is integrable over E .

The formula is well defined and finite. Let g, h belong to X . The function $g - h$ is measurable, being a difference of measurable real-valued functions. Let $\varphi: \mathbb{R} \rightarrow \mathbb{R}$ be defined by $\varphi(t) = |t|^p$; this is continuous on all of $\mathbb{R}$, since $p > 0$. Hence $|g - h|^p = \varphi \circ (g - h)$ is measurable, by Proposition 7 of Chapter 3, which asserts that the composition of a continuous real-valued function on $\mathbb{R}$ with a measurable real-valued function is measurable. Moreover, pointwise on E we have $|g - h| \leq |g| + |h|$, so by the monotonicity of $t \mapsto t^p$ and the preceding problem,

$$|g - h|^p \leq (|g| + |h|)^p \leq |g|^p + |h|^p.$$

Since $|g|^p$ and $|h|^p$ are integrable over E , so is their sum, and therefore by the monotonicity of integration for nonnegative measurable functions, $|g - h|^p$ is integrable over E and

$$0 \leq \rho_p(h, g) = \int_E |g - h|^p \leq \int_E |g|^p + \int_E |h|^p < \infty.$$

Thus ρ_p is a finite, nonnegative real-valued function on $X \times X$.

Symmetry. Since $|g - h| = |h - g|$ pointwise on E , we have $\rho_p(h, g) = \rho_p(g, h)$.

Vanishing on the diagonal. For $h \in X$, $|h - h|^p \equiv 0$ on E , so $\rho_p(h, h) = 0$.

The triangle inequality. Let f, g, h belong to X . At each point of E , the triangle inequality for the absolute value gives

$$|g - h| \leq |g - f| + |f - h|.$$

Since $t \mapsto t^p$ is increasing on $[0, \infty)$, raising both sides to the power p and then invoking the preceding problem with $a = |g - f|$ and $b = |f - h|$ gives, pointwise on E ,

$$|g - h|^p \leq (|g - f| + |f - h|)^p \leq |g - f|^p + |f - h|^p.$$

All three functions here are nonnegative and integrable over E , so by the monotonicity and linearity of integration,

$$\rho_p(h, g) = \int_E |g - h|^p \leq \int_E |g - f|^p + \int_E |f - h|^p = \rho_p(f, g) + \rho_p(h, f).$$

Thus ρ_p satisfies all the requirements of a metric except possibly the requirement that $\rho_p(h, g) = 0$ only if $h = g$; that is, ρ_p is a pseudometric on X .

Identification of the null pairs. We claim that for $g, h \in X$,

$$\rho_p(h, g) = 0 \text{ if and only if } g = h \text{ a.e. on } E.$$

The function $|g-h|^p$ is nonnegative and integrable over E . By Proposition 9 of Chapter 4, a nonnegative integrable function has integral zero over E if and only if it vanishes a.e. on E . Now $|g(x) - h(x)|^p = 0$ if and only if $|g(x) - h(x)| = 0$, that is, $g(x) = h(x)$, since $t^p = 0$ only for $t = 0$. Hence $\rho_p(h, g) = 0$ if and only if $g = h$ a.e. on E , which proves the claim. In particular ρ_p is genuinely only a pseudometric and not a metric: any two distinct functions in X that agree a.e. (for instance the zero function and the characteristic function of a single point, when E contains a point) are at ρ_p -distance 0.

The induced metric. Define $h \cong g$ provided $h = g$ a.e. on E . This is an equivalence relation on X : it is reflexive and symmetric trivially, and if $h = g$ off a set of measure zero Z_1 and $g = k$ off a set of measure zero Z_2 , then $h = k$ off $Z_1 \cup Z_2$, which has measure zero since the union of two sets of measure zero has measure zero. By the claim above, $h \cong g$ if and only if $\rho_p(h, g) = 0$, so this is exactly the equivalence relation that the pseudometric ρ_p determines, as described in the discussion of pseudometrics in Section 9.1.

Let $X/\cong$ denote the collection of equivalence classes and, for classes $[h]$ and $[g]$, define

$$\tilde{\rho}_p([h], [g]) = \rho_p(h, g).$$

This is well defined: suppose $h' \cong h$ and $g' \cong g$, say $h' = h$ off a set Z_1 of measure zero and $g' = g$ off a set Z_2 of measure zero, and put $Z = Z_1 \cup Z_2$, a set of measure zero. Then $|g' - h'|^p = |g - h|^p$ at every point of $E \sim Z$. Both $|g' - h'|^p$ and $|g - h|^p$ are integrable over E , by the first paragraph applied to the pairs g', h' and g, h , so Proposition 15 of Chapter 4 applies to each and gives

$$\rho_p(h', g') = \int_E |g' - h'|^p = \int_{E \sim Z} |g' - h'|^p = \int_{E \sim Z} |g - h|^p = \int_E |g - h|^p = \rho_p(h, g).$$

Finally, $\tilde{\rho}_p$ is a metric on $X/\cong$. It is nonnegative, real-valued and symmetric, and satisfies the triangle inequality, because ρ_p has all these properties and $\tilde{\rho}_p$ is computed by choosing representatives. And if $\tilde{\rho}_p([h], [g]) = 0$, then $\rho_p(h, g) = 0$, so $h = g$ a.e. on E , that is, $h \cong g$ and therefore $[h] = [g]$. Conversely $[h] = [g]$ gives $\tilde{\rho}_p([h], [g]) = \rho_p(h, h) = 0$. Hence ρ_p induces a metric on the collection of equivalence classes.

Problem 9.10. Let $\{(X_n, \rho_n)\}_{n=1}^\infty$ be a countable collection of metric spaces. Use Problem 6 to show that ρ_* defines a metric on the Cartesian product $\prod_{n=1}^\infty X_n$, where for points $x = \{x_n\}$ and $y = \{y_n\}$ in $\prod_{n=1}^\infty X_n$,

$$\rho_*(x, y) = \sum_{n=1}^\infty \frac{1}{2^n} \cdot \frac{\rho_n(x_n, y_n)}{1 + \rho_n(x_n, y_n)}.$$

Solution. Throughout, write $X = \prod_{n=1}^\infty X_n$ and, for a point $x = \{x_n\}$ and $y = \{y_n\}$ of X ,

$$d_n(x, y) = \frac{\rho_n(x_n, y_n)}{1 + \rho_n(x_n, y_n)}.$$

Recall from Problem 6 that for $a, b, c \geq 0$,

$$\text{if } a \leq b + c, \text{ then } \frac{a}{1+a} \leq \frac{b}{1+b} + \frac{c}{1+c}.$$

(For completeness: the function $\varphi(t) = t/(1+t) = 1 - 1/(1+t)$ is increasing on $[0, \infty)$, so $a \leq b + c$ gives $\varphi(a) \leq \varphi(b+c) = \frac{b}{1+b+c} + \frac{c}{1+b+c} \leq \frac{b}{1+b} + \frac{c}{1+c}$.)

The series converges, and ρ_* is a finite nonnegative function. Since $\rho_n(x_n, y_n) \geq 0$, we have $0 \leq d_n(x, y) < 1$ for every n , so the n th term of the defining series lies in $[0, 2^{-n}]$. The series is therefore

a series of nonnegative terms dominated termwise by the convergent geometric series $\sum 2^{-n}$; by the comparison test it converges, and

$$0 \leq \rho_*(x, y) \leq \sum_{n=1}^{\infty} \frac{1}{2^n} = 1.$$

Thus ρ_* is a well-defined nonnegative real-valued function on $X \times X$.

$\rho_*(x, y) = 0$ if and only if $x = y$. All terms of the series are nonnegative, so the sum vanishes if and only if every term vanishes, that is, if and only if $d_n(x, y) = 0$ for all n . Since $\varphi(t) = t/(1+t)$ vanishes only at $t = 0$, this happens if and only if $\rho_n(x_n, y_n) = 0$ for every n , and since each ρ_n is a metric on X_n this happens if and only if $x_n = y_n$ for every n , that is, if and only if $x = y$ as points of the Cartesian product.

Symmetry. Each ρ_n is symmetric, so $d_n(x, y) = d_n(y, x)$ for every n , and hence $\rho_*(x, y) = \rho_*(y, x)$.

The triangle inequality. Let $x = \{x_n\}$, $y = \{y_n\}$ and $z = \{z_n\}$ belong to X . Fix n and set

$$a = \rho_n(x_n, z_n), \quad b = \rho_n(x_n, y_n), \quad c = \rho_n(y_n, z_n),$$

all nonnegative. The triangle inequality for the metric ρ_n gives $a \leq b + c$, so Problem 6 yields

$$d_n(x, z) = \frac{a}{1+a} \leq \frac{b}{1+b} + \frac{c}{1+c} = d_n(x, y) + d_n(y, z).$$

Multiply by $2^{-n} > 0$ and sum over n . Each of the three series

$$\sum_{n=1}^{\infty} 2^{-n} d_n(x, z), \quad \sum_{n=1}^{\infty} 2^{-n} d_n(x, y), \quad \sum_{n=1}^{\infty} 2^{-n} d_n(y, z)$$

converges, as shown above, so the termwise inequality passes to the limits of the partial sums and we obtain

$$\rho_*(x, z) \leq \rho_*(x, y) + \rho_*(y, z).$$

All the requirements of a metric are met, so ρ_* is a metric on $\prod_{n=1}^{\infty} X_n$. This is the countable analogue of the product metric τ defined in Section 9.1 for a product of two metric spaces.

Problem 9.11. Let (X, ρ) be a metric space and A any set for which there is a one-to-one mapping f of A onto the set X . Show that there is a unique metric on A for which f is an isometry of metric spaces. (This is the sense in which an isometry amounts merely to a relabeling of the points in a space.)

Solution. Recall the definition from Section 9.1: a mapping f from a metric space (A, σ) to a metric space (X, ρ) is an isometry provided it maps A onto X and, for all $a_1, a_2 \in A$,

$$\rho(f(a_1), f(a_2)) = \sigma(a_1, a_2).$$

Uniqueness. Suppose σ is a metric on A for which $f: (A, \sigma) \rightarrow (X, \rho)$ is an isometry. Then by the very definition of isometry, for all a_1, a_2 in A ,

$$\sigma(a_1, a_2) = \rho(f(a_1), f(a_2)).$$

The right-hand side is determined by f and ρ alone. Hence there is at most one such metric, namely the one given by this formula; if σ and σ' both make f an isometry, then $\sigma(a_1, a_2) = \rho(f(a_1), f(a_2)) = \sigma'(a_1, a_2)$ for all $a_1, a_2 \in A$, so $\sigma = \sigma'$.

Existence. Define $\sigma: A \times A \rightarrow \mathbb{R}$ by

$$\sigma(a_1, a_2) = \rho(f(a_1), f(a_2)) \text{ for all } a_1, a_2 \in A.$$

We verify that σ is a metric on A .

- (i) Nonnegativity and finiteness: $\sigma(a_1, a_2) = \rho(f(a_1), f(a_2)) \geq 0$ and is a real number, since ρ is a nonnegative real-valued function on $X \times X$.
- (ii) $\sigma(a_1, a_2) = 0$ if and only if $a_1 = a_2$: if $a_1 = a_2$ then $f(a_1) = f(a_2)$ and so $\sigma(a_1, a_2) = \rho(f(a_1), f(a_1)) = 0$. Conversely, if $\sigma(a_1, a_2) = 0$, then $\rho(f(a_1), f(a_2)) = 0$, and since ρ is a metric on X this forces $f(a_1) = f(a_2)$; because f is one-to-one, $a_1 = a_2$. (This is the only place where the injectivity of f is used, and it is essential: without it σ would only be a pseudometric.)
- (iii) Symmetry: $\sigma(a_1, a_2) = \rho(f(a_1), f(a_2)) = \rho(f(a_2), f(a_1)) = \sigma(a_2, a_1)$, by the symmetry of ρ .
- (iv) The triangle inequality: for a_1, a_2, a_3 in A , the triangle inequality for ρ applied to the three points $f(a_1), f(a_2), f(a_3)$ of X gives

$$\sigma(a_1, a_3) = \rho(f(a_1), f(a_3)) \leq \rho(f(a_1), f(a_2)) + \rho(f(a_2), f(a_3)) = \sigma(a_1, a_2) + \sigma(a_2, a_3).$$

Thus (A, σ) is a metric space. Moreover f maps A onto X by hypothesis and satisfies $\rho(f(a_1), f(a_2)) = \sigma(a_1, a_2)$ by the definition of σ ; hence f is an isometry of (A, σ) onto (X, ρ) . Together with the uniqueness established above, this shows that σ is the one and only metric on A that makes f an isometry.

Problem 9.12. Show that the triangle inequality for Euclidean space $\mathbb{R}^n$ follows from the triangle inequality for $L^2[0, 1]$.

Solution. Fix the natural number n and partition $[0, 1]$ into the n disjoint measurable subintervals

$$I_k = \left[\frac{k-1}{n}, \frac{k}{n} \right), \quad k = 1, \dots, n-1, \quad I_n = \left[\frac{n-1}{n}, 1 \right],$$

each of measure $1/n$. Define a mapping Φ from $\mathbb{R}^n$ into the space of real-valued functions on $[0, 1]$ by

$$\Phi(x) = \sqrt{n} \sum_{k=1}^n x_k \chi_{I_k} \text{ for } x = (x_1, \dots, x_n) \in \mathbb{R}^n,$$

where χ_{I_k} is the characteristic function of I_k . Each $\Phi(x)$ is a simple, hence measurable, function on $[0, 1]$; it is bounded and $[0, 1]$ has finite measure, so $|\Phi(x)|^2$ is integrable over $[0, 1]$ and $\Phi(x)$ belongs to $L^2[0, 1]$.

Φ is linear. Since the I_k are disjoint, for $x, y \in \mathbb{R}^n$ and real α we have, pointwise on $[0, 1]$,

$$\Phi(x + y) = \sqrt{n} \sum_{k=1}^n (x_k + y_k) \chi_{I_k} = \Phi(x) + \Phi(y), \quad \Phi(\alpha x) = \alpha \Phi(x).$$

Φ preserves norms. Because the I_k are disjoint, $\Phi(x)^2 = n \sum_{k=1}^n x_k^2 \chi_{I_k}$ pointwise on $[0, 1]$. Hence, by the linearity of integration and $m(I_k) = 1/n$,

$$\|\Phi(x)\|_2^2 = \int_0^1 |\Phi(x)|^2 = n \sum_{k=1}^n x_k^2 m(I_k) = n \sum_{k=1}^n x_k^2 \cdot \frac{1}{n} = \sum_{k=1}^n x_k^2.$$

Taking square roots,

$$\|\Phi(x)\|_2 = [x_1^2 + \dots + x_n^2]^{1/2} = \|x\|,$$

the Euclidean norm of x .

The triangle inequality for the Euclidean norm. Let $x, y \in \mathbb{R}^n$. Using the two displayed properties of Φ and the triangle inequality for the $L^2[0, 1]$ norm (the Minkowski Inequality for $p = 2$),

$$\|x + y\| = \|\Phi(x + y)\|_2 = \|\Phi(x) + \Phi(y)\|_2 \leq \|\Phi(x)\|_2 + \|\Phi(y)\|_2 = \|x\| + \|y\|.$$

The triangle inequality for the Euclidean metric. As observed in Section 9.1, the triangle inequality for a norm is equivalent to the triangle inequality for the metric it induces. Explicitly, let $x, y, z \in \mathbb{R}^n$ and apply the inequality just proved to the vectors $x - y$ and $y - z$:

$$\rho(x, z) = \|x - z\| = \|(x - y) + (y - z)\| \leq \|x - y\| + \|y - z\| = \rho(x, y) + \rho(y, z).$$

This is the triangle inequality for Euclidean space $\mathbb{R}^n$, deduced from the triangle inequality for $L^2[0, 1]$.

Problem 9.13. In a metric space X , is it possible for $r > 0$ and two distinct points u and v in X to have $B(u, r) = B(v, r)$? Is this possible in Euclidean space $\mathbb{R}^n$? Is it possible in a normed linear space?

Solution. The answers are: yes for a general metric space; no in $\mathbb{R}^n$; and no in any normed linear space. A general metric space: it is possible. Let X be any set containing at least two points, equipped with the discrete metric ρ , so that $\rho(x, y) = 0$ if $x = y$ and $\rho(x, y) = 1$ if $x \neq y$. Take $r = 2$. For every point $x \in X$ and every $x' \in X$ we have $\rho(x', x) \leq 1 < 2$, so

$$B(x, 2) = \{x' \in X \mid \rho(x', x) < 2\} = X.$$

Hence if u and v are any two distinct points of X , then $B(u, 2) = X = B(v, 2)$. So in a general metric space two distinct points can certainly determine the same open ball of a given radius. (Concretely: $X = \{u, v\}$ with the discrete metric.)

Euclidean space $\mathbb{R}^n$: it is not possible. This is a special case of the normed linear space argument below, since the Euclidean metric on $\mathbb{R}^n$ is the metric induced by the Euclidean norm. We give the argument in that generality.

A normed linear space: it is not possible. Let X be a normed linear space with norm $\|\cdot\|$ and induced metric $\rho(x, y) = \|x - y\|$, let $r > 0$, and let u, v be distinct points of X . Set

$$d = \|u - v\| > 0 \quad \text{and} \quad e = \frac{1}{d}(u - v),$$

so that, by the homogeneity of the norm, $\|e\| = \frac{1}{d}\|u - v\| = 1$.

Choose a real number s with

$$\max\{0, r - d\} < s < r.$$

Such an s exists because $r - d < r$ and $0 < r$, so the interval $(\max\{0, r - d\}, r)$ is nonempty. Define the point

$$w = u + se \in X.$$

First, w belongs to $B(u, r)$: indeed $\rho(w, u) = \|w - u\| = \|se\| = s\|e\| = s < r$.

Second, w does not belong to $B(v, r)$: since $u - v = de$, we have

$$w - v = (u - v) + se = de + se = (d + s)e,$$

so, again by homogeneity of the norm,

$$\rho(w, v) = \|w - v\| = (d + s)\|e\| = d + s.$$

By the choice of s we have $s > r - d$, hence $d + s > r$, and therefore $\rho(w, v) > r$, so $w \notin B(v, r)$.

Thus $w \in B(u, r) \setminus B(v, r)$, and in particular $B(u, r) \neq B(v, r)$. Since u and v were arbitrary distinct points and $r > 0$ arbitrary, in a normed linear space distinct points always determine distinct open balls of any given radius. Applying this to $\mathbb{R}^n$ with the Euclidean norm answers the second question in the negative as well.

What makes the discrete example possible, and what the linear structure rules out, is the existence of points at distance exactly prescribed along the segment from v through u : in a normed linear space one can always move from u directly away from v by any amount less than r , and thereby escape $B(v, r)$ while remaining in $B(u, r)$.

Problem 9.14. Let (X, ρ) be a metric space in which $\{u_n\} \rightarrow u$ and $\{v_n\} \rightarrow v$. Show that $\{\rho(u_n, v_n)\} \rightarrow \rho(u, v)$.

Solution. Recall that $\{u_n\} \rightarrow u$ in (X, ρ) means that $\{\rho(u_n, u)\} \rightarrow 0$ as a sequence of real numbers, that is, for each $\epsilon > 0$ there is an index N such that $\rho(u_n, u) < \epsilon$ for all $n \geq N$.

A quadrilateral inequality. We claim that for all points a, b, c, d in X ,

$$|\rho(a, b) - \rho(c, d)| \leq \rho(a, c) + \rho(b, d).$$

To see this, apply the triangle inequality twice:

$$\rho(a, b) \leq \rho(a, c) + \rho(c, b) \leq \rho(a, c) + \rho(c, d) + \rho(d, b),$$

so, using the symmetry of ρ ,

$$\rho(a, b) - \rho(c, d) \leq \rho(a, c) + \rho(b, d).$$

Interchanging the roles of the pair (a, b) with the pair (c, d) in this computation gives

$$\rho(c, d) - \rho(a, b) \leq \rho(c, a) + \rho(d, b) = \rho(a, c) + \rho(b, d).$$

Since the absolute value of a real number is the larger of it and its negative, the two displayed inequalities together give the claim.

Conclusion. Apply the claim with $a = u_n$, $b = v_n$, $c = u$, $d = v$:

$$|\rho(u_n, v_n) - \rho(u, v)| \leq \rho(u_n, u) + \rho(v_n, v) \text{ for every index } n.$$

Let $\epsilon > 0$. Since $\{u_n\} \rightarrow u$, there is an index N_1 such that $\rho(u_n, u) < \epsilon/2$ for all $n \geq N_1$; since $\{v_n\} \rightarrow v$, there is an index N_2 such that $\rho(v_n, v) < \epsilon/2$ for all $n \geq N_2$. Set $N = \max\{N_1, N_2\}$. Then for all $n \geq N$,

$$|\rho(u_n, v_n) - \rho(u, v)| \leq \rho(u_n, u) + \rho(v_n, v) < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Since $\epsilon > 0$ was arbitrary, the sequence of real numbers $\{\rho(u_n, v_n)\}$ converges to $\rho(u, v)$.

Equivalently, this says that the metric $\rho: X \times X \rightarrow \mathbb{R}$ is a continuous mapping when $X \times X$ is given the product metric of Section 9.1, since convergence in that product metric is exactly coordinatewise convergence.

9.3 Problems 9.15–9.21

Problem 9.15. Let X be a metric space, x belong to X and $r > 0$.

- (i) Show that $\overline{B}(x, r)$ is closed and contains $B(x, r)$.
- (ii) Show that in a normed linear space X the closed ball $\overline{B}(x, r)$ is the closure of the open ball $B(x, r)$, but this is not so in a general metric space.

Solution. Throughout, ρ denotes the metric on X , and

$$B(x, r) = \{x' \in X \mid \rho(x', x) < r\}, \quad \overline{B}(x, r) = \{x' \in X \mid \rho(x', x) \leq r\}.$$

- (i) The inclusion $B(x, r) \subseteq \overline{B}(x, r)$ is immediate, since $\rho(x', x) < r$ implies $\rho(x', x) \leq r$.

To show $\overline{B}(x, r)$ is closed we show, by Proposition 4, that its complement $X \sim \overline{B}(x, r)$ is open. Let y belong to $X \sim \overline{B}(x, r)$, so that $\rho(y, x) > r$. Define

$$\delta = \rho(y, x) - r > 0.$$

We claim $B(y, \delta) \subseteq X \sim \overline{B}(x, r)$. Indeed, let z belong to $B(y, \delta)$. By the triangle inequality for ρ ,

$$\rho(y, x) \leq \rho(y, z) + \rho(z, x) < \delta + \rho(z, x),$$

so that

$$\rho(z, x) > \rho(y, x) - \delta = r.$$

Hence z does not belong to $\overline{B}(x, r)$. Thus every point of $X \sim \overline{B}(x, r)$ has an open ball about it that is contained in $X \sim \overline{B}(x, r)$; that is, $X \sim \overline{B}(x, r)$ is open. By Proposition 4, $\overline{B}(x, r)$ is closed.

- (ii) Now let X be a normed linear space, with norm $\|\cdot\|$ and induced metric $\rho(u, v) = \|u - v\|$. Denote by $\overline{B}(x, r)$ the closure of the open ball.

First, $\overline{B}(x, r)$ is a closed set containing $B(x, r)$ by part (i), so Proposition 3 (the closure of a set is the smallest closed set containing it) gives

$$\overline{B(x, r)} \subseteq \overline{B}(x, r).$$

For the reverse inclusion, let y satisfy $\|y - x\| \leq r$. For each natural number n define

$$y_n = x + \left(1 - \frac{1}{n}\right)(y - x),$$

which is a point of X because X is a linear space. By positive homogeneity of the norm,

$$\|y_n - x\| = \left(1 - \frac{1}{n}\right)\|y - x\| \leq \left(1 - \frac{1}{n}\right)r < r,$$

since $r > 0$. Thus y_n belongs to $B(x, r)$ for every n , so $\{y_n\}$ is a sequence in $B(x, r)$. Moreover

$$\|y_n - y\| = \frac{1}{n}\|y - x\| \leq \frac{r}{n} \rightarrow 0 \quad \text{as } n \rightarrow \infty,$$

so $\{y_n\} \rightarrow y$. By Proposition 6, y is a point of closure of $B(x, r)$, that is, y belongs to $\overline{B}(x, r)$. Therefore $\overline{B}(x, r) \subseteq \overline{B(x, r)}$, and the two sets are equal.

Finally we exhibit a metric space in which the equality fails. Let X be any set containing at least two points, equipped with the discrete metric

$$\rho(u, v) = \begin{cases} 0 & \text{if } u = v, \\ 1 & \text{if } u \neq v. \end{cases}$$

Fix $x \in X$ and take $r = 1$. Then

$$B(x, 1) = \{x' \in X \mid \rho(x', x) < 1\} = \{x\}, \quad \overline{B}(x, 1) = \{x' \in X \mid \rho(x', x) \leq 1\} = X.$$

In the discrete metric every subset of X is open, since for each point u of a subset S we have $B(u, 1/2) = \{u\} \subseteq S$. In particular $X \sim \{x\}$ is open, so by Proposition 4 the set $\{x\} = B(x, 1)$ is closed, and hence equals its own closure:

$$\overline{B(x, 1)} = \{x\}.$$

Since X has at least two points, $\{x\} \neq X = \overline{B}(x, 1)$. So in this metric space the closure of the open ball is a proper subset of the closed ball of the same radius.

Problem 9.16. Prove Proposition 2.

[Proposition 2 Let X be a subspace of the metric space Y and E a subset of X . Then E is open in X if and only if $E = X \cap \mathcal{O}$, where $\mathcal{O}$ is open in Y .]

Solution. Let ρ be the metric on Y ; by definition of metric subspace, the metric on X is the restriction of ρ to $X \times X$. For a point x of X and $r > 0$ write

$$B_Y(x, r) = \{y \in Y \mid \rho(y, x) < r\}, \quad B_X(x, r) = \{x' \in X \mid \rho(x', x) < r\}$$

for the open balls in Y and in X respectively. Directly from these definitions,

$$B_X(x, r) = X \cap B_Y(x, r) \quad \text{for all } x \in X, r > 0. \quad (*)$$

First suppose $E = X \cap \mathcal{O}$ with $\mathcal{O}$ open in Y . Let x belong to E . Then x belongs to $\mathcal{O}$, and since $\mathcal{O}$ is open in Y there is an $r > 0$ for which $B_Y(x, r) \subseteq \mathcal{O}$. Therefore, by (*),

$$B_X(x, r) = X \cap B_Y(x, r) \subseteq X \cap \mathcal{O} = E.$$

Thus each point of E is the center of an open ball of X contained in E , that is, E is open in X .

Conversely, suppose E is open in X . If $E = \emptyset$, take $\mathcal{O} = \emptyset$, which is open in Y by Proposition 1, and then $E = X \cap \mathcal{O}$. Otherwise, for each $x \in E$ choose, by the openness of E in X , a number $r_x > 0$ for which

$$B_X(x, r_x) \subseteq E.$$

Define

$$\mathcal{O} = \bigcup_{x \in E} B_Y(x, r_x).$$

Each $B_Y(x, r_x)$ is an open subset of Y (an open ball is open, as verified in the text), so $\mathcal{O}$ is open in Y by Proposition 1, which asserts that the union of any collection of open sets is open. Using (*) and the distributivity of intersection over union,

$$X \cap \mathcal{O} = \bigcup_{x \in E} (X \cap B_Y(x, r_x)) = \bigcup_{x \in E} B_X(x, r_x).$$

Every set in this last union is contained in E , so $X \cap \mathcal{O} \subseteq E$. On the other hand, each $x \in E$ belongs to $B_X(x, r_x)$, so $E \subseteq X \cap \mathcal{O}$. Therefore $E = X \cap \mathcal{O}$ with $\mathcal{O}$ open in Y .

Problem 9.17. Prove Proposition 7.

[Proposition 7 Let ρ and σ be equivalent metrics on a nonempty set X . Then a subset of X is open in the metric space (X, ρ) if and only if it is open in the metric space (X, σ) .]

Solution. By the definition of equivalent metrics, there are positive numbers c_1 and c_2 such that

$$c_1 \cdot \sigma(x_1, x_2) \leq \rho(x_1, x_2) \leq c_2 \cdot \sigma(x_1, x_2) \quad \text{for all } x_1, x_2 \in X. \quad (*)$$

For $x \in X$ and $r > 0$ write

$$B_\rho(x, r) = \{x' \in X \mid \rho(x', x) < r\}, \quad B_\sigma(x, r) = \{x' \in X \mid \sigma(x', x) < r\}.$$

We first record two inclusions between these balls.

Claim 1: $B_\sigma(x, r/c_2) \subseteq B_\rho(x, r)$ for every $x \in X$ and $r > 0$. Indeed, if $\sigma(x', x) < r/c_2$, then the right-hand inequality in (*) gives

$$\rho(x', x) \leq c_2 \cdot \sigma(x', x) < c_2 \cdot \frac{r}{c_2} = r,$$

so x' belongs to $B_\rho(x, r)$.

Claim 2: $B_\rho(x, c_1 r) \subseteq B_\sigma(x, r)$ for every $x \in X$ and $r > 0$. Indeed, if $\rho(x', x) < c_1 r$, then the left-hand inequality in (*) gives

$$c_1 \cdot \sigma(x', x) \leq \rho(x', x) < c_1 r,$$

and dividing by $c_1 > 0$ yields $\sigma(x', x) < r$, so x' belongs to $B_\sigma(x, r)$.

Now let $\mathcal{O}$ be a subset of X that is open in (X, ρ) . Let x belong to $\mathcal{O}$. There is an $r > 0$ for which $B_\rho(x, r) \subseteq \mathcal{O}$. Set $r' = r/c_2 > 0$. By Claim 1,

$$B_\sigma(x, r') \subseteq B_\rho(x, r) \subseteq \mathcal{O}.$$

Thus every point of $\mathcal{O}$ is the center of an open ball with respect to σ that is contained in $\mathcal{O}$; that is, $\mathcal{O}$ is open in (X, σ) .

Conversely, let $\mathcal{O}$ be open in (X, σ) and let x belong to $\mathcal{O}$. There is an $r > 0$ for which $B_\sigma(x, r) \subseteq \mathcal{O}$. Set $r'' = c_1 r > 0$. By Claim 2,

$$B_\rho(x, r'') \subseteq B_\sigma(x, r) \subseteq \mathcal{O},$$

so $\mathcal{O}$ is open in (X, ρ) .

Hence the open subsets of (X, ρ) and of (X, σ) are exactly the same. Consequently, by Proposition 4 the closed subsets agree as well. Convergence also agrees: if $\{x_n\} \rightarrow x$ in (X, ρ) , then $\sigma(x_n, x) \leq \rho(x_n, x)/c_1 \rightarrow 0$ by the left-hand inequality in (*), so $\{x_n\} \rightarrow x$ in (X, σ) ; and if $\{x_n\} \rightarrow x$ in (X, σ) , then $\rho(x_n, x) \leq c_2 \cdot \sigma(x_n, x) \rightarrow 0$ by the right-hand inequality in (*).

Problem 9.18. Let X be a subspace of the metric space Y and A a subset of X . Show that A is closed in X if and only if $A = X \cap F$, where F is closed in Y .

Solution. Since $A \subseteq X \subseteq Y$, we will repeatedly use the elementary set identity

$$X \sim (X \sim A) = A, \quad (*)$$

valid because $A \subseteq X$, and the identity

$$X \cap (Y \sim S) = X \sim S \quad \text{for any } S \subseteq Y, \quad (**)$$

valid because $X \subseteq Y$.

Suppose first that A is closed in X . By Proposition 4 applied in the metric space X , the set $X \sim A$ is open in X . By Proposition 2 there is a set $\mathcal{O}$, open in Y , with

$$X \sim A = X \cap \mathcal{O}.$$

Put $F = Y \sim \mathcal{O}$. By Proposition 4 applied in the metric space Y , the set F is closed in Y . Using $(**)$ and then $(*)$,

$$X \cap F = X \cap (Y \sim \mathcal{O}) = X \sim \mathcal{O} = X \sim (X \cap \mathcal{O}) = X \sim (X \sim A) = A.$$

Here the third equality holds because for a point of X , belonging to $\mathcal{O}$ is the same as belonging to $X \cap \mathcal{O}$. Thus $A = X \cap F$ with F closed in Y .

Conversely, suppose $A = X \cap F$ with F closed in Y . Put $\mathcal{O} = Y \sim F$, which is open in Y by Proposition 4. Then, using $(**)$,

$$X \cap \mathcal{O} = X \cap (Y \sim F) = X \sim F = X \sim (X \cap F) = X \sim A,$$

where again the third equality holds because a point of X lies in F precisely when it lies in $X \cap F$. Hence $X \sim A$ is the intersection of X with a set open in Y , so by Proposition 2 the set $X \sim A$ is open in X . By Proposition 4 applied in the metric space X , its complement in X , namely $X \sim (X \sim A) = A$, is closed in X .

Problem 9.19. Let X be a subspace of the metric space Y .

(i) If $\mathcal{O}$ is an open subset of the metric subspace X , is $\mathcal{O}$ an open subset of Y ? What if X is an open subset of Y ?

(ii) If F is a closed subset of the metric subspace X , is F a closed subset of Y ? What if X is a closed subset of Y ?

Solution. (i) In general the answer is no. Take $Y = \mathbb{R}$ with the Euclidean metric and $X = [0, 1]$ as a metric subspace. The set $\mathcal{O} = [0, 1] = X$ is open in the metric space X , since X is the whole space and Proposition 1 tells us the whole space is open. But $\mathcal{O}$ is not open in $\mathbb{R}$: no open ball $(-\epsilon, \epsilon)$ centered at the point $0 \in \mathcal{O}$ is contained in $[0, 1]$, since such a ball contains the negative number $-\epsilon/2$.

However, if X is an open subset of Y , then the answer is yes. Indeed, let $\mathcal{O}$ be open in the metric subspace X . By Proposition 2 there is a set $\mathcal{U}$, open in Y , with $\mathcal{O} = X \cap \mathcal{U}$. Since X is open in Y and $\mathcal{U}$ is open in Y , Proposition 1 tells us that the intersection of two open subsets of Y is open in Y . Hence $\mathcal{O} = X \cap \mathcal{U}$ is open in Y .

(ii) In general the answer is no. Take $Y = \mathbb{R}$ with the Euclidean metric and $X = (0, 1)$ as a metric subspace. The set $F = (0, 1) = X$ is closed in the metric space X , since by Proposition 5 the whole space is closed. But F is not closed in $\mathbb{R}$: the point 0 is a point of closure of $(0, 1)$ in $\mathbb{R}$, because every neighborhood of 0 in $\mathbb{R}$ contains an interval $(-\epsilon, \epsilon)$ and hence contains points of $(0, 1)$; yet 0 does not belong to F . (Equivalently, by Proposition 6, the sequence $\{1/n\}_{n \geq 2}$ lies in F and converges in $\mathbb{R}$ to $0 \notin F$.)

However, if X is a closed subset of Y , then the answer is yes. Indeed, let F be closed in the metric

subspace X . By the preceding problem there is a set G , closed in Y , with $F = X \cap G$. Since X is closed in Y and G is closed in Y , Proposition 5 tells us that the intersection of any collection of closed subsets of Y is closed in Y . Hence $F = X \cap G$ is closed in Y .

Problem 9.20. For a subset E of a metric space X , a point $x \in X$ is called an interior point of E provided there is an open ball centered at x that is contained in E : the collection of interior points of E is called the interior of E and denoted by $\text{int } E$. Show that $\text{int } E$ is always open and E is open if and only if $E = \text{int } E$.

Solution. Let ρ denote the metric on X , and for $x \in X$ and $r > 0$ let $B(x, r) = \{x' \in X \mid \rho(x', x) < r\}$ be the open ball centered at x of radius r .

We first observe that $\text{int } E \subseteq E$. Indeed, if x is an interior point of E , there is an $r > 0$ with $B(x, r) \subseteq E$; since $\rho(x, x) = 0 < r$, the point x belongs to $B(x, r)$ and hence to E .

Next we show $\text{int } E$ is open. Let x belong to $\text{int } E$ and choose $r > 0$ with $B(x, r) \subseteq E$. We claim

$$B(x, r) \subseteq \text{int } E.$$

Let x' belong to $B(x, r)$. As verified in the text, an open ball is an open set; explicitly, with $r' = r - \rho(x', x) > 0$ we have $B(x', r') \subseteq B(x, r)$. Therefore

$$B(x', r') \subseteq B(x, r) \subseteq E,$$

so x' is an interior point of E , that is, x' belongs to $\text{int } E$. This proves the claim. Thus every point of $\text{int } E$ is the center of an open ball contained in $\text{int } E$, and hence $\text{int } E$ is open. (Note that if $\text{int } E$ is empty it is open by Proposition 1, and the argument above is vacuous in that case.)

Finally we prove the stated characterization of openness.

Suppose E is open. Let x belong to E . By the definition of an open set there is an open ball centered at x contained in E , so x belongs to $\text{int } E$. Hence $E \subseteq \text{int } E$. Combined with the inclusion $\text{int } E \subseteq E$ established above, $E = \text{int } E$.

Conversely, suppose $E = \text{int } E$. Since $\text{int } E$ is open, so is E . (Directly: if $x \in E = \text{int } E$, then by the definition of interior point there is an open ball centered at x contained in E ; as x was arbitrary, E is open.)

Problem 9.21. For a subset E of a metric space X , a point $x \in X$ is called an exterior point of E provided there is an open ball centered at x that is contained in $X \sim E$: the collection of exterior points of E is called the exterior of E and denoted by $\text{ext } E$. Show that $\text{ext } E$ is always open. Show that E is closed if and only if $X \sim E = \text{ext } E$.

Solution. Let ρ denote the metric on X and let $B(x, r) = \{x' \in X \mid \rho(x', x) < r\}$ denote the open ball centered at x of radius r .

Compare the definition of exterior point with the definition of interior point in the preceding problem: a point $x \in X$ is an exterior point of E if and only if there is an open ball centered at x contained in $X \sim E$, that is, if and only if x is an interior point of the set $X \sim E$. Therefore

$$\text{ext } E = \text{int}(X \sim E). \quad (*)$$

Openness of $\text{ext } E$. By the preceding problem, the interior of any subset of X is open; applying this to the subset $X \sim E$ and using (*), we conclude that $\text{ext } E$ is open. For completeness, here is the argument written out directly. Let x belong to $\text{ext } E$ and choose $r > 0$ with $B(x, r) \subseteq X \sim E$. If x' belongs to $B(x, r)$, then setting $r' = r - \rho(x', x) > 0$ we have, as verified in the text, $B(x', r') \subseteq B(x, r) \subseteq X \sim E$, so x' belongs to $\text{ext } E$. Hence $B(x, r) \subseteq \text{ext } E$, and $\text{ext } E$ is open.

The characterization of closedness. By the preceding problem applied to the set $X \sim E$,

$$X \sim E \text{ is open} \iff X \sim E = \text{int}(X \sim E).$$

By (*), the right-hand condition is exactly $X \sim E = \text{ext } E$. By Proposition 4, a subset of a metric space X is open if and only if its complement in X is closed; since $X \sim (X \sim E) = E$, this says that $X \sim E$ is open if and only if E is closed. Chaining the two equivalences,

$$E \text{ is closed} \iff X \sim E \text{ is open} \iff X \sim E = \text{ext } E,$$

which is the assertion to be proved.

Two remarks. First, the inclusion $\text{ext } E \subseteq X \sim E$ always holds, since by the preceding problem $\text{int}(X \sim E) \subseteq X \sim E$; so the condition $X \sim E = \text{ext } E$ carries content only in the direction $X \sim E \subseteq \text{ext } E$. Second, it is worth recording the direct form of the result: E is closed exactly when every point not in E has an open ball about it missing E entirely, which is precisely the statement that no point of $X \sim E$ is a point of closure of E , that is, that E contains all of its points of closure.

9.4 Problems 9.22–9.28

Problem 9.22. For a subset E of a metric space X , a point $x \in X$ is called a boundary point of E provided every open ball centered at x contains points in E and points in $X \sim E$: the collection of boundary points of E is called the boundary of E and denoted by $\text{bd } E$. Show (i) that $\text{bd } E$ is always closed, (ii) that E is open if and only if $E \cap \text{bd } E = \emptyset$, and (iii) that E is closed if and only if $\text{bd } E \subseteq E$.

Solution. Throughout, recall that a point $x \in X$ is a point of closure of a set A provided every neighborhood of x contains a point of A ; since every neighborhood of x contains an open ball centered at x , and every open ball centered at x is itself a neighborhood of x , this is equivalent to the statement that every open ball centered at x contains a point of A .

Preliminary identity. Directly from the definitions,

$$\text{bd } E = \overline{E} \cap \overline{X \sim E}.$$

Indeed, $x \in \text{bd } E$ means precisely that every open ball centered at x meets E and meets $X \sim E$, i.e. that x is a point of closure of E and a point of closure of $X \sim E$.

Note also the symmetry

$$\text{bd}(X \sim E) = \overline{X \sim E} \cap \overline{X \sim (X \sim E)} = \overline{X \sim E} \cap \overline{E} = \text{bd } E,$$

since $X \sim (X \sim E) = E$. So a set and its complement have the same boundary.

(i) $\text{bd } E$ is closed. By Proposition 3, the closure of any subset of X is closed; hence $\overline{E}$ and $\overline{X \sim E}$ are closed. By Proposition 5, the intersection of any collection of closed subsets of X is closed. Therefore $\text{bd } E = \overline{E} \cap \overline{X \sim E}$ is closed.

(ii) E is open if and only if $E \cap \text{bd } E = \emptyset$.

Suppose first that E is open, and let $x \in E$. By the definition of an open set there is an $r > 0$ with $B(x, r) \subseteq E$. Then $B(x, r)$ contains no point of $X \sim E$, so x fails the defining condition for a boundary point: $x \notin \text{bd } E$. As $x \in E$ was arbitrary, $E \cap \text{bd } E = \emptyset$.

Conversely, suppose $E \cap \text{bd } E = \emptyset$, and let $x \in E$. Then $x \notin \text{bd } E$, so there is some $r > 0$ such that the ball $B(x, r)$ fails to contain a point of E or fails to contain a point of $X \sim E$. But x itself belongs to $B(x, r) \cap E$ (as $\rho(x, x) = 0 < r$), so $B(x, r)$ does contain a point of E . Hence $B(x, r)$ contains no point of $X \sim E$, that is, $B(x, r) \subseteq E$. Since each point of E is the center of an open ball contained in E , the set E is open.

(iii) E is closed if and only if $\text{bd } E \subseteq E$.

By Proposition 4, E is closed if and only if its complement $X \sim E$ is open. By part (ii) applied to the set $X \sim E$, the set $X \sim E$ is open if and only if

$$(X \sim E) \cap \text{bd}(X \sim E) = \emptyset.$$

By the symmetry noted above, $\text{bd}(X \sim E) = \text{bd } E$, so this condition reads $(X \sim E) \cap \text{bd } E = \emptyset$, which says exactly that no boundary point of E lies outside E , i.e. $\text{bd } E \subseteq E$. Combining the two equivalences: E is closed if and only if $\text{bd } E \subseteq E$.

Problem 9.23. Let A and B be subsets of a metric space X . Show that if $A \subseteq B$, then $\overline{A} \subseteq \overline{B}$. Also, show that $\overline{(A \cup B)} = \overline{A} \cup \overline{B}$ and $\overline{(A \cap B)} \subseteq \overline{A} \cap \overline{B}$.

Solution. Recall that $x \in \overline{A}$ means that every neighborhood of x contains a point of A ; equivalently, every open ball $B(x, r)$, $r > 0$, contains a point of A (every such ball is a neighborhood of x , and every neighborhood of x contains such a ball).

Monotonicity. Assume $A \subseteq B$ and let $x \in \overline{A}$. Given $r > 0$, the ball $B(x, r)$ contains a point of A , and that point lies in B since $A \subseteq B$. Hence every ball centered at x contains a point of B , i.e. $x \in \overline{B}$. Thus $\overline{A} \subseteq \overline{B}$. (This is the assertion recorded in the proof of Proposition 3.)

The union. We prove both inclusions.

Since $A \subseteq A \cup B$ and $B \subseteq A \cup B$, monotonicity gives $\overline{A} \subseteq \overline{A \cup B}$ and $\overline{B} \subseteq \overline{A \cup B}$, so

$$\overline{A} \cup \overline{B} \subseteq \overline{A \cup B}.$$

For the reverse inclusion, let $x \notin \overline{A \cup B}$. Since $x \notin \overline{A}$, there is $r_1 > 0$ with $B(x, r_1) \cap A = \emptyset$; since $x \notin \overline{B}$, there is $r_2 > 0$ with $B(x, r_2) \cap B = \emptyset$. Put $r = \min\{r_1, r_2\} > 0$. Then $B(x, r) \subseteq B(x, r_1)$ and $B(x, r) \subseteq B(x, r_2)$, so

$$B(x, r) \cap (A \cup B) = (B(x, r) \cap A) \cup (B(x, r) \cap B) = \emptyset,$$

whence $x \notin \overline{A \cup B}$. Taking contrapositives, $\overline{A \cup B} \subseteq \overline{A} \cup \overline{B}$, and therefore

$$\overline{A \cup B} = \overline{A} \cup \overline{B}.$$

(Alternatively: by Proposition 3 each of $\overline{A}$, $\overline{B}$ is closed, so by Proposition 5 their union is closed; it contains $A \cup B$, and $\overline{A \cup B}$ is the smallest closed set containing $A \cup B$, again by Proposition 3.)

The intersection. Since $A \cap B \subseteq A$ and $A \cap B \subseteq B$, monotonicity yields $\overline{A \cap B} \subseteq \overline{A}$ and $\overline{A \cap B} \subseteq \overline{B}$, hence

$$\overline{A \cap B} \subseteq \overline{A} \cap \overline{B}.$$

This inclusion may be strict, so no equality holds in general. Take $X = \mathbb{R}$ with the usual metric, $A = \mathbb{Q}$ and $B = \mathbb{R} \setminus \mathbb{Q}$. Then $A \cap B = \emptyset$, so $\overline{A \cap B} = \emptyset$, while $\overline{A} = \overline{B} = \mathbb{R}$ because every open interval contains both a rational and an irrational number; thus $\overline{A} \cap \overline{B} = \mathbb{R}$.

Problem 9.24. Show that for a subset E of a metric space X , the closure of E is the intersection of all closed subsets of X that contain E .

Solution. Let $\mathcal{F}$ denote the collection of all closed subsets of X that contain E , and set

$$C = \bigcap_{F \in \mathcal{F}} F.$$

The collection $\mathcal{F}$ is nonempty: by Proposition 5 the whole space X is closed, and clearly $E \subseteq X$, so $X \in \mathcal{F}$. Hence the intersection defining C is taken over a nonempty family and is a well-defined subset of X . We show $\overline{E} = C$ by proving each inclusion.

First, $\overline{E} \subseteq C$. Let $F \in \mathcal{F}$, so F is closed and $E \subseteq F$. By the monotonicity of closure (established in the proof of Proposition 3: if $A \subseteq B$ then $\overline{A} \subseteq \overline{B}$), $\overline{E} \subseteq \overline{F}$. Since F is closed, F contains all of its points of closure, that is $\overline{F} = F$. Hence $\overline{E} \subseteq F$. As F was an arbitrary member of $\mathcal{F}$, we conclude $\overline{E} \subseteq \bigcap_{F \in \mathcal{F}} F = C$. (This is exactly the final assertion of Proposition 3: $\overline{E}$ is the smallest closed set containing E .)

Second, $C \subseteq \overline{E}$. By Proposition 3, the set $\overline{E}$ is closed, and $E \subseteq \overline{E}$ always holds. Therefore $\overline{E}$ is itself one of the sets in the family $\mathcal{F}$. An intersection of a family of sets is contained in each member of the family, so

$$C = \bigcap_{F \in \mathcal{F}} F \subseteq \overline{E}.$$

The two inclusions give $\overline{E} = C$, i.e. the closure of E is precisely the intersection of all closed subsets of X containing E .

Two remarks. Since by Proposition 5 the intersection of any collection of closed subsets of X is closed, this description makes it evident again that $\overline{E}$ is closed. And it exhibits $\overline{E}$ as the smallest closed superset of E : it is closed, contains E , and is contained in every closed set containing E .

Problem 9.25. Exhibit a continuous mapping that is not uniformly continuous and a uniformly continuous mapping that is not Lipschitz.

Solution. In both examples the metric spaces are subsets of $\mathbb{R}$ with the usual metric $\rho(u, v) = |u - v|$. A continuous mapping that is not uniformly continuous. Let $X = \mathbb{R}$, $Y = \mathbb{R}$ and $f(x) = x^2$. f is continuous: fix $x \in \mathbb{R}$ and let $\epsilon > 0$. Put $\delta = \min\{1, \epsilon/(2|x| + 1)\}$. If $|x' - x| < \delta$ then $|x' + x| \leq |x' - x| + 2|x| < \delta + 2|x|$, so

$$|f(x') - f(x)| = |x' - x| \cdot |x' + x| < \delta \cdot (2|x| + 1) \leq \epsilon.$$

Thus the ϵ - δ criterion holds at every point of $\mathbb{R}$, and so by the ϵ - δ Criterion for Continuity the mapping f is continuous on $\mathbb{R}$. (Note that δ here depends on x as well as on ϵ ; the next paragraph shows that this dependence cannot be removed.)

f is not uniformly continuous: take the challenge $\epsilon_0 = 1$ and let $\delta > 0$ be arbitrary. Choose a natural number n with $n\delta > 1$, and set $u = n$, $v = n + \delta/2$. Then $|u - v| = \delta/2 < \delta$, while

$$|f(u) - f(v)| = |u - v| |u + v| = \frac{\delta}{2} \left(2n + \frac{\delta}{2} \right) = n\delta + \frac{\delta^2}{4} > 1 = \epsilon_0.$$

So no $\delta > 0$ responds to the challenge $\epsilon_0 = 1$, and f fails to be uniformly continuous.

A uniformly continuous mapping that is not Lipschitz. Let $X = [0, 1]$, $Y = \mathbb{R}$ and $g(x) = \sqrt{x}$.

First we establish the inequality

$$|\sqrt{u} - \sqrt{v}| \leq \sqrt{|u - v|} \quad \text{for all } u, v \geq 0.$$

By symmetry we may assume $u \geq v \geq 0$. Since all terms are nonnegative,

$$(\sqrt{v} + \sqrt{u - v})^2 = v + 2\sqrt{v(u - v)} + (u - v) \geq u,$$

and taking square roots (the square root is increasing on $[0, \infty)$) gives $\sqrt{v} + \sqrt{u - v} \geq \sqrt{u}$, that is $\sqrt{u} - \sqrt{v} \leq \sqrt{u - v} = \sqrt{|u - v|}$, as claimed.

g is uniformly continuous: given $\epsilon > 0$, set $\delta = \epsilon^2 > 0$. If $u, v \in [0, 1]$ satisfy $|u - v| < \delta$, then

$$|g(u) - g(v)| = |\sqrt{u} - \sqrt{v}| \leq \sqrt{|u - v|} < \sqrt{\delta} = \epsilon.$$

Since δ depends only on ϵ and not on the points, g is uniformly continuous on $[0, 1]$.

g is not Lipschitz: suppose there were a $c \geq 0$ with $|g(u) - g(v)| \leq c|u - v|$ for all $u, v \in [0, 1]$. Take $v = 0$ and $u = 1/n^2$ for a natural number n . Then

$$\frac{1}{n} = \left| \sqrt{1/n^2} - \sqrt{0} \right| \leq c \cdot \frac{1}{n^2},$$

so $n \leq c$ for every natural number n , which is impossible. Hence no such c exists.

These two examples show that the implications recorded in the text, Lipschitz $\Rightarrow$ uniformly continuous $\Rightarrow$ continuous, are both strict.

Problem 9.26. Show that every mapping from a metric space (X, ρ) to a metric space (Y, σ) is continuous if ρ is the discrete metric.

Solution. Recall the discrete metric on a nonempty set X : $\rho(x, y) = 0$ if $x = y$ and $\rho(x, y) = 1$ if $x \neq y$. The key observation is that for every $x \in X$ the open ball of radius 1 centered at x reduces to the single point x :

$$B(x, 1) = \{x' \in X \mid \rho(x', x) < 1\} = \{x\},$$

because $\rho(x', x)$ takes only the values 0 and 1, and $\rho(x', x) < 1$ forces $\rho(x', x) = 0$, i.e. $x' = x$ by property (ii) of a metric.

Now let f be any mapping from X to Y , and let $x \in X$. We verify the ϵ - δ criterion for continuity at x . Let $\epsilon > 0$ be given and take $\delta = 1$. If $x' \in X$ satisfies $\rho(x, x') < \delta = 1$, then by the observation above $x' = x$, so $f(x') = f(x)$ and therefore

$$\sigma(f(x), f(x')) = \sigma(f(x), f(x)) = 0 < \epsilon.$$

Equivalently, $f(B(x, 1)) = \{f(x)\} \subseteq B(f(x), \epsilon)$. By the ϵ - δ Criterion for Continuity, f is continuous at x . Since $x \in X$ was arbitrary, f is continuous.

Two alternative arguments. Using the definition of continuity by sequences: if $\{x_n\} \rightarrow x$ in (X, ρ) , then choosing $\epsilon = 1$ in the definition of convergence gives an index N with $\rho(x_n, x) < 1$, hence $x_n = x$, for all $n \geq N$; consequently $f(x_n) = f(x)$ for $n \geq N$, so $\sigma(f(x_n), f(x)) = 0$ for $n \geq N$ and $\{f(x_n)\} \rightarrow f(x)$.

Using Proposition 8: every subset A of X is open in the discrete metric, since for each $x \in A$ we have $B(x, 1) = \{x\} \subseteq A$. Hence for every open subset $\mathcal{O}$ of Y the set $f^{-1}(\mathcal{O})$, being a subset of X , is open in X ; by Proposition 8, f is continuous.

Note that the argument shows more: taking $\delta = 1$ independently of the point x , every such mapping is in fact uniformly continuous.

Problem 9.27. Suppose there is a continuous, one-to-one mapping from a metric space (X, ρ) to a metric space (Y, σ) , where σ is the discrete metric. Show that every subset of X is open.

Solution. Let $f: X \rightarrow Y$ be continuous and one-to-one, where σ is the discrete metric on Y , so that $\sigma(y, y') = 0$ if $y = y'$ and $\sigma(y, y') = 1$ if $y \neq y'$.

Step 1: every singleton subset of X is open. Fix $x \in X$. Apply the ϵ - δ Criterion for Continuity at x with the challenge $\epsilon = 1$: there is a $\delta > 0$ for which

$$f(B(x, \delta)) \subseteq B(f(x), 1).$$

As in the preceding problem, in the discrete metric $B(f(x), 1) = \{f(x)\}$, since σ takes only the values 0 and 1. Hence $f(x') = f(x)$ for every $x' \in B(x, \delta)$. Because f is one-to-one, this forces $x' = x$. Therefore

$$B(x, \delta) = \{x\},$$

and in particular the ball $B(x, \delta)$, which is centered at x , is contained in $\{x\}$. So $\{x\}$ is open.

Step 2: every subset of X is open. Let $A \subseteq X$. If $A = \emptyset$, it is open by Proposition 1. Otherwise

$$A = \bigcup_{x \in A} \{x\},$$

a union of a collection of open subsets of X by Step 1, and hence open by Proposition 1.

Therefore every subset of X is open. (Equivalently, by Proposition 4, every subset of X is also closed, since the complement of any subset is a subset and hence open.)

Alternative phrasing of Step 1 using Proposition 8: for each $x \in X$ the singleton $\{f(x)\} = B(f(x), 1)$ is an open subset of Y , being an open ball. Since f is continuous, Proposition 8 gives that $f^{-1}(\{f(x)\})$ is open in X ; and since f is one-to-one, $f^{-1}(\{f(x)\}) = \{x\}$. So $\{x\}$ is open.

Note where injectivity is needed: without it the conclusion fails. For instance, if $X = \mathbb{R}$ with the usual metric, Y any set with the discrete metric, and f constant, then f is continuous but the subsets of X are certainly not all open.

Problem 9.28. For a metric space (X, ρ) , show that the metric $\rho: X \times X \rightarrow \mathbb{R}$ is continuous, where $X \times X$ has the product metric.

Solution. The product metric τ on $X \times X$ is defined, as in Section 9.1, by

$$\tau((x_1, x_2), (y_1, y_2)) = \left\{ [\rho(x_1, y_1)]^2 + [\rho(x_2, y_2)]^2 \right\}^{1/2},$$

and $\mathbb{R}$ carries its usual metric $|s - t|$. We show that $\rho: (X \times X, \tau) \rightarrow \mathbb{R}$ is Lipschitz, with Lipschitz constant $c = \sqrt{2}$; since a Lipschitz mapping is uniformly continuous, and a uniformly continuous mapping is continuous, this proves the assertion.

Step 1: a quadrilateral inequality. For all $x_1, x_2, y_1, y_2 \in X$,

$$|\rho(x_1, x_2) - \rho(y_1, y_2)| \leq \rho(x_1, y_1) + \rho(x_2, y_2).$$

Indeed, two applications of the triangle inequality for ρ give

$$\rho(x_1, x_2) \leq \rho(x_1, y_1) + \rho(y_1, x_2) \leq \rho(x_1, y_1) + \rho(y_1, y_2) + \rho(y_2, x_2),$$

and since $\rho(y_2, x_2) = \rho(x_2, y_2)$ by the symmetry of a metric, this rearranges to

$$\rho(x_1, x_2) - \rho(y_1, y_2) \leq \rho(x_1, y_1) + \rho(x_2, y_2).$$

Interchanging the roles of the pair (x_1, x_2) and the pair (y_1, y_2) gives the same bound for $\rho(y_1, y_2) - \rho(x_1, x_2)$, and the two together give the stated inequality on absolute values.

Step 2: comparison with the product metric. For nonnegative reals a, b we have $2ab \leq a^2 + b^2$, hence

$$(a + b)^2 = a^2 + 2ab + b^2 \leq 2(a^2 + b^2), \quad \text{so} \quad a + b \leq \sqrt{2} (a^2 + b^2)^{1/2}.$$

Applying this with $a = \rho(x_1, y_1)$ and $b = \rho(x_2, y_2)$ and combining with Step 1,

$$|\rho(x_1, x_2) - \rho(y_1, y_2)| \leq \sqrt{2} \left\{ [\rho(x_1, y_1)]^2 + [\rho(x_2, y_2)]^2 \right\}^{1/2} = \sqrt{2} \tau((x_1, x_2), (y_1, y_2)).$$

Step 3: conclusion. To keep the two roles of the symbol ρ apart, write $F: X \times X \rightarrow \mathbb{R}$ for the mapping under consideration, so that $F(x_1, x_2) = \rho(x_1, x_2)$. With $u = (x_1, x_2)$ and $v = (y_1, y_2)$ denoting points of $X \times X$, Step 2 says

$$|F(u) - F(v)| \leq \sqrt{2} \cdot \tau(u, v) \quad \text{for all } u, v \in X \times X,$$

which is precisely the Lipschitz condition for F with constant $c = \sqrt{2} > 0$. As observed in the text, a Lipschitz mapping is uniformly continuous: given $\epsilon > 0$, the choice $\delta = \epsilon/\sqrt{2}$ responds to the challenge, since $\tau(u, v) < \delta$ implies $|F(u) - F(v)| \leq \sqrt{2} \tau(u, v) < \epsilon$. And a uniformly continuous mapping is continuous, as the text infers from the ϵ - δ Criterion for Continuity at a point. Hence the metric ρ , viewed as the mapping F from $X \times X$ with the product metric to $\mathbb{R}$ with its usual metric, is continuous.

Remark. Step 1 alone already yields the assertion of Problem 14: if $\{u_n\} \rightarrow u$ and $\{v_n\} \rightarrow v$ in X , then

$$|\rho(u_n, v_n) - \rho(u, v)| \leq \rho(u_n, u) + \rho(v_n, v) \rightarrow 0,$$

so $\{\rho(u_n, v_n)\} \rightarrow \rho(u, v)$ in $\mathbb{R}$. Conversely, the elementary bounds

$$\max\{a, b\} \leq (a^2 + b^2)^{1/2} \leq \sqrt{2} \max\{a, b\} \quad (a, b \geq 0)$$

show that a sequence converges in $(X \times X, \tau)$ if and only if both of its coordinate sequences converge in (X, ρ) ; so the continuity of ρ on $X \times X$ established above and the statement of Problem 14 are two formulations of the same fact.

9.5 Problems 9.29–9.35

Problem 9.29. Let z be a point in the metric space (X, ρ) . Define the function $f: X \rightarrow \mathbb{R}$ by $f(x) = \rho(x, z)$. Show that f is uniformly continuous.

Solution. We show that f is Lipschitz with Lipschitz constant $c = 1$, and then invoke the Example following the definition of uniform continuity, which observes that a Lipschitz mapping is uniformly continuous.

Let $u, v \in X$. By the triangle inequality for the metric ρ ,

$$\rho(u, z) \leq \rho(u, v) + \rho(v, z),$$

so that

$$f(u) - f(v) = \rho(u, z) - \rho(v, z) \leq \rho(u, v).$$

Interchanging the roles of u and v in this argument gives

$$f(v) - f(u) = \rho(v, z) - \rho(u, z) \leq \rho(v, u) = \rho(u, v),$$

where we used the symmetry of ρ . Since $|f(u) - f(v)|$ equals either $f(u) - f(v)$ or $f(v) - f(u)$, the two displayed inequalities together give

$$|f(u) - f(v)| \leq \rho(u, v) \quad \text{for all } u, v \in X.$$

The metric on $\mathbb{R}$ is $\sigma(s, t) = |s - t|$, so the above says precisely that

$$\sigma(f(u), f(v)) \leq 1 \cdot \rho(u, v) \quad \text{for all } u, v \in X,$$

that is, f is Lipschitz with $c = 1$.

To exhibit the uniform continuity explicitly: let $\epsilon > 0$ be given and set $\delta = \epsilon$. Then $\delta > 0$, and if $u, v \in X$ satisfy $\rho(u, v) < \delta$, we have

$$|f(u) - f(v)| \leq \rho(u, v) < \delta = \epsilon.$$

Since the choice of δ depends only on ϵ and not on the points u, v , the function f is uniformly continuous on X .

Problem 9.30. Show that the composition of uniformly continuous mappings between metric spaces, when defined, is uniformly continuous.

Solution. Let (X, ρ) , (Y, σ) and (Z, τ) be metric spaces, and let $f: X \rightarrow Y$ and $g: Y \rightarrow Z$ be uniformly continuous. We must show that the composition $g \circ f: X \rightarrow Z$, which is defined since the range of f lies in the domain of g , is uniformly continuous.

Let $\epsilon > 0$ be given.

Since $g: Y \rightarrow Z$ is uniformly continuous, there is an $\eta > 0$ such that

$$\text{for all } y_1, y_2 \in Y, \text{ if } \sigma(y_1, y_2) < \eta, \text{ then } \tau(g(y_1), g(y_2)) < \epsilon.$$

Observe that η depends only on ϵ .

Now apply the uniform continuity of $f: X \rightarrow Y$ to the positive number η : there is a $\delta > 0$ such that

$$\text{for all } u, v \in X, \text{ if } \rho(u, v) < \delta, \text{ then } \sigma(f(u), f(v)) < \eta.$$

Observe that δ depends only on η , and hence, through η , only on ϵ . In particular δ is independent of the points of X at which it will be used.

We claim this δ responds to the challenge ϵ for the mapping $g \circ f$. Indeed, let $u, v \in X$ satisfy $\rho(u, v) < \delta$. By the choice of δ ,

$$\sigma(f(u), f(v)) < \eta.$$

Since $f(u)$ and $f(v)$ are points of Y , the choice of η applied to the pair $y_1 = f(u)$, $y_2 = f(v)$ yields

$$\tau(g(f(u)), g(f(v))) < \epsilon, \quad \text{that is,} \quad \tau((g \circ f)(u), (g \circ f)(v)) < \epsilon.$$

Thus for every $\epsilon > 0$ there is a $\delta > 0$ such that for all $u, v \in X$, if $\rho(u, v) < \delta$ then $\tau((g \circ f)(u), (g \circ f)(v)) < \epsilon$. By definition, $g \circ f$ is uniformly continuous.

Finally, an arbitrary finite composition of uniformly continuous mappings is uniformly continuous, by induction on the number of mappings composed, the case of two mappings being what we have just proved.

Problem 9.31. Show that a continuous mapping between metric spaces remains continuous if an equivalent metric is imposed on the domain and an equivalent metric is imposed on the range.

Solution. Recall the definition: two metrics ρ and ρ' on a set X are equivalent provided there are positive numbers c_1 and c_2 such that

$$c_1 \rho(x_1, x_2) \leq \rho'(x_1, x_2) \leq c_2 \rho(x_1, x_2) \quad \text{for all } x_1, x_2 \in X.$$

Let $f: X \rightarrow Y$ be continuous as a mapping from (X, ρ) to (Y, σ) . Let ρ' be a metric on X equivalent to ρ and let σ' be a metric on Y equivalent to σ . We must show f is continuous as a mapping from (X, ρ') to (Y, σ') .

Argument by open sets. Let $\mathcal{O}$ be an open subset of the metric space (Y, σ') . Since σ' and σ are equivalent metrics on Y , Proposition 7 tells us that a subset of Y is open in (Y, σ') if and only if it is open in (Y, σ) . Hence $\mathcal{O}$ is open in (Y, σ) . Since $f: (X, \rho) \rightarrow (Y, \sigma)$ is continuous, Proposition 8 tells us that $f^{-1}(\mathcal{O})$ is an open subset of (X, ρ) . Since ρ and ρ' are equivalent metrics on X , Proposition 7, applied now on X , tells us that $f^{-1}(\mathcal{O})$ is also open in (X, ρ') .

Thus the inverse image under f of every open subset of (Y, σ') is an open subset of (X, ρ') . By Proposition 8 again, now in the direction that this criterion implies continuity, the mapping $f: (X, \rho') \rightarrow (Y, \sigma')$ is continuous.

A direct ϵ - δ argument. It is instructive to verify this without Propositions 7 and 8. Choose positive constants with

$$c_1 \rho(x_1, x_2) \leq \rho'(x_1, x_2) \leq c_2 \rho(x_1, x_2), \quad d_1 \sigma(y_1, y_2) \leq \sigma'(y_1, y_2) \leq d_2 \sigma(y_1, y_2)$$

for all $x_1, x_2 \in X$ and all $y_1, y_2 \in Y$.

Fix $x \in X$ and let $\epsilon > 0$. Since $f: (X, \rho) \rightarrow (Y, \sigma)$ is continuous at x , the ϵ - δ criterion for continuity provides a $\delta > 0$ such that

$$\text{if } \rho(x, x') < \delta, \text{ then } \sigma(f(x), f(x')) < \epsilon/d_2.$$

Set $\delta' = c_1 \delta > 0$. Suppose $x' \in X$ satisfies $\rho'(x, x') < \delta'$. From $c_1 \rho(x, x') \leq \rho'(x, x') < c_1 \delta$ we get $\rho(x, x') < \delta$, whence $\sigma(f(x), f(x')) < \epsilon/d_2$ and therefore

$$\sigma'(f(x), f(x')) \leq d_2 \sigma(f(x), f(x')) < d_2 \cdot \frac{\epsilon}{d_2} = \epsilon.$$

So the ϵ - δ criterion holds for $f: (X, \rho') \rightarrow (Y, \sigma')$ at the arbitrary point x , and f is continuous with respect to the new pair of metrics.

Note that only the inequalities $c_1 \rho \leq \rho'$ and $\sigma' \leq d_2 \sigma$ were used; the remaining two inequalities give the converse implication, so continuity with respect to one pair of metrics is in fact equivalent to continuity with respect to the other.

Problem 9.32. For a nonempty subset E of the metric space (X, ρ) and a point $x \in X$, define the

distance from x to E , $\text{dist}(x, E)$, as follows:

$$\text{dist}(x, E) = \inf\{\rho(x, y) \mid y \in E\}.$$

- (i) Show that the distance function $f: X \rightarrow \mathbb{R}$ defined by $f(x) = \text{dist}(x, E)$, for $x \in X$, is continuous.
- (ii) Show that $\{x \in X \mid \text{dist}(x, E) = 0\} = \overline{E}$.

Solution. First note that f is well defined and real-valued: since E is nonempty, the set $\{\rho(x, y) \mid y \in E\}$ is a nonempty set of real numbers bounded below by 0, so its infimum exists and satisfies $0 \leq f(x) < \infty$.

(i) We prove the Lipschitz estimate

$$|f(u) - f(v)| \leq \rho(u, v) \quad \text{for all } u, v \in X,$$

which, as noted in the Example following the definition of uniform continuity, implies that f is uniformly continuous and in particular continuous.

Let $u, v \in X$ and let $y \in E$ be arbitrary. By the triangle inequality,

$$\rho(u, y) \leq \rho(u, v) + \rho(v, y).$$

Since $f(u) = \text{dist}(u, E)$ is a lower bound for $\{\rho(u, y) \mid y \in E\}$, we have $f(u) \leq \rho(u, y)$, and therefore

$$f(u) \leq \rho(u, v) + \rho(v, y) \quad \text{for every } y \in E.$$

Thus $f(u) - \rho(u, v)$ is a lower bound for the set $\{\rho(v, y) \mid y \in E\}$. Since $\text{dist}(v, E)$ is the greatest lower bound of that set,

$$f(u) - \rho(u, v) \leq \text{dist}(v, E) = f(v), \quad \text{that is,} \quad f(u) - f(v) \leq \rho(u, v).$$

Interchanging u and v and using the symmetry of ρ gives $f(v) - f(u) \leq \rho(u, v)$. Combining the two inequalities yields $|f(u) - f(v)| \leq \rho(u, v)$, as claimed.

Explicitly, given $\epsilon > 0$, the choice $\delta = \epsilon$ has the property that $\rho(u, v) < \delta$ implies $|f(u) - f(v)| < \epsilon$; so f is uniformly continuous on X , hence continuous.

(ii) Recall that $\overline{E}$, the closure of E , is the set of points of closure of E , and that a point $x \in X$ is a point of closure of E provided every open ball $B(x, r)$ centered at x contains a point of E .

Suppose first that $f(x) = \text{dist}(x, E) = 0$. Let $r > 0$. Since 0 is the greatest lower bound of $\{\rho(x, y) \mid y \in E\}$ and $r > 0$, the number r is not a lower bound of this set; hence there is a point $y \in E$ with $\rho(x, y) < r$, that is, $y \in B(x, r) \cap E$. As $r > 0$ was arbitrary, every open ball centered at x contains a point of E , so x is a point of closure of E and thus $x \in \overline{E}$.

Conversely, suppose $x \in \overline{E}$. Let $r > 0$. Then $B(x, r)$ contains a point y of E , so $\rho(x, y) < r$ and hence

$$0 \leq \text{dist}(x, E) \leq \rho(x, y) < r.$$

Since this holds for every $r > 0$, we must have $\text{dist}(x, E) = 0$; for if $\text{dist}(x, E) = c > 0$, taking $r = c$ would give the contradiction $c < c$.

Therefore $\{x \in X \mid \text{dist}(x, E) = 0\} = \overline{E}$.

In particular, since a set is closed if and only if it equals its closure, E is closed if and only if $E = \{x \in X \mid \text{dist}(x, E) = 0\}$.

Problem 9.33. Show that a subset E of a metric space X is open if and only if there is a continuous real-valued function f on X for which $E = \{x \in X \mid f(x) > 0\}$.

Solution. Let (X, ρ) be a metric space and $E \subseteq X$.

Sufficiency. Suppose there is a continuous function $f: X \rightarrow \mathbb{R}$ with $E = \{x \in X \mid f(x) > 0\}$. The set $\mathcal{O} = (0, \infty)$ is an open subset of $\mathbb{R}$: indeed, if $t > 0$ then the ball $B(t, t) = (0, 2t)$ is contained in

$(0, \infty)$. Since f is continuous, Proposition 8 tells us that $f^{-1}(\mathcal{O})$ is an open subset of X . But

$$f^{-1}((0, \infty)) = \{x \in X \mid f(x) > 0\} = E,$$

so E is open.

Necessity. Suppose E is open. We construct such an f .

Case 1: $E = X$. Take $f \equiv 1$, the constant function. A constant function is continuous (it maps every sequence to a constant sequence), and $\{x \in X \mid f(x) > 0\} = X = E$.

Case 2: $E \neq X$. Then the complement $F = X \sim E$ is a nonempty subset of X , and it is closed: by Proposition 4, a subset of a metric space is open if and only if its complement is closed, and the complement of F in X is the open set E . Define

$$f(x) = \text{dist}(x, F) = \inf\{\rho(x, y) \mid y \in F\} \quad \text{for } x \in X.$$

This is well defined and real-valued because F is nonempty, and by part (i) of the preceding problem f is continuous (indeed Lipschitz, with $|f(u) - f(v)| \leq \rho(u, v)$).

We claim $E = \{x \in X \mid f(x) > 0\}$. Since $\rho \geq 0$, each set $\{\rho(x, y) \mid y \in F\}$ is bounded below by 0, so $f \geq 0$ on all of X ; consequently $\{x \in X \mid f(x) > 0\} = X \sim \{x \in X \mid f(x) = 0\}$, and it suffices to show that

$$\{x \in X \mid f(x) = 0\} = F.$$

By part (ii) of the preceding problem, $\{x \in X \mid \text{dist}(x, F) = 0\} = \overline{F}$. Since F is closed, $\overline{F} = F$. Hence $\{x \mid f(x) = 0\} = F$, and therefore

$$\{x \in X \mid f(x) > 0\} = X \sim \{x \in X \mid f(x) = 0\} = X \sim F = E.$$

Thus in either case there is a continuous real-valued f on X with $E = \{x \in X \mid f(x) > 0\}$, and the proof is complete.

Remark. No separate treatment of $E = \emptyset$ is needed. If $X \neq \emptyset$ then $E = \emptyset$ falls under Case 2, where $F = X$ and $f \equiv 0$, since $\rho(x, x) = 0$ for each $x \in X$; if $X = \emptyset$ then $E = X$ and Case 1 applies. In any event one may simply take $f \equiv -1$, for which $\{x \in X \mid f(x) > 0\} = \emptyset = E$.

Problem 9.34. Show that a subset E of a metric space X is closed if and only if there is a continuous real-valued function f on X for which $E = f^{-1}(0)$.

Solution. Let (X, ρ) be a metric space and $E \subseteq X$. Here $f^{-1}(0)$ denotes $f^{-1}(\{0\}) = \{x \in X \mid f(x) = 0\}$. Sufficiency. Suppose $f: X \rightarrow \mathbb{R}$ is continuous and $E = f^{-1}(0)$. The set $\mathbb{R} \sim \{0\}$ is open in $\mathbb{R}$: if $t \neq 0$, then the ball $B(t, |t|)$ consists of points s with $|s - t| < |t|$, and no such s can be 0. Since f is continuous, Proposition 8 tells us that $f^{-1}(\mathbb{R} \sim \{0\})$ is open in X . Taking inverse images commutes with complements: a point $x \in X$ lies in $f^{-1}(\mathbb{R} \sim \{0\})$ if and only if $f(x) \neq 0$, that is, if and only if $x \notin f^{-1}(\{0\})$. Hence

$$f^{-1}(\mathbb{R} \sim \{0\}) = X \sim f^{-1}(\{0\}) = X \sim E.$$

Thus $X \sim E$ is open, and therefore, by Proposition 4, E is closed.

Necessity. Suppose E is closed.

Case 1: $E = \emptyset$. Take $f \equiv 1$. This constant function is continuous and $f^{-1}(0) = \emptyset = E$.

Case 2: $E \neq \emptyset$. Define

$$f(x) = \text{dist}(x, E) = \inf\{\rho(x, y) \mid y \in E\} \quad \text{for } x \in X.$$

Since E is nonempty this is a well-defined real-valued function, and by part (i) of Problem 32 it is continuous (indeed Lipschitz, satisfying $|f(u) - f(v)| \leq \rho(u, v)$).

By part (ii) of Problem 32,

$$f^{-1}(0) = \{x \in X \mid \text{dist}(x, E) = 0\} = \overline{E}.$$

Since E is closed, $E = \overline{E}$, and therefore $f^{-1}(0) = E$.

In both cases we have produced a continuous real-valued f on X with $E = f^{-1}(0)$, which completes the proof.

Remark. The verification in the sufficiency direction shows more generally that the inverse image of a closed set under a continuous mapping is closed; this is the content of the next problem.

Problem 9.35. Let X and Y be metric spaces. Prove that $f: X \rightarrow Y$ is continuous if and only if $f^{-1}(C)$ is closed in X whenever C is closed in Y .

Solution. The proof rests on Proposition 8, which characterizes continuity by the openness of inverse images of open sets, together with the set-theoretic identity

$$f^{-1}(Y \sim A) = X \sim f^{-1}(A) \quad \text{for every } A \subseteq Y,$$

which we refer to as the complementation identity. To verify it: a point $x \in X$ belongs to $f^{-1}(Y \sim A)$ if and only if $f(x) \in Y \sim A$, that is, if and only if $f(x) \notin A$; and this holds if and only if $x \notin f^{-1}(A)$, that is, if and only if $x \in X \sim f^{-1}(A)$. (Note that f is defined on all of X , so every $x \in X$ has an image $f(x) \in Y$, and the equivalence is valid.)

Necessity. Suppose f is continuous, and let C be a closed subset of Y . Then $\mathcal{O} = Y \sim C$ is open in Y . By Proposition 8, $f^{-1}(\mathcal{O})$ is open in X . By the complementation identity with $A = C$,

$$f^{-1}(\mathcal{O}) = f^{-1}(Y \sim C) = X \sim f^{-1}(C).$$

Hence $X \sim f^{-1}(C)$ is open in X , and therefore, by Proposition 4, $f^{-1}(C)$ is closed in X .

Sufficiency. Suppose $f^{-1}(C)$ is closed in X whenever C is closed in Y . Let $\mathcal{O}$ be an open subset of Y . Then $C = Y \sim \mathcal{O}$ is closed in Y , so by hypothesis $f^{-1}(C)$ is closed in X . By the complementation identity with $A = \mathcal{O}$,

$$X \sim f^{-1}(\mathcal{O}) = f^{-1}(Y \sim \mathcal{O}) = f^{-1}(C),$$

which is closed in X . Therefore $f^{-1}(\mathcal{O})$, being the complement in X of the closed set $f^{-1}(C)$, is open in X by Proposition 4.

Thus the inverse image under f of every open subset of Y is open in X , and Proposition 8 gives that $f: X \rightarrow Y$ is continuous.

Combining the two directions: f is continuous if and only if $f^{-1}(C)$ is closed in X for every closed subset C of Y .

9.6 Problems 9.36–9.42

Problem 9.36. Let $X = C[a, b]$. Define the function $\psi: X \rightarrow \mathbb{R}$ by

$$\psi(f) = \int_a^b f(x) dx \quad \text{for each } f \text{ in } X.$$

Show that ψ is Lipschitz on the metric space X , where X has the metric induced by the maximum norm.

Solution. Recall that the metric on $X = C[a, b]$ induced by the maximum norm is

$$\rho(f, g) = \|f - g\|_{\max} = \max_{x \in [a, b]} |f(x) - g(x)|,$$

the maximum being attained because $|f - g|$ is continuous on the closed, bounded interval $[a, b]$ (by the Extreme Value Theorem). On $\mathbb{R}$ we use the usual metric $|s - t|$. To say that ψ is Lipschitz is to say that there is a constant $c \geq 0$ for which

$$|\psi(f) - \psi(g)| \leq c \cdot \rho(f, g) \quad \text{for all } f, g \in X.$$

We claim $c = b - a$ works.

First observe that ψ is well defined: each f in $C[a, b]$ is continuous, hence Lebesgue measurable and bounded on $[a, b]$, and $[a, b]$ has finite measure, so f is integrable over $[a, b]$ and $\int_a^b f$ is a real number. Now let f and g belong to X . By the linearity of integration,

$$\psi(f) - \psi(g) = \int_a^b f(x) dx - \int_a^b g(x) dx = \int_a^b [f(x) - g(x)] dx.$$

Since $|\int_a^b h| \leq \int_a^b |h|$ for an integrable h , we have

$$|\psi(f) - \psi(g)| \leq \int_a^b |f(x) - g(x)| dx.$$

For every x in $[a, b]$ we have the pointwise bound $|f(x) - g(x)| \leq \|f - g\|_{\max}$, and the integral is monotone, so

$$\int_a^b |f(x) - g(x)| dx \leq \int_a^b \|f - g\|_{\max} dx = (b - a) \|f - g\|_{\max}.$$

Combining the two displays,

$$|\psi(f) - \psi(g)| \leq (b - a) \|f - g\|_{\max} = (b - a) \rho(f, g).$$

Thus ψ is Lipschitz with Lipschitz constant $b - a$. In particular ψ is uniformly continuous on X : given $\epsilon > 0$, take $\delta = \epsilon/(b - a + 1)$; if $\rho(f, g) < \delta$ then $|\psi(f) - \psi(g)| \leq (b - a)\rho(f, g) < \epsilon$.

It is worth noting that the constant $b - a$ is sharp: taking $g = 0$ and $f \equiv 1$ gives $|\psi(f) - \psi(g)| = b - a$ while $\rho(f, g) = 1$, so no smaller constant can serve.

We remark finally that the first display in the chain above already gives $|\psi(f) - \psi(g)| \leq \int_a^b |f - g| = \|f - g\|_1$, so ψ is also Lipschitz, with constant 1, for the metric that X inherits from the $L^1[a, b]$ norm. The estimate asked for here is the one against the maximum norm, which is the metric used for $C[a, b]$ throughout this chapter.

Problem 9.37. In a metric space X , show (i) that a convergent sequence is Cauchy and (ii) that a Cauchy sequence is bounded.

Solution. Let (X, ρ) be a metric space and $\{x_n\}$ a sequence in X . Recall the definitions in force: $\{x_n\}$ converges to $x \in X$ provided $\lim_{n \rightarrow \infty} \rho(x_n, x) = 0$; $\{x_n\}$ is Cauchy provided for each $\epsilon > 0$ there is an index N for which $\rho(x_n, x_m) < \epsilon$ whenever $n, m \geq N$; and a nonempty subset E of X is bounded provided $\text{diam } E = \sup\{\rho(x, y) \mid x, y \in E\}$ is finite. A sequence is called bounded provided the set of its terms is a bounded subset of X .

Part (i): a convergent sequence is Cauchy.

Suppose $\{x_n\} \rightarrow x$ in X . Let $\epsilon > 0$. Since $\rho(x_n, x) \rightarrow 0$, there is an index N such that

$$\rho(x_n, x) < \epsilon/2 \quad \text{for all } n \geq N.$$

Let $n, m \geq N$. By the triangle inequality and the symmetry of ρ ,

$$\rho(x_n, x_m) \leq \rho(x_n, x) + \rho(x, x_m) < \epsilon/2 + \epsilon/2 = \epsilon.$$

Since $\epsilon > 0$ was arbitrary, $\{x_n\}$ is Cauchy.

Part (ii): a Cauchy sequence is bounded.

Suppose $\{x_n\}$ is Cauchy. Apply the Cauchy criterion with $\epsilon = 1$: there is an index N for which

$$\rho(x_n, x_m) < 1 \quad \text{whenever } n, m \geq N.$$

In particular, taking $m = N$,

$$\rho(x_n, x_N) < 1 \quad \text{for all } n \geq N.$$

The remaining terms $x_1, \dots, x_{N-1}$ are finite in number, so we may define

$$M = \max\{1, \rho(x_1, x_N), \rho(x_2, x_N), \dots, \rho(x_{N-1}, x_N)\},$$

a finite real number (the maximum of a finite set of reals exists). Then

$$\rho(x_n, x_N) \leq M \quad \text{for every index } n,$$

since for $n < N$ this holds by the definition of M , and for $n \geq N$ we have $\rho(x_n, x_N) < 1 \leq M$.

Now let $E = \{x_n \mid n \in \mathbb{N}\}$ be the set of terms of the sequence. For any two indices n and m , the triangle inequality gives

$$\rho(x_n, x_m) \leq \rho(x_n, x_N) + \rho(x_N, x_m) \leq M + M = 2M.$$

Hence $\text{diam } E \leq 2M < \infty$, that is, E is a bounded subset of X . Equivalently, E is contained in the closed ball of radius M about x_N . Therefore $\{x_n\}$ is bounded.

Combining (i) and (ii): every convergent sequence in a metric space is bounded, since it is Cauchy by (i) and hence bounded by (ii).

Problem 9.38. In a metric space X , show that a Cauchy sequence converges if and only if it has a convergent subsequence.

Solution. Let (X, ρ) be a metric space and let $\{x_n\}$ be a Cauchy sequence in X .

Suppose first that $\{x_n\}$ converges, say to $x \in X$. Then $\{x_n\}$ is itself a subsequence of $\{x_n\}$ (take $n_k = k$), and it converges. So $\{x_n\}$ has a convergent subsequence. (Note that this implication does not use the Cauchy hypothesis; indeed every subsequence of a convergent sequence converges to the same limit, since if $\{n_k\}$ is strictly increasing then $n_k \geq k$ for every k , so $\rho(x_{n_k}, x) \rightarrow 0$ whenever $\rho(x_n, x) \rightarrow 0$.)

Conversely, suppose $\{x_n\}$ is Cauchy and possesses a subsequence $\{x_{n_k}\}$ that converges to some point $x \in X$. We claim that the whole sequence $\{x_n\}$ converges to x .

Let $\epsilon > 0$. Since $\{x_n\}$ is Cauchy, there is an index N for which

$$\rho(x_n, x_m) < \epsilon/2 \quad \text{whenever } n, m \geq N.$$

Since $\{x_{n_k}\}$ converges to x , there is an index K_1 for which

$$\rho(x_{n_k}, x) < \epsilon/2 \quad \text{whenever } k \geq K_1.$$

Because $\{n_k\}$ is a strictly increasing sequence of natural numbers, $n_k \geq k$ for every k ; hence choosing any index k_0 with $k_0 \geq \max\{K_1, N\}$ we have both $n_{k_0} \geq k_0 \geq N$ and $\rho(x_{n_{k_0}}, x) < \epsilon/2$.

Now let $n \geq N$. Since $n_{k_0} \geq N$ as well, the Cauchy estimate applies to the pair (n, n_{k_0}) , and the triangle inequality gives

$$\rho(x_n, x) \leq \rho(x_n, x_{n_{k_0}}) + \rho(x_{n_{k_0}}, x) < \epsilon/2 + \epsilon/2 = \epsilon.$$

Thus for each $\epsilon > 0$ there is an index N with $\rho(x_n, x) < \epsilon$ for all $n \geq N$; that is, $\lim_{n \rightarrow \infty} \rho(x_n, x) = 0$, so $\{x_n\}$ converges to x .

This completes the proof of both implications. The hypothesis that $\{x_n\}$ be Cauchy is essential for the converse: in $\mathbb{R}$ the sequence $x_n = (-1)^n$ has convergent subsequences but does not converge. This is the fact used in the proof of Proposition 10 (completeness of $C[a, b]$) and in the proof of the Cantor Intersection Theorem, where a Cauchy sequence is shown to converge by exhibiting a convergent subsequence.

Problem 9.39. Suppose that $\{x_n\}$ is a sequence in a complete metric space (X, ρ) and for each index n , $\rho(x_n, x_{n+1}) < 1/2^n$. Show that $\{x_n\}$ converges. Does $\{x_n\}$ converge if for each index n , $\rho(x_n, x_{n+1}) < 1/n$?

Solution. First part. Assume $\rho(x_n, x_{n+1}) < 1/2^n$ for every index n . We show $\{x_n\}$ is Cauchy; completeness of X then delivers convergence.

Let n and m be indices with $m > n$. Repeated application of the triangle inequality along the chain $x_n, x_{n+1}, \dots, x_m$ gives

$$\rho(x_n, x_m) \leq \sum_{j=n}^{m-1} \rho(x_j, x_{j+1}) < \sum_{j=n}^{m-1} \frac{1}{2^j} < \sum_{j=n}^{\infty} \frac{1}{2^j} = \frac{1}{2^{n-1}},$$

the last equality being the sum of a geometric series with ratio $1/2$. By symmetry of ρ the same bound holds when $m < n$ with n replaced by $\min\{n, m\}$; and it is trivially true when $m = n$. Hence

$$\rho(x_n, x_m) \leq \frac{1}{2^{\min\{n, m\}-1}} \quad \text{for all } n, m.$$

Now let $\epsilon > 0$. Since $1/2^{N-1} \rightarrow 0$ as $N \rightarrow \infty$, choose N with $1/2^{N-1} < \epsilon$. If $n, m \geq N$ then $\min\{n, m\} \geq N$, so

$$\rho(x_n, x_m) \leq \frac{1}{2^{\min\{n, m\}-1}} \leq \frac{1}{2^{N-1}} < \epsilon.$$

Therefore $\{x_n\}$ is a Cauchy sequence in X . Since (X, ρ) is complete, $\{x_n\}$ converges to a point of X . The essential feature used is that $\sum_{n=1}^{\infty} 1/2^n$ converges; the identical argument shows more generally that if $\rho(x_n, x_{n+1}) \leq a_n$ for all n , where $\sum a_n < \infty$, then $\{x_n\}$ is Cauchy, since the tails $\sum_{j \geq n} a_j$ tend to 0. This is exactly the device used in the proof of Proposition 10 for $C[a, b]$.

Second part. The answer is no: the condition $\rho(x_n, x_{n+1}) < 1/n$ does not force convergence, even in a complete space.

For a counterexample take $X = \mathbb{R}$ with the usual metric $\rho(s, t) = |s - t|$, which is complete (this is the completeness axiom for the real numbers, as noted in the text). Define

$$x_n = \sum_{k=1}^n \frac{1}{k+1} = \frac{1}{2} + \frac{1}{3} + \cdots + \frac{1}{n+1}.$$

Then for each index n ,

$$\rho(x_n, x_{n+1}) = |x_{n+1} - x_n| = \frac{1}{n+2} < \frac{1}{n},$$

so the hypothesis of the second question is met. But $\{x_n\}$ does not converge: the harmonic series diverges, so $x_n \rightarrow \infty$. Explicitly, grouping terms,

$$x_{2^m-1} \geq \sum_{k=2}^{2^m} \frac{1}{k} \geq \sum_{i=1}^{m-1} \sum_{k=2^i+1}^{2^{i+1}} \frac{1}{k} \geq \sum_{i=1}^{m-1} 2^i \cdot \frac{1}{2^{i+1}} = \frac{m-1}{2},$$

which is unbounded in m . An unbounded sequence cannot converge, since by Problem 37 a convergent sequence is Cauchy and hence bounded. Therefore $\{x_n\}$ diverges.

The point of the contrast is that $\sum_n 1/2^n$ converges while $\sum_n 1/n$ does not; the hypothesis $\rho(x_n, x_{n+1}) < 1/n$ controls consecutive terms but permits the accumulated displacement $\sum_{j=n}^{m-1} 1/j$ between x_n and x_m to remain large no matter how big n is.

Problem 9.40. Provide an example of a descending countable collection of closed, nonempty sets of real numbers whose intersection is empty. Does this contradict the Cantor Intersection Theorem?

Solution. For each index n define

$$F_n = [n, \infty) = \{x \in \mathbb{R} \mid x \geq n\}.$$

Each F_n is nonempty (it contains n). Each F_n is closed in $\mathbb{R}$: its complement $(-\infty, n)$ is open, since for $x < n$ the open interval of radius $n - x$ about x is contained in $(-\infty, n)$. The collection is descending, that is $F_{n+1} \subseteq F_n$ for every n , because $x \geq n+1$ implies $x \geq n$.

The intersection is empty:

$$\bigcap_{n=1}^{\infty} F_n = \emptyset.$$

Indeed, if x belonged to every F_n , then $x \geq n$ for every natural number n , contradicting the Archimedean property of $\mathbb{R}$ (for each real x there is a natural number n with $n > x$).

Thus $\{F_n\}_{n=1}^{\infty}$ is a descending countable collection of nonempty closed subsets of $\mathbb{R}$ with empty intersection.

This does not contradict the Cantor Intersection Theorem. That theorem asserts that a metric space X is complete if and only if whenever $\{F_n\}_{n=1}^{\infty}$ is a contracting sequence of nonempty closed subsets of X , there is a point $x \in X$ for which $\bigcap_{n=1}^{\infty} F_n = \{x\}$. By definition, a descending sequence $\{F_n\}$ of nonempty subsets of X is contracting provided

$$\lim_{n \rightarrow \infty} \text{diam}(F_n) = 0,$$

where $\text{diam } E = \sup\{|x - y| \mid x, y \in E\}$. Our sequence fails this hypothesis completely: for every n ,

$$\text{diam}(F_n) = \sup\{|x - y| \mid x, y \geq n\} = \infty,$$

since F_n contains points n and $n+k$ for every natural number k . So $\{F_n\}$ is not a contracting sequence, and the theorem says nothing about it. In particular no conclusion about $\bigcap_n F_n$ is available from the theorem, and the completeness of $\mathbb{R}$ is not impugned.

A final remark explains why unboundedness was unavoidable here, so that no example of the required kind could have had contracting, or even merely bounded, sets. Suppose $\{F_n\}$ is a descending sequence of nonempty closed subsets of $\mathbb{R}$ and some F_N is bounded; we show $\bigcap_{n=1}^{\infty} F_n \neq \emptyset$. For each $n \geq N$ select a point $y_n \in F_n$. Since $\{F_n\}$ is descending, every y_n with $n \geq N$ belongs to F_N , so $\{y_n\}_{n \geq N}$ is a bounded sequence of real numbers. By the Bolzano-Weierstrass Theorem it has a subsequence $\{y_{n_k}\}$ converging to some real number y . Fix an index m . For all k with $n_k \geq \max\{m, N\}$ we have $y_{n_k} \in F_{n_k} \subseteq F_m$, since $\{F_n\}$ is descending; thus y is the limit of a sequence in the closed set F_m , and hence $y \in F_m$ by Proposition 6. As m was arbitrary, $y \in \bigcap_{n=1}^{\infty} F_n$, and the intersection is not empty. Consequently, in any example of the required kind, every one of the sets must be unbounded, that is, must have infinite diameter, exactly as in the example above.

Problem 9.41. Let ρ and σ be equivalent metrics on a nonempty set X . Show that (X, ρ) is complete if and only if (X, σ) is complete.

Solution. Recall the definition: two metrics ρ and σ on a set X are equivalent provided there are positive numbers c_1 and c_2 such that

$$c_1 \cdot \sigma(x_1, x_2) \leq \rho(x_1, x_2) \leq c_2 \cdot \sigma(x_1, x_2) \quad \text{for all } x_1, x_2 \in X.$$

Call this pair of inequalities (*).

Observe first that this relation is symmetric in ρ and σ . Dividing (*) through by the positive constants gives, for all $x_1, x_2 \in X$,

$$\frac{1}{c_2} \rho(x_1, x_2) \leq \sigma(x_1, x_2) \leq \frac{1}{c_1} \rho(x_1, x_2),$$

which is (*) with the roles of ρ and σ interchanged and with the constants $1/c_2$ and $1/c_1$, both positive. Consequently it suffices to prove one implication; the other follows by exchanging the names of the two metrics.

We prove two auxiliary facts.

Claim 1: a sequence $\{x_n\}$ in X is Cauchy in (X, ρ) if and only if it is Cauchy in (X, σ) .

Suppose $\{x_n\}$ is σ -Cauchy and let $\epsilon > 0$. Since $c_2 > 0$, there is an index N such that $\sigma(x_n, x_m) < \epsilon/c_2$ whenever $n, m \geq N$. Then by the right-hand inequality of (*), for $n, m \geq N$,

$$\rho(x_n, x_m) \leq c_2 \cdot \sigma(x_n, x_m) < c_2 \cdot \frac{\epsilon}{c_2} = \epsilon.$$

So $\{x_n\}$ is ρ -Cauchy. The converse follows from the symmetry just noted.

Claim 2: a sequence $\{x_n\}$ converges to a point x in (X, ρ) if and only if it converges to the same point x in (X, σ) .

If $\rho(x_n, x) \rightarrow 0$, then by the left-hand inequality of $(*)$,

$$0 \leq \sigma(x_n, x) \leq \frac{1}{c_1} \rho(x_n, x) \rightarrow 0,$$

so $\sigma(x_n, x) \rightarrow 0$. Again the converse follows by symmetry. (This is also immediate from Proposition 7, which asserts that equivalent metrics on X determine the same open sets, hence the same closed sets and the same convergent sequences with the same limits.)

Now suppose (X, ρ) is complete, and let $\{x_n\}$ be a Cauchy sequence in (X, σ) . By Claim 1, $\{x_n\}$ is Cauchy in (X, ρ) . By the completeness of (X, ρ) , there is a point $x \in X$ with $\rho(x_n, x) \rightarrow 0$. By Claim 2, $\sigma(x_n, x) \rightarrow 0$, so $\{x_n\}$ converges in (X, σ) to the point x of X . Since $\{x_n\}$ was an arbitrary σ -Cauchy sequence, (X, σ) is complete.

By the symmetry of the equivalence relation established at the outset, the same argument with ρ and σ interchanged shows that if (X, σ) is complete then so is (X, ρ) . Therefore (X, ρ) is complete if and only if (X, σ) is complete.

It is worth stressing that equivalence of metrics in the sense of $(*)$ is strictly stronger than the requirement that the two metrics induce the same topology, and it is the two-sided linear comparison that makes Claim 1 work. Completeness is not a topological invariant: on $X = (0, 1)$ the usual metric $\rho(s, t) = |s - t|$ and the metric $\sigma(s, t) = |\tan(\pi s - \pi/2) - \tan(\pi t - \pi/2)|$ induce exactly the same open subsets of $(0, 1)$, yet (X, ρ) is not complete (the sequence $x_n = 1/n$ is ρ -Cauchy with no limit in X) while (X, σ) is complete, being isometric to $\mathbb{R}$. These two metrics are therefore not equivalent in the sense of $(*)$. What the present problem shows is that the stronger relation $(*)$ does preserve completeness, because it preserves the class of Cauchy sequences and not merely the class of convergent ones.

Problem 9.42. Prove that the product of two complete metric spaces is complete.

Solution. Let (X_1, ρ_1) and (X_2, ρ_2) be complete metric spaces, and let τ be the product metric on the Cartesian product $X_1 \times X_2$, defined for (x_1, x_2) and (y_1, y_2) in $X_1 \times X_2$ by

$$\tau((x_1, x_2), (y_1, y_2)) = \left\{ [\rho_1(x_1, y_1)]^2 + [\rho_2(x_2, y_2)]^2 \right\}^{1/2}.$$

We must show that $(X_1 \times X_2, \tau)$ is complete.

We first record the elementary comparison estimates that drive the proof. For nonnegative reals a and b we have $a^2 \leq a^2 + b^2$ and $b^2 \leq a^2 + b^2$, and also $a^2 + b^2 \leq (a + b)^2$. Taking square roots (the square root is increasing on $[0, \infty)$),

$$\max\{a, b\} \leq \sqrt{a^2 + b^2} \leq a + b.$$

Applying this with $a = \rho_1(x_1, y_1)$ and $b = \rho_2(x_2, y_2)$ gives, for all $x = (x_1, x_2)$ and $y = (y_1, y_2)$ in $X_1 \times X_2$,

$$\rho_1(x_1, y_1) \leq \tau(x, y), \quad \rho_2(x_2, y_2) \leq \tau(x, y),$$

and

$$\tau(x, y) \leq \rho_1(x_1, y_1) + \rho_2(x_2, y_2).$$

Now let $\{z_n\}$ be a Cauchy sequence in $(X_1 \times X_2, \tau)$, and write $z_n = (x_n, y_n)$ with $x_n \in X_1$ and $y_n \in X_2$. The coordinate sequences are Cauchy. Indeed, let $\epsilon > 0$. There is an index N such that $\tau(z_n, z_m) < \epsilon$ whenever $n, m \geq N$. For such n, m the first pair of estimates gives

$$\rho_1(x_n, x_m) \leq \tau(z_n, z_m) < \epsilon \quad \text{and} \quad \rho_2(y_n, y_m) \leq \tau(z_n, z_m) < \epsilon.$$

Hence $\{x_n\}$ is Cauchy in (X_1, ρ_1) and $\{y_n\}$ is Cauchy in (X_2, ρ_2) .

Since (X_1, ρ_1) is complete, there is a point $x \in X_1$ with $\lim_{n \rightarrow \infty} \rho_1(x_n, x) = 0$. Since (X_2, ρ_2) is complete, there is a point $y \in X_2$ with $\lim_{n \rightarrow \infty} \rho_2(y_n, y) = 0$. Set $z = (x, y)$, a point of $X_1 \times X_2$.

We claim $\{z_n\}$ converges to z in the product metric. Let $\epsilon > 0$. Choose N_1 with $\rho_1(x_n, x) < \epsilon/2$ for $n \geq N_1$, and N_2 with $\rho_2(y_n, y) < \epsilon/2$ for $n \geq N_2$. Put $N = \max\{N_1, N_2\}$. Then for $n \geq N$, by the second estimate above,

$$\tau(z_n, z) \leq \rho_1(x_n, x) + \rho_2(y_n, y) < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Therefore $\lim_{n \rightarrow \infty} \tau(z_n, z) = 0$, that is, $\{z_n\}$ converges in $X_1 \times X_2$ to the point z of $X_1 \times X_2$.

Since every Cauchy sequence in $(X_1 \times X_2, \tau)$ converges to a point of $X_1 \times X_2$, the product is complete.

Two remarks. First, the argument in fact establishes the sharper statement that a sequence in $X_1 \times X_2$ is τ -Cauchy (respectively, τ -convergent) if and only if both of its coordinate sequences are Cauchy (respectively, convergent) in their factors; the forward direction is the display above, and the reverse direction follows from $\tau(z, w) \leq \rho_1 + \rho_2$ exactly as in the last paragraph. Second, the same proof applies verbatim to any of the standard product metrics

$$\tau_1 = \rho_1 + \rho_2, \quad \tau_\infty = \max\{\rho_1, \rho_2\},$$

since the inequalities $\tau_\infty \leq \tau \leq \tau_1 \leq 2\tau_\infty$ show that all three are equivalent metrics on $X_1 \times X_2$ in the sense of the definition of Section 9.1; by Problem 41 completeness for one is completeness for all. Finally, by induction, the product of finitely many complete metric spaces is complete; the countable case is treated in Problem 45.

9.7 Problems 9.43–9.49

Problem 9.43. For a mapping f of the metric space (X, ρ) to the metric space (Y, σ) , show that f is uniformly continuous if and only if for any two sequences $\{u_n\}$ and $\{v_n\}$ in X ,

$$\text{if } \lim_{n \rightarrow \infty} \rho(u_n, v_n) = 0, \text{ then } \lim_{n \rightarrow \infty} \sigma(f(u_n), f(v_n)) = 0.$$

Solution. Recall that f is uniformly continuous provided that for each $\epsilon > 0$ there is a $\delta > 0$ such that for all u, v in X , if $\rho(u, v) < \delta$ then $\sigma(f(u), f(v)) < \epsilon$.

Necessity. Assume f is uniformly continuous, and let $\{u_n\}, \{v_n\}$ be sequences in X with $\lim_{n \rightarrow \infty} \rho(u_n, v_n) = 0$. Let $\epsilon > 0$. Choose $\delta > 0$ responding to this ϵ in the definition of uniform continuity. Since $\rho(u_n, v_n) \rightarrow 0$, there is an index N such that $\rho(u_n, v_n) < \delta$ for all $n \geq N$. Then, by the choice of δ ,

$$\sigma(f(u_n), f(v_n)) < \epsilon \quad \text{for all } n \geq N.$$

Since $\epsilon > 0$ was arbitrary, $\lim_{n \rightarrow \infty} \sigma(f(u_n), f(v_n)) = 0$.

Sufficiency. We argue by contraposition: assume f is not uniformly continuous and produce two sequences that violate the stated implication. Failure of uniform continuity means: there is an $\epsilon_0 > 0$ such that for every $\delta > 0$ there exist points u, v in X with

$$\rho(u, v) < \delta \quad \text{while} \quad \sigma(f(u), f(v)) \geq \epsilon_0.$$

For each index n apply this with $\delta = 1/n$ to select points u_n, v_n in X for which

$$\rho(u_n, v_n) < \frac{1}{n} \quad \text{and} \quad \sigma(f(u_n), f(v_n)) \geq \epsilon_0.$$

Then $\{u_n\}$ and $\{v_n\}$ are sequences in X with $\lim_{n \rightarrow \infty} \rho(u_n, v_n) = 0$, since $0 \leq \rho(u_n, v_n) < 1/n$ for every n . On the other hand $\sigma(f(u_n), f(v_n)) \geq \epsilon_0 > 0$ for every n , so the sequence of real numbers $\{\sigma(f(u_n), f(v_n))\}$ certainly does not converge to 0. Thus the sequential criterion fails.

Equivalently: if the sequential criterion holds for every pair of sequences, then f must be uniformly continuous. This completes the proof.

Problem 9.44. Use the outline below to prove the following extension property for uniformly continuous mappings: Let X and Y be metric spaces, with Y complete, and f a uniformly continuous mapping from a subset E of X to Y . Then f has a unique uniformly continuous extension to a mapping $\bar{f}$ of $\bar{E}$ to Y .

- (i) Show that f maps Cauchy sequences in E to Cauchy sequences in Y .
- (ii) For $x \in \bar{E}$, choose a sequence $\{x_n\}$ in E that converges to x and define $\bar{f}(x)$ to be the limit of $\{f(x_n)\}$. Use Problem 43 to show that $\bar{f}(x)$ is properly defined.
- (iii) Show that $\bar{f}$ is uniformly continuous on $\bar{E}$.
- (iv) Show that the above extension is unique since any two such extensions are continuous mappings on $\bar{E}$ that take the same values on the dense subset E of $\bar{E}$.

Solution. Write ρ for the metric on X and σ for the metric on Y . We record once the elementary inequality that will be used repeatedly: for points a, b, c, e of a metric space with metric d ,

$$|d(a, b) - d(c, e)| \leq d(a, c) + d(b, e),$$

which follows from two applications of the triangle inequality. In particular, if $a_n \rightarrow a$ and $b_n \rightarrow b$ then $d(a_n, b_n) \rightarrow d(a, b)$; the metric is continuous in its two variables jointly.

(i) f carries Cauchy sequences to Cauchy sequences. Let $\{x_n\}$ be a Cauchy sequence in E and let $\epsilon > 0$. By the uniform continuity of f there is a $\delta > 0$ such that $\sigma(f(u), f(v)) < \epsilon$ whenever $u, v \in E$ and $\rho(u, v) < \delta$. Since $\{x_n\}$ is Cauchy there is an index N with $\rho(x_n, x_m) < \delta$ for all $n, m \geq N$. Hence $\sigma(f(x_n), f(x_m)) < \epsilon$ for all $n, m \geq N$. Therefore $\{f(x_n)\}$ is a Cauchy sequence in Y .

(ii) The definition of $\bar{f}$ is proper. Let $x \in \bar{E}$. By Proposition 6 of this chapter, a point of closure of E is the limit of a sequence in E , so there is a sequence $\{x_n\}$ in E with $x_n \rightarrow x$. A convergent sequence is Cauchy (Problem 37), so $\{x_n\}$ is Cauchy in E , and by (i) $\{f(x_n)\}$ is a Cauchy sequence in Y . Since Y is complete, $\{f(x_n)\}$ converges to a point of Y ; call it y .

We must check y does not depend on the chosen sequence. Let $\{x_n\}$ and $\{x'_n\}$ be two sequences in E converging to x , with $f(x_n) \rightarrow y$ and $f(x'_n) \rightarrow y'$. Then

$$0 \leq \rho(x_n, x'_n) \leq \rho(x_n, x) + \rho(x, x'_n) \rightarrow 0,$$

so $\lim_{n \rightarrow \infty} \rho(x_n, x'_n) = 0$. Since f is uniformly continuous on E , Problem 43 (applied to f regarded as a mapping of the metric subspace E into Y) gives

$$\lim_{n \rightarrow \infty} \sigma(f(x_n), f(x'_n)) = 0.$$

On the other hand, by the continuity of the metric noted above, $\sigma(f(x_n), f(x'_n)) \rightarrow \sigma(y, y')$. Hence $\sigma(y, y') = 0$, that is, $y = y'$. Therefore

$$\bar{f}(x) := \lim_{n \rightarrow \infty} f(x_n) \quad (\{x_n\} \subseteq E, x_n \rightarrow x)$$

is a well-defined mapping of $\bar{E}$ into Y . Moreover, if $x \in E$ we may take the constant sequence $x_n = x$ for all n , and then $\bar{f}(x) = f(x)$. Thus $\bar{f}$ is an extension of f .

(iii) $\bar{f}$ is uniformly continuous on $\bar{E}$. Let $\epsilon > 0$. Choose $\delta > 0$ such that

$$u, v \in E, \rho(u, v) < \delta \implies \sigma(f(u), f(v)) < \epsilon/2.$$

We claim that if $x, x' \in \bar{E}$ and $\rho(x, x') < \delta/2$, then $\sigma(\bar{f}(x), \bar{f}(x')) \leq \epsilon/2 < \epsilon$. Indeed, choose sequences $\{x_n\}, \{x'_n\}$ in E with $x_n \rightarrow x$ and $x'_n \rightarrow x'$; by (ii), $f(x_n) \rightarrow \bar{f}(x)$ and $f(x'_n) \rightarrow \bar{f}(x')$. By the continuity of ρ , $\rho(x_n, x'_n) \rightarrow \rho(x, x') < \delta/2$, so there is an index N with $\rho(x_n, x'_n) < \delta$ for $n \geq N$, and therefore

$$\sigma(f(x_n), f(x'_n)) < \epsilon/2 \quad \text{for all } n \geq N.$$

Letting $n \rightarrow \infty$ and using the continuity of σ ,

$$\sigma(\bar{f}(x), \bar{f}(x')) = \lim_{n \rightarrow \infty} \sigma(f(x_n), f(x'_n)) \leq \epsilon/2 < \epsilon.$$

Since $\epsilon > 0$ was arbitrary and $\delta/2$ depends only on ϵ , $\bar{f}$ is uniformly continuous on $\bar{E}$.

(iv) Uniqueness. Suppose g and h are continuous mappings of $\bar{E}$ into Y that agree with f on E ; in particular this covers any two uniformly continuous extensions of f . Let $x \in \bar{E}$ and choose a sequence $\{x_n\}$ in E with $x_n \rightarrow x$; such a sequence exists by Proposition 6 of this chapter, that is, precisely because E is dense in $\bar{E}$. By Proposition 8 of this chapter, continuity of a mapping between metric spaces is equivalent to sequential continuity, so

$$g(x) = \lim_{n \rightarrow \infty} g(x_n) = \lim_{n \rightarrow \infty} f(x_n) = \lim_{n \rightarrow \infty} h(x_n) = h(x),$$

the limits being taken in Y and the middle equalities holding because $x_n \in E$. Since $x \in \bar{E}$ was arbitrary, $g = h$. Hence the uniformly continuous extension $\bar{f}$ constructed in (ii)-(iii) is the only one.

Problem 9.45. Consider the countable collection of metric spaces $\{(X_n, \rho_n)\}_{n=1}^{\infty}$. For the Cartesian product of these sets $Z = \prod_{n=1}^{\infty} X_n$, define σ on $Z \times Z$ by setting, for $x = \{x_n\}$, $y = \{y_n\}$,

$$\sigma(x, y) = \sum_{n=1}^{\infty} 2^{-n} \rho_n^*(x_n, y_n) \quad \text{where each } \rho_n^* = \rho_n / (1 + \rho_n).$$

- (i) Show that σ is a metric.
- (ii) Show that (Z, σ) is complete if and only if each (X_n, ρ_n) is complete.

Solution. Throughout, each X_n is assumed nonempty. (This is the only reading under which the assertion in (ii) is correct: if some X_j were empty, then $Z = \emptyset$ would be complete no matter how the remaining factors behave.)

A scalar lemma. Let $\varphi(t) = t/(1+t)$ for $t \geq 0$. Then φ is strictly increasing, since $\varphi'(t) = (1+t)^{-2} > 0$; $0 \leq \varphi(t) < 1$; $\varphi(t) = 0$ only for $t = 0$; and φ is subadditive: for $s, t \geq 0$,

$$\varphi(s+t) = \frac{s}{1+s+t} + \frac{t}{1+s+t} \leq \frac{s}{1+s} + \frac{t}{1+t} = \varphi(s) + \varphi(t).$$

Its inverse on $[0, 1)$ is $\psi(u) = u/(1-u)$.

Step 1: each $\rho_n^* = \varphi \circ \rho_n$ is a metric on X_n , and it has the same Cauchy and convergent sequences as ρ_n . Nonnegativity and symmetry are inherited from ρ_n ; $\rho_n^*(u, v) = 0$ iff $\rho_n(u, v) = 0$ iff $u = v$. For the triangle inequality, using monotonicity and then subadditivity of φ ,

$$\rho_n^*(u, w) = \varphi(\rho_n(u, w)) \leq \varphi(\rho_n(u, v) + \rho_n(v, w)) \leq \rho_n^*(u, v) + \rho_n^*(v, w).$$

Furthermore $\rho_n^* \leq \rho_n$, while for $\epsilon > 0$ the implication $\rho_n^*(u, v) < \varphi(\epsilon) \Rightarrow \rho_n(u, v) < \epsilon$ holds because φ is strictly increasing and $\varphi(\epsilon) > 0$. These two comparisons give, for any $\epsilon > 0$ and any $u, v \in X_n$,

$$\rho_n(u, v) < \epsilon \implies \rho_n^*(u, v) < \epsilon, \quad \rho_n^*(u, v) < \varphi(\epsilon) \implies \rho_n(u, v) < \epsilon,$$

Hence a sequence in X_n is ρ_n -Cauchy if and only if it is ρ_n^* -Cauchy, and it ρ_n -converges to a point u if and only if it ρ_n^* -converges to u . (We do not claim that ρ_n and ρ_n^* are equivalent metrics in the sense defined in Section 9.1: that definition demands two-sided bounds by positive constant multiples of each other, and such bounds fail as soon as ρ_n is unbounded, since $\rho_n^* < 1$ always. The one-sided comparisons just proved are all we shall use.)

Step 2: (i) σ is a metric on Z . Since $0 \leq 2^{-n} \rho_n^*(x_n, y_n) \leq 2^{-n}$, the defining series converges and $0 \leq \sigma(x, y) \leq 1$; so σ is a well-defined finite, nonnegative, symmetric function. If $\sigma(x, y) = 0$ then every term of a convergent series of nonnegative terms vanishes, so $\rho_n^*(x_n, y_n) = 0$, i.e. $x_n = y_n$, for every n ; thus $x = y$. Conversely $\sigma(x, x) = 0$. For the triangle inequality, apply the triangle inequality for ρ_n^* in each coordinate and sum the (convergent, nonnegative) series:

$$\sigma(x, z) = \sum_{n=1}^{\infty} 2^{-n} \rho_n^*(x_n, z_n) \leq \sum_{n=1}^{\infty} 2^{-n} [\rho_n^*(x_n, y_n) + \rho_n^*(y_n, z_n)] = \sigma(x, y) + \sigma(y, z).$$

Step 3: σ -Cauchyness and σ -convergence are coordinatewise. Fix m . From the definition, since all terms are nonnegative,

$$2^{-m} \rho_m^*(x_m, y_m) \leq \sigma(x, y) \quad \text{for all } x, y \in Z. \quad (*)$$

Conversely, given $\epsilon > 0$ choose N with $\sum_{n>N} 2^{-n} < \epsilon/2$; then for all $x, y \in Z$,

$$\sigma(x, y) \leq \sum_{n=1}^N 2^{-n} \rho_n^*(x_n, y_n) + \frac{\epsilon}{2}. \quad (**)$$

Let $\{x^{(k)}\}$ be a sequence in Z , $x^{(k)} = \{x_n^{(k)}\}_{n \geq 1}$.

If $\{x^{(k)}\}$ is σ -Cauchy, then by $(*)$ each coordinate sequence $\{x_n^{(k)}\}_{k \geq 1}$ is ρ_n^* -Cauchy, hence ρ_n -Cauchy by Step 1. Conversely, if every coordinate sequence is Cauchy, let $\epsilon > 0$ and pick N as in $(**)$; choose K so large that $\rho_n^*(x_n^{(k)}, x_n^{(j)}) < \epsilon/2$ for all $k, j \geq K$ and all $n = 1, \dots, N$ (finitely many conditions). Then for $k, j \geq K$, by $(**)$,

$$\sigma(x^{(k)}, x^{(j)}) \leq \frac{\epsilon}{2} \sum_{n=1}^N 2^{-n} + \frac{\epsilon}{2} < \epsilon.$$

So $\{x^{(k)}\}$ is σ -Cauchy. The identical argument, with $x^{(j)}$ replaced by a fixed $x \in Z$, shows that $x^{(k)} \rightarrow x$ in (Z, σ) if and only if $x_n^{(k)} \rightarrow x_n$ in (X_n, ρ_n) for every n .

Step 4: (ii) the equivalence. Suppose each (X_n, ρ_n) is complete, and let $\{x^{(k)}\}$ be a Cauchy sequence in (Z, σ) . By Step 3 each coordinate sequence $\{x_n^{(k)}\}_{k \geq 1}$ is Cauchy in (X_n, ρ_n) , so it converges to some $x_n \in X_n$. Put $x = \{x_n\} \in Z$. By Step 3 again, $x^{(k)} \rightarrow x$ in (Z, σ) . Hence (Z, σ) is complete.

Conversely, suppose (Z, σ) is complete and fix an index m ; we show (X_m, ρ_m) is complete. For each $n \neq m$ select a point $a_n \in X_n$. Let $\{u^{(k)}\}$ be a Cauchy sequence in (X_m, ρ_m) , and define $x^{(k)} \in Z$ by

$$x_m^{(k)} = u^{(k)}, \quad x_n^{(k)} = a_n \quad (n \neq m).$$

Every coordinate sequence of $\{x^{(k)}\}$ is Cauchy — the m -th by hypothesis, the others because they are constant — so by Step 3 $\{x^{(k)}\}$ is Cauchy in (Z, σ) , and by completeness it converges to some $x \in Z$. By Step 3 the m -th coordinates converge: $u^{(k)} \rightarrow x_m$ in (X_m, ρ_m) . Thus every Cauchy sequence in X_m converges in X_m , i.e. (X_m, ρ_m) is complete. Since m was arbitrary, every factor is complete.

Problem 9.46. For each index n , define $f_n(x) = \alpha x^n + \beta \cos(x/n)$ for $0 \leq x \leq 1$. For what values of the parameters α and β is the sequence $\{f_n\}$ a Cauchy sequence in the metric space $C[0, 1]$?

Solution. Here $C[0, 1]$ carries the uniform metric

$$\rho(f, g) = \max_{0 \leq x \leq 1} |f(x) - g(x)|,$$

so a sequence is Cauchy in $C[0, 1]$ precisely when it is uniformly Cauchy on $[0, 1]$.

Answer: $\{f_n\}$ is Cauchy in $C[0, 1]$ if and only if $\alpha = 0$; the parameter β may be any real number.

Write $f_n = g_n + h_n$ where

$$g_n(x) = \alpha x^n, \quad h_n(x) = \beta \cos(x/n), \quad 0 \leq x \leq 1.$$

Step 1: $\{h_n\}$ is always uniformly Cauchy. Using $1 - \cos t = 2 \sin^2(t/2)$ and $|\sin s| \leq |s|$, for $0 \leq x \leq 1$,

$$|\cos(x/n) - 1| = 2 \sin^2\left(\frac{x}{2n}\right) \leq 2 \left(\frac{x}{2n}\right)^2 = \frac{x^2}{2n^2} \leq \frac{1}{2n^2}.$$

Hence, denoting by c the constant function with value β ,

$$\rho(h_n, c) = \max_{0 \leq x \leq 1} |\beta| |\cos(x/n) - 1| \leq \frac{|\beta|}{2n^2} \longrightarrow 0.$$

So $h_n \rightarrow c$ in $C[0, 1]$; in particular $\{h_n\}$ is a Cauchy sequence in $C[0, 1]$ (a convergent sequence is Cauchy, Problem 37), for every value of β .

Step 2: $\{f_n\}$ is Cauchy if and only if $\{g_n\}$ is Cauchy. Since $g_n = f_n - h_n$ and $f_n = g_n + h_n$, and since for any functions u_n, v_n one has

$$\rho(u_n + v_n, u_m + v_m) \leq \rho(u_n, u_m) + \rho(v_n, v_m),$$

the sum of two Cauchy sequences in $C[0, 1]$ is Cauchy. By Step 1 the sequence $\{h_n\}$, and likewise $\{-h_n\}$, is Cauchy; therefore $\{f_n\} = \{g_n + h_n\}$ is Cauchy if $\{g_n\}$ is, and $\{g_n\} = \{f_n + (-h_n)\}$ is Cauchy if $\{f_n\}$ is.

Step 3: $\{g_n\}$ is Cauchy if and only if $\alpha = 0$. If $\alpha = 0$ then $g_n \equiv 0$ for every n and the sequence is trivially Cauchy.

Suppose $\alpha \neq 0$. For each index n put $x_n = 2^{-1/n}$, so that $0 < x_n \leq 1$ and

$$x_n^n = \frac{1}{2}, \quad x_n^{2n} = \frac{1}{4}.$$

Then

$$\rho(g_n, g_{2n}) = \max_{0 \leq x \leq 1} |\alpha| |x^n - x^{2n}| \geq |\alpha| |x_n^n - x_n^{2n}| = \frac{|\alpha|}{4} > 0.$$

Thus with $\epsilon = |\alpha|/4$ there is, for every index N , a pair of indices $n, m \geq N$ (namely n and $m = 2n$ with $n \geq N$) for which $\rho(g_n, g_m) \geq \epsilon$. Hence $\{g_n\}$ is not Cauchy.

Combining Steps 2 and 3: $\{f_n\}$ is a Cauchy sequence in $C[0, 1]$ exactly when $\alpha = 0$, and then, by Step 1, f_n converges uniformly on $[0, 1]$ to the constant function β . For $\alpha \neq 0$ the sequence fails to be Cauchy for every β . (This is consistent with the completeness of $C[0, 1]$: for $\alpha \neq 0$ the pointwise limit of f_n is β on $[0, 1)$ and $\alpha + \beta$ at $x = 1$, a discontinuous function, so no uniform limit in $C[0, 1]$ can exist.)

Problem 9.47. Let $\mathcal{D}$ be the subspace of $C[0, 1]$ consisting of the continuous functions $f : [0, 1] \rightarrow \mathbb{R}$ that are differentiable on $(0, 1)$. Is $\mathcal{D}$ complete?

Solution. No: $\mathcal{D}$ is not complete.

Recall that $C[0, 1]$ carries the metric induced by the maximum norm, $\rho(f, g) = \max_{0 \leq x \leq 1} |f(x) - g(x)|$, that this metric space is complete by Proposition 10 of this chapter, and that by Proposition 11 of this chapter a subset of a complete metric space is a complete metric subspace if and only if it is a closed subset. So it suffices to exhibit a sequence in $\mathcal{D}$ that is Cauchy in $\mathcal{D}$ but whose limit in $C[0, 1]$ fails to be differentiable on all of $(0, 1)$.

The example. Define

$$f(x) = \left|x - \frac{1}{2}\right|, \quad f_n(x) = \sqrt{\left(x - \frac{1}{2}\right)^2 + \frac{1}{n^2}} \quad (0 \leq x \leq 1, n \geq 1).$$

Each f_n belongs to $\mathcal{D}$. The function $t \mapsto \sqrt{t^2 + n^{-2}}$ is the composition of the polynomial $t \mapsto t^2 + n^{-2}$, which takes values in $[n^{-2}, \infty) \subseteq (0, \infty)$, with the square root, which is differentiable on $(0, \infty)$. Hence f_n is continuous on $[0, 1]$ and differentiable at every point of $(0, 1)$ (indeed at every real number), with

$$f'_n(x) = \frac{x - \frac{1}{2}}{\sqrt{(x - \frac{1}{2})^2 + n^{-2}}}.$$

$f_n \rightarrow f$ uniformly on $[0, 1]$. Put $t = x - \frac{1}{2}$ and $a = 1/n > 0$. Rationalizing,

$$0 \leq \sqrt{t^2 + a^2} - |t| = \frac{a^2}{\sqrt{t^2 + a^2} + |t|} \leq \frac{a^2}{a} = a.$$

Hence

$$\rho(f_n, f) = \max_{0 \leq x \leq 1} |f_n(x) - f(x)| \leq \frac{1}{n} \longrightarrow 0.$$

So $f_n \rightarrow f$ in the metric space $C[0, 1]$; in particular $\{f_n\}$ is a Cauchy sequence in $C[0, 1]$, and since all its terms lie in $\mathcal{D}$, it is a Cauchy sequence in the metric subspace $\mathcal{D}$.
 $f \notin \mathcal{D}$. The point $\frac{1}{2}$ lies in $(0, 1)$, and for $h \neq 0$,

$$\frac{f(\frac{1}{2} + h) - f(\frac{1}{2})}{h} = \frac{|h|}{h} = \begin{cases} 1, & h > 0, \\ -1, & h < 0, \end{cases}$$

so the difference quotient has no limit as $h \rightarrow 0$: f is not differentiable at $\frac{1}{2}$. Thus f is continuous on $[0, 1]$ but $f \notin \mathcal{D}$.

Conclusion. Suppose, for the sake of contradiction, that $\{f_n\}$ converged in the metric space $\mathcal{D}$ to some $g \in \mathcal{D}$. Then $\rho(f_n, g) \rightarrow 0$, so $f_n \rightarrow g$ in $C[0, 1]$ as well. Limits in a metric space are unique, and $f_n \rightarrow f$ in $C[0, 1]$; hence $g = f$. But $f \notin \mathcal{D}$, a contradiction. Therefore $\{f_n\}$ is a Cauchy sequence in $\mathcal{D}$ with no limit in $\mathcal{D}$, and $\mathcal{D}$ is not complete.

(Equivalently: f is a point of $C[0, 1]$ that is a limit of points of $\mathcal{D}$ but does not belong to $\mathcal{D}$, so $\mathcal{D}$ is not a closed subset of the complete space $C[0, 1]$. In fact $\mathcal{D}$ is very far from closed: it contains all polynomials, so by the Weierstrass Approximation Theorem $\mathcal{D}$ is dense in $C[0, 1]$ while being a proper subset of it.)

Problem 9.48. Define $\mathcal{L}$ to be the subspace of $C[0, 1]$ consisting of the functions $f : [0, 1] \rightarrow \mathbb{R}$ that are Lipschitz. Is $\mathcal{L}$ complete?

Solution. No: $\mathcal{L}$ is not complete.

Recall that $f : [0, 1] \rightarrow \mathbb{R}$ is Lipschitz provided there is a constant $c \geq 0$ with $|f(u) - f(v)| \leq c|u - v|$ for all $u, v \in [0, 1]$; such an f is (uniformly) continuous, so $\mathcal{L} \subseteq C[0, 1]$. As in the preceding problem, $C[0, 1]$ with $\rho(f, g) = \max_{0 \leq x \leq 1} |f(x) - g(x)|$ is complete by Proposition 10 of this chapter, and by Proposition 11 of this chapter a metric subspace of a complete metric space is complete if and only if it is a closed subset. We exhibit a Cauchy sequence in $\mathcal{L}$ whose limit in $C[0, 1]$ is not Lipschitz.

The example. Define

$$f(x) = \sqrt{x}, \quad f_n(x) = \sqrt{x + \frac{1}{n}} \quad (0 \leq x \leq 1, n \geq 1).$$

Each f_n belongs to $\mathcal{L}$. For $u, v \in [0, 1]$, rationalizing,

$$|f_n(u) - f_n(v)| = \frac{|u - v|}{\sqrt{u + \frac{1}{n}} + \sqrt{v + \frac{1}{n}}} \leq \frac{|u - v|}{2/\sqrt{n}} = \frac{\sqrt{n}}{2} |u - v|,$$

since $u + \frac{1}{n} \geq \frac{1}{n}$ and $v + \frac{1}{n} \geq \frac{1}{n}$. So f_n is Lipschitz with constant $\sqrt{n}/2$, and f_n is continuous on $[0, 1]$; thus $f_n \in \mathcal{L}$.

$f_n \rightarrow f$ uniformly on $[0, 1]$. For $0 \leq x \leq 1$,

$$0 \leq \sqrt{x + \frac{1}{n}} - \sqrt{x} = \frac{1/n}{\sqrt{x + \frac{1}{n}} + \sqrt{x}} \leq \frac{1/n}{\sqrt{1/n}} = \frac{1}{\sqrt{n}},$$

so $\rho(f_n, f) \leq 1/\sqrt{n} \rightarrow 0$. Hence $f_n \rightarrow f$ in $C[0, 1]$, and therefore $\{f_n\}$ is a Cauchy sequence in $C[0, 1]$; since every f_n lies in $\mathcal{L}$, it is a Cauchy sequence in the metric subspace $\mathcal{L}$.

$f \notin \mathcal{L}$. Suppose $\sqrt{\cdot}$ were Lipschitz on $[0, 1]$ with constant c . Taking $v = 0$ and $u = x \in (0, 1]$ gives $\sqrt{x} \leq cx$, that is, $c \geq 1/\sqrt{x}$ for every $x \in (0, 1]$. Letting $x \rightarrow 0^+$ makes the right-hand side unbounded, which is impossible for a finite c . So $f(x) = \sqrt{x}$ is continuous on $[0, 1]$ but not Lipschitz.

Conclusion. If $\{f_n\}$ had a limit g in the metric space $\mathcal{L}$, then $f_n \rightarrow g$ in $C[0, 1]$; by uniqueness of limits in $C[0, 1]$ and $f_n \rightarrow f$, we would get $g = f$, contradicting $f \notin \mathcal{L}$. Hence $\{f_n\}$ is a Cauchy sequence in $\mathcal{L}$ that fails to converge in $\mathcal{L}$, and $\mathcal{L}$ is not complete.

(As before, this says exactly that $\mathcal{L}$ is not a closed subset of $C[0, 1]$. Since $\mathcal{L}$ contains all polynomials, the Weierstrass Approximation Theorem shows $\mathcal{L}$ is in fact a dense proper subspace of $C[0, 1]$.)

Problem 9.49. For a metric space (X, ρ) , complete the following outline of a proof of Theorem 13:

- (i) If $\{x_n\}$ and $\{y_n\}$ are Cauchy sequences in X , show that $\{\rho(x_n, y_n)\}$ is a Cauchy sequence of real numbers and therefore converges.
- (ii) Define X' to be the set of Cauchy sequences in X . For two Cauchy sequences in X , $\{x_n\}$ and $\{y_n\}$, define $\rho'(\{x_n\}, \{y_n\}) = \lim \rho(x_n, y_n)$. Show that this defines a pseudometric ρ' on X' .
- (iii) Define two members of X' , that is, two Cauchy sequences $\{x_n\}$ and $\{y_n\}$ in X , to be equivalent, provided $\rho'(\{x_n\}, \{y_n\}) = 0$. Show that this is an equivalence relation in X' and denote by $\hat{X}$ the set of equivalence classes. Define the distance $\hat{\rho}$ between two equivalence classes to be the ρ' distance between representatives of the classes. Show that $\hat{\rho}$ is properly defined and is a metric on $\hat{X}$.
- (iv) Show that the metric space $(\hat{X}, \hat{\rho})$ is complete. [Hint: If $\{x_n\}$ is a Cauchy sequence from X , we may assume (by taking subsequences) that $\rho(x_n, x_{n+1}) < 2^{-n}$ for all n . If $\{\{x_{n,m}\}_{n=1}^{\infty}\}_{m=1}^{\infty}$ is a sequence of such Cauchy sequences that represents a Cauchy sequence in $\hat{X}$, then the sequence $\{x_{n,n}\}_{n=1}^{\infty}$ is a Cauchy sequence from X that represents the limit of the Cauchy sequences from $\hat{X}$.]
- (v) Define the mapping h from X to $\hat{X}$ by defining, for $x \in X$, $h(x)$ to be the equivalence class of the constant sequence all of whose terms are x . Show that $h(X)$ is dense in $\hat{X}$ and that $\hat{\rho}(h(u), h(v)) = \rho(u, v)$ for all $u, v \in X$.
- (vi) Define the set $\tilde{X}$ to be the disjoint union of X and $\hat{X} \sim h(X)$. For $u, v \in \tilde{X}$, define $\tilde{\rho}(u, v)$ as follows: $\tilde{\rho}(u, v) = \rho(u, v)$ if $u, v \in X$; $\tilde{\rho}(u, v) = \hat{\rho}(u, v)$ for $u, v \in \hat{X} \sim h(X)$; and $\tilde{\rho}(u, v) = \hat{\rho}(h(u), v)$ for $u \in X, v \in \hat{X} \sim h(X)$. From the preceding two parts conclude that the metric space $(\tilde{X}, \tilde{\rho})$ is a complete metric space containing (X, ρ) as a dense subspace.

Solution. We use repeatedly the quadrilateral inequality, valid in any metric space and obtained from two applications of the triangle inequality:

$$|\rho(a, b) - \rho(c, d)| \leq \rho(a, c) + \rho(b, d). \quad (\text{Q})$$

Part (i). Let $\{x_n\}, \{y_n\}$ be Cauchy in X and let $\epsilon > 0$. Choose N so large that $\rho(x_n, x_m) < \epsilon/2$ and $\rho(y_n, y_m) < \epsilon/2$ for all $n, m \geq N$. By (Q), for $n, m \geq N$,

$$|\rho(x_n, y_n) - \rho(x_m, y_m)| \leq \rho(x_n, x_m) + \rho(y_n, y_m) < \epsilon.$$

Thus $\{\rho(x_n, y_n)\}$ is a Cauchy sequence of real numbers, and since $\mathbb{R}$ is complete it converges.

Part (ii). By (i) the formula $\rho'(\{x_n\}, \{y_n\}) = \lim_{n \rightarrow \infty} \rho(x_n, y_n)$ assigns a real number to every ordered pair of elements of X' , and this number is nonnegative as a limit of nonnegative numbers. Symmetry is clear from the symmetry of ρ , and $\rho'(\{x_n\}, \{x_n\}) = \lim \rho(x_n, x_n) = 0$. For the triangle inequality, if $\{x_n\}, \{y_n\}, \{z_n\} \in X'$ then $\rho(x_n, z_n) \leq \rho(x_n, y_n) + \rho(y_n, z_n)$ for every n ; letting $n \rightarrow \infty$ and using that all three limits exist,

$$\rho'(\{x_n\}, \{z_n\}) \leq \rho'(\{x_n\}, \{y_n\}) + \rho'(\{y_n\}, \{z_n\}).$$

Hence ρ' is a pseudometric. It is not a metric: distinct Cauchy sequences with the same limit (for instance $\{1/n\}$ and $\{-1/n\}$ in $\mathbb{R}$) are at ρ' -distance 0.

Part (iii). Define $s \sim t$ for $s, t \in X'$ to mean $\rho'(s, t) = 0$. Reflexivity holds since $\rho'(s, s) = 0$; symmetry holds since ρ' is symmetric; and if $\rho'(s, t) = 0$ and $\rho'(t, w) = 0$ then $0 \leq \rho'(s, w) \leq \rho'(s, t) + \rho'(t, w) = 0$, giving transitivity. Let $\hat{X} = X'/\sim$ and write $[s]$ for the class of s .

Set $\hat{\rho}([s], [t]) = \rho'(s, t)$. This is properly defined: if $s \sim s'$ and $t \sim t'$, then by the pseudometric triangle inequality used twice,

$$|\rho'(s, t) - \rho'(s', t')| \leq \rho'(s, s') + \rho'(t, t') = 0,$$

so $\rho'(s, t) = \rho'(s', t')$. (The displayed inequality is the analogue of (Q) for a pseudometric, proved the same way.) Nonnegativity, symmetry, and the triangle inequality for $\hat{\rho}$ are inherited from ρ' . Finally $\hat{\rho}([s], [t]) = 0$ means $\rho'(s, t) = 0$, that is $s \sim t$, that is $[s] = [t]$. So $\hat{\rho}$ is a metric on $\hat{X}$.

Part (iv). Call a Cauchy sequence $\{x_n\}$ in X rapid provided $\rho(x_n, x_{n+1}) < 2^{-n}$ for all n .

Every class in $\widehat{X}$ has a rapid representative. Indeed, let $\{x_n\}$ be Cauchy. Choose indices $n_1 < n_2 < \dots$ with $n_k \geq k$ and $\rho(x_p, x_q) < 2^{-k}$ for all $p, q \geq n_k$. Then $\{x_{n_k}\}_k$ is rapid, and

$$\rho'(\{x_n\}, \{x_{n_k}\}) = \lim_{k \rightarrow \infty} \rho(x_k, x_{n_k}) = 0$$

because $k, n_k \geq k$ and $\{x_n\}$ is Cauchy. So $\{x_{n_k}\} \sim \{x_n\}$.

If $\{x_n\}$ is rapid then for $m \geq n$,

$$\rho(x_n, x_m) \leq \sum_{j=n}^{m-1} \rho(x_j, x_{j+1}) < \sum_{j=n}^{\infty} 2^{-j} = 2^{1-n}. \quad (1)$$

Consequently, if $s = \{x_n\}$ and $t = \{y_n\}$ are both rapid, then by (Q) and (1), for $m \geq n$,

$$|\rho(x_n, y_n) - \rho(x_m, y_m)| \leq \rho(x_n, x_m) + \rho(y_n, y_m) < 2^{2-n};$$

letting $m \rightarrow \infty$ gives the key estimate

$$|\rho(x_n, y_n) - \widehat{\rho}([s], [t])| \leq 2^{2-n} \quad \text{for all } n. \quad (2)$$

Now let $\{\xi_m\}$ be a Cauchy sequence in $(\widehat{X}, \widehat{\rho})$, and for each m choose a rapid representative $\{x_{n,m}\}_{n=1}^{\infty}$ of ξ_m . Put $z_n = x_{n,n}$.

The diagonal sequence $\{z_n\}$ is Cauchy in X . Fix n, m and let $k \geq \max\{n, m\}$. Using the triangle inequality, then (1) twice and (2) once,

$$\rho(z_n, z_m) \leq \rho(x_{n,n}, x_{k,n}) + \rho(x_{k,n}, x_{k,m}) + \rho(x_{k,m}, x_{m,m}) < 2^{1-n} + [\widehat{\rho}(\xi_n, \xi_m) + 2^{2-k}] + 2^{1-m}.$$

Since this holds for every $k \geq \max\{n, m\}$, letting $k \rightarrow \infty$ yields

$$\rho(z_n, z_m) \leq 2^{1-n} + 2^{1-m} + \widehat{\rho}(\xi_n, \xi_m). \quad (3)$$

Given $\epsilon > 0$, choose N with $\widehat{\rho}(\xi_n, \xi_m) < \epsilon/2$ for $n, m \geq N$ and with $2^{1-N} < \epsilon/4$; then $\rho(z_n, z_m) < \epsilon$ for $n, m \geq N$. So $\{z_n\} \in X'$; let $\zeta = [\{z_n\}] \in \widehat{X}$.

$\{\xi_m\}$ converges to ζ . By definition,

$$\widehat{\rho}(\xi_m, \zeta) = \rho'(\{x_{n,m}\}_n, \{z_n\}_n) = \lim_{n \rightarrow \infty} \rho(x_{n,m}, x_{n,n}).$$

Let $\epsilon > 0$ and choose N with $\widehat{\rho}(\xi_m, \xi_n) < \epsilon/2$ for all $n, m \geq N$ and with $2^{2-N} < \epsilon/2$. For $m \geq N$ and $n \geq N$, the sequences $\{x_{\cdot, m}\}$ and $\{x_{\cdot, n}\}$ are rapid, so (2) gives

$$\rho(x_{n,m}, x_{n,n}) \leq \widehat{\rho}(\xi_m, \xi_n) + 2^{2-n} < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Letting $n \rightarrow \infty$ with $m \geq N$ fixed gives $\widehat{\rho}(\xi_m, \zeta) \leq \epsilon$. Hence $\widehat{\rho}(\xi_m, \zeta) \rightarrow 0$, that is $\xi_m \rightarrow \zeta$ in $\widehat{X}$. Therefore $(\widehat{X}, \widehat{\rho})$ is complete.

Part (v). For $x \in X$ the constant sequence $c_x = (x, x, x, \dots)$ is Cauchy, so $h(x) = [c_x]$ is a well-defined element of $\widehat{X}$. For $u, v \in X$,

$$\widehat{\rho}(h(u), h(v)) = \rho'(c_u, c_v) = \lim_{n \rightarrow \infty} \rho(u, v) = \rho(u, v),$$

so h is an isometry of X into $\widehat{X}$; in particular h is one-to-one.

To see $h(X)$ is dense in $\widehat{X}$, let $\xi \in \widehat{X}$, choose a representative Cauchy sequence $\{x_n\}$, and let $r > 0$. Choose N with $\rho(x_n, x_m) < r/2$ for all $n, m \geq N$. Then

$$\widehat{\rho}(h(x_N), \xi) = \rho'(c_{x_N}, \{x_n\}) = \lim_{m \rightarrow \infty} \rho(x_N, x_m) \leq \frac{r}{2} < r,$$

the limit existing by (i) and being at most $r/2$ because $\rho(x_N, x_m) < r/2$ for every $m \geq N$. So the open ball of radius r about ξ contains the point $h(x_N)$ of $h(X)$. Since $\xi \in \widehat{X}$ and $r > 0$ were arbitrary, every nonempty open subset of $\widehat{X}$ contains a point of $h(X)$; that is, $h(X)$ is dense in $\widehat{X}$.

Part (vi). Let $\tilde{X}$ be the disjoint union of X and $\hat{X} \sim h(X)$, with $\tilde{\rho}$ defined as in the statement (and symmetrically in the mixed case, $\tilde{\rho}(v, u) = \hat{\rho}(h(u), v)$ for $u \in X, v \in \hat{X} \sim h(X)$). Define

$$H : \tilde{X} \rightarrow \hat{X}, \quad H(u) = h(u) \quad (u \in X), \quad H(v) = v \quad (v \in \hat{X} \sim h(X)).$$

Since h maps X one-to-one onto $h(X)$ and the identity maps $\hat{X} \sim h(X)$ onto itself, and since $\hat{X}$ is the disjoint union of $h(X)$ and $\hat{X} \sim h(X)$, the map H is a one-to-one mapping of $\tilde{X}$ onto $\hat{X}$.

Moreover $\tilde{\rho}(u, v) = \hat{\rho}(H(u), H(v))$ for all $u, v \in \tilde{X}$. Indeed, there are three cases, and each is exactly one clause of the definition of $\tilde{\rho}$: if $u, v \in X$ then $\hat{\rho}(H(u), H(v)) = \hat{\rho}(h(u), h(v)) = \rho(u, v)$ by part (v); if $u, v \in \hat{X} \sim h(X)$ then $\hat{\rho}(H(u), H(v)) = \hat{\rho}(u, v)$; and if $u \in X, v \in \hat{X} \sim h(X)$ then $\hat{\rho}(H(u), H(v)) = \hat{\rho}(h(u), v)$.

Consequently $\tilde{\rho}$ is a metric on $\tilde{X}$: nonnegativity, symmetry and the triangle inequality transfer immediately from $\hat{\rho}$ through the bijection H , and $\tilde{\rho}(u, v) = 0$ forces $H(u) = H(v)$, hence $u = v$ since H is one-to-one. Thus H is an isometry of $(\tilde{X}, \tilde{\rho})$ onto $(\hat{X}, \hat{\rho})$.

An isometry onto carries Cauchy sequences to Cauchy sequences and convergent sequences to convergent sequences, in both directions; therefore $(\tilde{X}, \tilde{\rho})$ is complete because $(\hat{X}, \hat{\rho})$ is complete by part (iv). Explicitly, if $\{u_k\}$ is Cauchy in $\tilde{X}$ then $\{H(u_k)\}$ is Cauchy in $\hat{X}$, so $H(u_k) \rightarrow \xi$ for some $\xi \in \hat{X}$; writing $u = H^{-1}(\xi)$ we get $\tilde{\rho}(u_k, u) = \hat{\rho}(H(u_k), \xi) \rightarrow 0$.

By the first clause of the definition, $\tilde{\rho}(u, v) = \rho(u, v)$ for all $u, v \in X$, so (X, ρ) is a metric subspace of $(\tilde{X}, \tilde{\rho})$. Finally X is dense in $\tilde{X}$: let $u \in \tilde{X}$ and $\epsilon > 0$. Since $h(X) = H(X)$ is dense in $\hat{X}$ by part (v), there is $x \in X$ with $\hat{\rho}(h(x), H(u)) < \epsilon$, and then $\tilde{\rho}(x, u) = \hat{\rho}(H(x), H(u)) < \epsilon$. So every open ball in $\tilde{X}$ meets X .

Therefore $(\tilde{X}, \tilde{\rho})$ is a complete metric space, X is a dense subset of $\tilde{X}$, and $\rho(u, v) = \tilde{\rho}(u, v)$ for all $u, v \in X$. This is precisely the assertion of Theorem 13.

9.8 Problems 9.50–9.56

Problem 9.50. Show that any two completions of a metric space X are isometric by way of an isometry that is the identity mapping on X .

Solution. Let (X, ρ) be a metric space and let $(\tilde{X}_1, \tilde{\rho}_1)$ and $(\tilde{X}_2, \tilde{\rho}_2)$ be two completions of (X, ρ) . By the definition following Theorem 13, this means: each $\tilde{X}_i$ is a complete metric space, X is a dense subset of $\tilde{X}_i$, and

$$\tilde{\rho}_i(u, v) = \rho(u, v) \quad \text{for all } u, v \in X, \quad i = 1, 2.$$

We construct an isometry f of $\tilde{X}_1$ onto $\tilde{X}_2$ that fixes each point of X .

We use twice the following elementary consequence of the triangle inequality, valid in any metric space (Y, σ) : if $y_n \rightarrow y$ and $z_n \rightarrow z$ in Y , then

$$|\sigma(y_n, z_n) - \sigma(y, z)| \leq \sigma(y_n, y) + \sigma(z_n, z),$$

so that $\lim_{n \rightarrow \infty} \sigma(y_n, z_n) = \sigma(y, z)$. Indeed, $\sigma(y_n, z_n) \leq \sigma(y_n, y) + \sigma(y, z) + \sigma(z, z_n)$ and symmetrically $\sigma(y, z) \leq \sigma(y, y_n) + \sigma(y_n, z_n) + \sigma(z_n, z)$.

Definition of f . Let $u \in \tilde{X}_1$. Since X is dense in $\tilde{X}_1$, there is a sequence $\{u_n\}$ in X with $u_n \rightarrow u$ in $\tilde{X}_1$. A convergent sequence is Cauchy (Problem 37), so $\{u_n\}$ is Cauchy with respect to $\tilde{\rho}_1$. But the terms u_n lie in X , and on X the three metrics $\tilde{\rho}_1, \rho, \tilde{\rho}_2$ agree. Hence $\{u_n\}$ is a Cauchy sequence in the metric space $\tilde{X}_2$, and since $\tilde{X}_2$ is complete it converges to a point of $\tilde{X}_2$. Define

$$f(u) = \lim_{n \rightarrow \infty} u_n \quad (\text{limit taken in } \tilde{X}_2).$$

This is properly defined. Suppose $\{u_n\}$ and $\{u'_n\}$ are two sequences in X that converge to u in $\tilde{X}_1$, with $\tilde{X}_2$ -limits w and w' respectively. Then

$$\rho(u_n, u'_n) = \tilde{\rho}_1(u_n, u'_n) \leq \tilde{\rho}_1(u_n, u) + \tilde{\rho}_1(u, u'_n) \rightarrow 0,$$

while by the observation above, applied in $\tilde{X}_2$,

$$\tilde{\rho}_2(w, w') = \lim_{n \rightarrow \infty} \tilde{\rho}_2(u_n, u'_n) = \lim_{n \rightarrow \infty} \rho(u_n, u'_n) = 0.$$

Therefore $w = w'$.

f is the identity on X . If $u \in X$, we may take $u_n = u$ for all n , since this sequence lies in X and converges to u in $\tilde{X}_1$. Hence $f(u) = u$.

f preserves distances. Let $u, v \in \tilde{X}_1$ and choose sequences $\{u_n\}, \{v_n\}$ in X with $u_n \rightarrow u$ and $v_n \rightarrow v$ in $\tilde{X}_1$. By the definition of f , $u_n \rightarrow f(u)$ and $v_n \rightarrow f(v)$ in $\tilde{X}_2$. Applying the observation above in $\tilde{X}_2$ and then in $\tilde{X}_1$, and using that the metrics agree on X ,

$$\tilde{\rho}_2(f(u), f(v)) = \lim_{n \rightarrow \infty} \tilde{\rho}_2(u_n, v_n) = \lim_{n \rightarrow \infty} \rho(u_n, v_n) = \lim_{n \rightarrow \infty} \tilde{\rho}_1(u_n, v_n) = \tilde{\rho}_1(u, v).$$

In particular f is one-to-one: if $f(u) = f(v)$ then $\tilde{\rho}_1(u, v) = \tilde{\rho}_2(f(u), f(v)) = 0$, so $u = v$.

f maps $\tilde{X}_1$ onto $\tilde{X}_2$. Let $w \in \tilde{X}_2$. Since X is dense in $\tilde{X}_2$, there is a sequence $\{w_n\}$ in X with $w_n \rightarrow w$ in $\tilde{X}_2$. As above, $\{w_n\}$ is Cauchy with respect to $\tilde{\rho}_2$, hence, the terms lying in X , Cauchy with respect to ρ and therefore with respect to $\tilde{\rho}_1$. Since $\tilde{X}_1$ is complete, $\{w_n\}$ converges in $\tilde{X}_1$ to some point u . The sequence $\{w_n\}$ then lies in X and converges to u in $\tilde{X}_1$, so by the definition of f ,

$$f(u) = \lim_{n \rightarrow \infty} w_n = w \quad (\text{limit in } \tilde{X}_2),$$

the last equality because limits in the metric space $\tilde{X}_2$ are unique. Hence f is onto.

Thus f maps $\tilde{X}_1$ onto $\tilde{X}_2$ and satisfies $\tilde{\rho}_2(f(u), f(v)) = \tilde{\rho}_1(u, v)$ for all $u, v \in \tilde{X}_1$; that is, f is an isometry, and it is the identity mapping on X . Any two completions of X are therefore isometric by way of an isometry that is the identity on X .

Finally, such an isometry is unique. If g is any continuous mapping of $\tilde{X}_1$ into $\tilde{X}_2$ with $g = f$ on X , then for $u \in \tilde{X}_1$ and $\{u_n\}$ a sequence in the dense set X converging to u , continuity gives $g(u) = \lim_n g(u_n) = \lim_n f(u_n) = f(u)$. Since an isometry is certainly continuous, f is the only isometry of $\tilde{X}_1$ onto $\tilde{X}_2$ that is the identity on X .

Problem 9.51. Consider the metric space $\mathbb{Q}$ consisting of the rational numbers with the metric induced by the absolute value. Which subspaces of $\mathbb{Q}$ are complete and which are compact?

Solution. Throughout, E denotes a subset of $\mathbb{Q}$, regarded as a metric space with the metric $\rho(p, q) = |p - q|$, and $\overline{E}$ denotes the closure of E in $\mathbb{R}$. The answer is:

E is a complete metric space if and only if E is a closed subset of $\mathbb{R}$; and E is a compact metric space if and only if E is a closed and bounded subset of $\mathbb{R}$, that is, if and only if E is a compact subset of $\mathbb{R}$.

Completeness. Suppose first that E is closed as a subset of $\mathbb{R}$. Let $\{q_n\}$ be a Cauchy sequence in the metric space E . Since the metric on E is the restriction of the metric on $\mathbb{R}$, $\{q_n\}$ is a Cauchy sequence of real numbers, and $\mathbb{R}$ is complete, so $q_n \rightarrow x$ for some $x \in \mathbb{R}$. Every ball about x in $\mathbb{R}$ contains points of E , namely tails of $\{q_n\}$, so $x \in \overline{E} = E$. Since the metric on E is the restriction of that on $\mathbb{R}$, $\{q_n\}$ converges to x in the metric space E . Hence E is complete.

Conversely, suppose the metric space E is complete and let $x \in \overline{E}$. By the characterization of closure points by sequences (Proposition 6 of this chapter, applied in $\mathbb{R}$), there is a sequence $\{q_n\}$ in E with $q_n \rightarrow x$ in $\mathbb{R}$. A convergent sequence is Cauchy (Problem 37), so $\{q_n\}$ is Cauchy in $\mathbb{R}$ and hence in E . By completeness of E , $q_n \rightarrow q$ for some $q \in E$; this convergence also holds in $\mathbb{R}$. Limits in $\mathbb{R}$ are unique, so $x = q \in E$. Thus $\overline{E} = E$, that is, E is closed in $\mathbb{R}$.

Compactness. Total boundedness of E is an intrinsic property of the metric space E and does not refer to the ambient space. By Proposition 15, a subset of Euclidean space $\mathbb{R}^n$ is bounded if and only if it is totally bounded; taking $n = 1$, the subset E of $\mathbb{R}$ is totally bounded if and only if it is bounded. By the Characterization of Compactness Theorem (Theorem 16), E is compact if and only if E is complete and totally bounded, hence, by the previous paragraph, if and only if E is a closed and bounded subset of $\mathbb{R}$. By the Heine–Borel Theorem this is exactly the statement that E is a compact subset of $\mathbb{R}$.

(Consistently, a subset of $\mathbb{Q}$ that is closed and bounded in $\mathbb{R}$ contains all of its real points of closure, and these therefore are rational.)

Which sets these are. The description above is intrinsic once one notes what it forbids. Claim: no nonempty subset of $\mathbb{Q}$ that is open in $\mathbb{Q}$ is complete. Indeed, let $U \subseteq \mathbb{Q}$ be open in $\mathbb{Q}$ and nonempty, and let $q \in U$. There is an $r > 0$ with $\{p \in \mathbb{Q} : |p - q| < r\} \subseteq U$. Choose an irrational number ξ with $|\xi - q| < r/2$, which is possible since the irrationals are dense in $\mathbb{R}$. By the density of $\mathbb{Q}$ in $\mathbb{R}$, choose rationals p_n with $|p_n - \xi| < \min\{1/n, r/2\}$. Then $|p_n - q| < r$, so $\{p_n\}$ is a sequence in U ; it converges in $\mathbb{R}$ to ξ and hence is Cauchy. If it converged to a point $p \in U \subseteq \mathbb{Q}$, then by uniqueness of limits in $\mathbb{R}$ we would get $p = \xi$, contradicting the irrationality of ξ . So U is not complete.

Consequently every complete subspace E of $\mathbb{Q}$ has empty interior in $\mathbb{Q}$. For suppose E contained a nonempty subset U that is open in $\mathbb{Q}$. By the first part of the solution E is closed in $\mathbb{R}$. The sequence $\{p_n\}$ constructed in the preceding paragraph from U lies in $U \subseteq E$ and converges in $\mathbb{R}$ to the irrational number ξ , so $\xi \in \overline{E} = E \subseteq \mathbb{Q}$, a contradiction. Being closed in $\mathbb{R}$, such an E is also closed in $\mathbb{Q}$, so its closure in $\mathbb{Q}$ is E itself; having empty interior in $\mathbb{Q}$, each complete subspace of $\mathbb{Q}$ is therefore nowhere dense in $\mathbb{Q}$. In particular $\mathbb{Q}$ itself is neither complete nor compact, since $\mathbb{Q}$ is not a closed subset of $\mathbb{R}$, and no ball in $\mathbb{Q}$ is complete or compact, a ball being nonempty and open in $\mathbb{Q}$.

Indeed no point of $\mathbb{Q}$ has a compact neighborhood. Suppose $K \subseteq \mathbb{Q}$ were a neighborhood of $q \in \mathbb{Q}$ that is compact as a metric subspace of $\mathbb{Q}$, say $\{p \in \mathbb{Q} : |p - q| < r\} \subseteq K$ with $r > 0$. By Theorem 16 a compact metric space is complete, so by the first part of this solution K is a closed subset of $\mathbb{R}$. Choose an irrational ξ with $|\xi - q| < r/2$ and rationals p_n with $|p_n - \xi| < \min\{1/n, r/2\}$, as in the preceding paragraph. Then $|p_n - q| < r$, so each p_n lies in K , and $p_n \rightarrow \xi$ in $\mathbb{R}$, so ξ is a point of closure of K in $\mathbb{R}$ and hence $\xi \in K \subseteq \mathbb{Q}$. This contradicts the irrationality of ξ . Thus $\mathbb{Q}$ is nowhere locally compact.

Examples. Every finite subset of $\mathbb{Q}$ is compact. The set $\mathbb{Z}$ is closed and unbounded in $\mathbb{R}$, hence a complete but noncompact subspace of $\mathbb{Q}$. The set $E = \{0\} \cup \{1/n : n \in \mathbb{N}\}$ is a closed and bounded subset of $\mathbb{R}$ consisting of rationals, hence an infinite compact subspace of $\mathbb{Q}$. The set $E = \mathbb{Q} \cap [0, 1]$ is bounded but not closed in $\mathbb{R}$, hence totally bounded but neither complete nor compact.

Problem 9.52. Let $B = B(x, r)$ be an open ball in Euclidean space $\mathbb{R}^n$. Show that B fails to be compact by (i) showing B is not sequentially compact, (ii) finding an open cover of B without any finite subcover, and (iii) showing B is not closed.

Solution. Here $r > 0$ and $B = B(x, r) = \{y \in \mathbb{R}^n : \|y - x\| < r\}$, regarded as a metric subspace of $\mathbb{R}^n$ with the Euclidean metric. Fix the unit vector $e = (1, 0, \dots, 0)$, so $\|e\| = 1$, and set

$$z = x + re, \quad y_k = x + \left(1 - \frac{1}{k}\right) re \quad \text{for } k \in \mathbb{N}.$$

Then $\|y_k - x\| = (1 - 1/k)r < r$, so each y_k belongs to B , while $\|z - x\| = r$, so z does not belong to B . Moreover

$$\|y_k - z\| = \frac{r}{k} \rightarrow 0,$$

so $\{y_k\}$ converges to z in $\mathbb{R}^n$.

(i) B is not sequentially compact. Consider the sequence $\{y_k\}$ in B just defined. Let $\{y_{k_j}\}$ be any subsequence. Since $\{y_k\}$ converges to z in $\mathbb{R}^n$, so does every subsequence. Suppose $\{y_{k_j}\}$ converged, in the metric space B , to a point $w \in B$. The metric on B is the restriction of the Euclidean metric, so $\{y_{k_j}\}$ would also converge to w in $\mathbb{R}^n$. Limits in a metric space are unique, so $w = z$; but $z \notin B$, a contradiction. Hence no subsequence of $\{y_k\}$ converges to a point of B , and B is not sequentially compact. By the Characterization of Compactness Theorem (Theorem 16), B is not compact.

(ii) An open cover of B with no finite subcover. For each natural number k put

$$\mathcal{O}_k = B\left(x, \left(1 - \frac{1}{k}\right)r\right),$$

the open ball in $\mathbb{R}^n$ of radius $(1 - 1/k)r$ about x . Each $\mathcal{O}_k$ is an open subset of $\mathbb{R}^n$ contained in B , hence $\mathcal{O}_k = \mathcal{O}_k \cap B$ is an open subset of the metric subspace B (Proposition 2). The collection $\{\mathcal{O}_k\}_{k=1}^\infty$

covers B : if $y \in B$ then $\|y - x\| < r$, so, choosing by the Archimedean property a natural number k with $1/k < 1 - \|y - x\|/r$, we get $\|y - x\| < (1 - 1/k)r$ and thus $y \in \mathcal{O}_k$. The collection is ascending, $\mathcal{O}_1 \subseteq \mathcal{O}_2 \subseteq \dots$, so any finite subcollection $\mathcal{O}_{k_1}, \dots, \mathcal{O}_{k_m}$ has union $\mathcal{O}_K$, where $K = \max\{k_1, \dots, k_m\}$. But the point

$$u = x + \left(1 - \frac{1}{2K}\right)re$$

satisfies $\|u - x\| = (1 - 1/(2K))r < r$, so $u \in B$, while $\|u - x\| = (1 - 1/(2K))r > (1 - 1/K)r$, so $u \notin \mathcal{O}_K$. Hence no finite subcollection covers B , and B is not compact.

(iii) B is not closed, and a compact subspace must be closed. The point $z = x + re$ is the limit of the sequence $\{y_k\}$ of points of B , so by Proposition 6 it is a point of closure of B in $\mathbb{R}^n$; since $z \notin B$, the set B is not a closed subset of $\mathbb{R}^n$.

To conclude noncompactness, we check that a compact subspace K of a metric space X is a closed subset of X . Let w be a point of closure of K in X . By Proposition 6 there is a sequence $\{w_k\}$ in K with $w_k \rightarrow w$ in X . By Theorem 16, K is sequentially compact, so some subsequence $\{w_{k_j}\}$ converges to a point $w' \in K$; this convergence holds in X as well, since the metric on K is the restriction of that on X . But $\{w_{k_j}\}$, being a subsequence of $\{w_k\}$, also converges to w in X . By uniqueness of limits, $w = w' \in K$. Hence K is closed in X .

Since B is not a closed subset of $\mathbb{R}^n$, the metric subspace B is not compact.

Problem 9.53. When is a nonempty set X with the discrete metric a compact metric space?

Solution. Recall the discrete metric on a nonempty set X : $\rho(u, v) = 0$ if $u = v$, and $\rho(u, v) = 1$ if $u \neq v$. The answer is: (X, ρ) is compact if and only if X is a finite set.

Suppose first that X is finite, say $X = \{x_1, \dots, x_m\}$. Let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be an open cover of X . For each index i with $1 \leq i \leq m$ choose $\lambda_i \in \Lambda$ with $x_i \in \mathcal{O}_{\lambda_i}$. Then $\{\mathcal{O}_{\lambda_i}\}_{i=1}^m$ is a finite subcollection of the cover whose union contains every point of X , hence a finite subcover. Therefore X is compact. (This argument uses nothing about the metric: a finite metric space is always compact.)

Now suppose X is infinite; we show X is not compact. For each $u \in X$ we have, by the definition of ρ ,

$$B(u, 1/2) = \{v \in X : \rho(u, v) < 1/2\} = \{u\},$$

so every singleton, and hence every subset of X , is open. Thus $\{\{u\}\}_{u \in X}$ is an open cover of X . A finite subcollection $\{u_1\}, \dots, \{u_m\}$ has union the finite set $\{u_1, \dots, u_m\}$, which is a proper subset of the infinite set X and therefore fails to cover X . So this open cover admits no finite subcover, and X is not compact.

The same conclusion follows from the Characterization of Compactness Theorem (Theorem 16), and this route explains where the failure lies. The discrete metric space X is always complete: if $\{x_n\}$ is Cauchy, then choosing N so that $\rho(x_n, x_m) < 1/2$ for $n, m \geq N$ forces $x_n = x_m$ for all $n, m \geq N$, so $\{x_n\}$ is eventually equal to the constant x_N and hence converges to $x_N \in X$. So by Theorem 16, X is compact if and only if it is totally bounded. Taking $\epsilon = 1/2$ in the definition of total boundedness, X is covered by finitely many balls of radius $1/2$, each of which is a singleton by the computation above; hence X is finite. Conversely a finite metric space is trivially totally bounded, being the union of the finitely many balls $B(x, \epsilon)$, $x \in X$, for any $\epsilon > 0$.

Thus a nonempty set with the discrete metric is a compact metric space precisely when it is finite.

Problem 9.54. Let ρ and σ be equivalent metrics on a nonempty set X . Show that the metric space (X, ρ) is compact if and only if the metric space (X, σ) is compact.

Solution. By the definition of equivalence of metrics there are positive numbers c_1 and c_2 for which

$$c_1 \cdot \sigma(x_1, x_2) \leq \rho(x_1, x_2) \leq c_2 \cdot \sigma(x_1, x_2) \quad \text{for all } x_1, x_2 \in X.$$

The key point is that the two metrics determine the same open sets; this is Proposition 7, whose short

proof we include for completeness. Write $B_\rho(x, \epsilon)$ and $B_\sigma(x, \epsilon)$ for the balls with respect to ρ and σ . Let $x \in X$ and $\epsilon > 0$. If $\sigma(x, y) < \epsilon/c_2$, then $\rho(x, y) \leq c_2 \cdot \sigma(x, y) < \epsilon$; hence

$$B_\sigma(x, \epsilon/c_2) \subseteq B_\rho(x, \epsilon).$$

If $\rho(x, y) < c_1\epsilon$, then $c_1 \cdot \sigma(x, y) \leq \rho(x, y) < c_1\epsilon$, so $\sigma(x, y) < \epsilon$; hence

$$B_\rho(x, c_1\epsilon) \subseteq B_\sigma(x, \epsilon).$$

Now let $\mathcal{O}$ be open in (X, ρ) and let $x \in \mathcal{O}$. There is an $\epsilon > 0$ with $B_\rho(x, \epsilon) \subseteq \mathcal{O}$, and then $B_\sigma(x, \epsilon/c_2) \subseteq B_\rho(x, \epsilon) \subseteq \mathcal{O}$. Thus $\mathcal{O}$ is open in (X, σ) . Interchanging the roles of the two metrics, using the second inclusion in place of the first, shows that every set open in (X, σ) is open in (X, ρ) . Hence the metric spaces (X, ρ) and (X, σ) have exactly the same open sets.

Suppose now that (X, ρ) is compact, and let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be a cover of X by sets open in (X, σ) . By the preceding paragraph each $\mathcal{O}_\lambda$ is open in (X, ρ) , so $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ is an open cover of the compact space (X, ρ) and therefore has a finite subcollection whose union is X . That same finite subcollection is a finite subcover of the original cover. Hence (X, σ) is compact. By symmetry, if (X, σ) is compact then so is (X, ρ) .

Therefore (X, ρ) is compact if and only if (X, σ) is compact.

Alternatively, one may argue through Theorem 16. The displayed inequalities show that $\rho(x_n, x) \rightarrow 0$ if and only if $\sigma(x_n, x) \rightarrow 0$, so the two metrics have the same convergent sequences with the same limits; hence a sequence has a subsequence converging in (X, ρ) if and only if it has one converging in (X, σ) . So (X, ρ) is sequentially compact if and only if (X, σ) is, and by the Characterization of Compactness Theorem the same equivalence holds for compactness.

Problem 9.55. Show that the Cartesian product of two compact metric spaces also is compact.

Solution. Let (X_1, ρ_1) and (X_2, ρ_2) be compact metric spaces and let τ be the product metric on the Cartesian product $X_1 \times X_2$, defined in Section 9.1 by

$$\tau((x_1, x_2), (y_1, y_2)) = \{[\rho_1(x_1, y_1)]^2 + [\rho_2(x_2, y_2)]^2\}^{1/2}.$$

We first record how convergence in $(X_1 \times X_2, \tau)$ relates to convergence in the factors. From the definition of τ we have, for all points (x_1, x_2) and (y_1, y_2) of the product,

$$\max\{\rho_1(x_1, y_1), \rho_2(x_2, y_2)\} \leq \tau((x_1, x_2), (y_1, y_2)) \leq \rho_1(x_1, y_1) + \rho_2(x_2, y_2),$$

the left inequality because each summand under the square root is dominated by the sum, and the right inequality because $a^2 + b^2 \leq (a + b)^2$ for $a, b \geq 0$. Consequently a sequence $\{(x_n, y_n)\}$ in $X_1 \times X_2$ converges to (x, y) with respect to τ if and only if $\{x_n\}$ converges to x in (X_1, ρ_1) and $\{y_n\}$ converges to y in (X_2, ρ_2) .

We show that $X_1 \times X_2$ is sequentially compact; by the Characterization of Compactness Theorem (Theorem 16) this is equivalent to compactness.

Let $\{(x_n, y_n)\}_{n=1}^\infty$ be a sequence in $X_1 \times X_2$. Since X_1 is compact, it is sequentially compact by Theorem 16. Applying this to the sequence $\{x_n\}$ in X_1 , there is a strictly increasing sequence of indices $\{n_k\}$ and a point $x \in X_1$ for which

$$\lim_{k \rightarrow \infty} \rho_1(x_{n_k}, x) = 0.$$

Now consider the sequence $\{y_{n_k}\}_{k=1}^\infty$ in X_2 . Since X_2 is compact, it too is sequentially compact by Theorem 16, so there is a strictly increasing sequence of indices $\{k_j\}$ and a point $y \in X_2$ for which

$$\lim_{j \rightarrow \infty} \rho_2(y_{n_{k_j}}, y) = 0.$$

Set $m_j = n_{k_j}$. Then $\{m_j\}$ is strictly increasing, so $\{(x_{m_j}, y_{m_j})\}$ is a subsequence of $\{(x_n, y_n)\}$. Moreover $\{x_{m_j}\}$ is a subsequence of the convergent sequence $\{x_{n_k}\}$ and hence also converges to x , while $\{y_{m_j}\}$

converges to y by construction. By the equivalence recorded above,

$$\lim_{j \rightarrow \infty} \tau((x_{m_j}, y_{m_j}), (x, y)) = 0,$$

that is, the subsequence $\{(x_{m_j}, y_{m_j})\}$ converges in $X_1 \times X_2$ to the point (x, y) of $X_1 \times X_2$.

Thus every sequence in $X_1 \times X_2$ has a subsequence converging to a point of $X_1 \times X_2$, so $X_1 \times X_2$ is sequentially compact. By Theorem 16, $(X_1 \times X_2, \tau)$ is compact.

Problem 9.56. Show that the Cartesian product of two totally bounded metric spaces also is totally bounded.

Solution. Let (X_1, ρ_1) and (X_2, ρ_2) be totally bounded metric spaces and let τ be the product metric on $X_1 \times X_2$,

$$\tau((x_1, x_2), (y_1, y_2)) = \{[\rho_1(x_1, y_1)]^2 + [\rho_2(x_2, y_2)]^2\}^{1/2}.$$

We must show that for each $\epsilon > 0$ the space $X_1 \times X_2$ can be covered by a finite number of open balls, with respect to τ , of radius ϵ .

Let $\epsilon > 0$ and put $\delta = \epsilon/\sqrt{2} > 0$. Since X_1 is totally bounded, there are points $u_1, \dots, u_m$ in X_1 with

$$X_1 = \bigcup_{i=1}^m B_{\rho_1}(u_i, \delta),$$

and since X_2 is totally bounded, there are points $v_1, \dots, v_n$ in X_2 with

$$X_2 = \bigcup_{j=1}^n B_{\rho_2}(v_j, \delta).$$

(If either factor is empty the product is empty and there is nothing to prove, so we may assume both are nonempty and hence that $m, n \geq 1$.)

Consider the finite collection of $m \cdot n$ open balls in $(X_1 \times X_2, \tau)$,

$$\{B_\tau((u_i, v_j), \epsilon) : 1 \leq i \leq m, 1 \leq j \leq n\}.$$

We claim these cover $X_1 \times X_2$. Let $(x_1, x_2) \in X_1 \times X_2$. By the first display there is an index i with $\rho_1(x_1, u_i) < \delta$, and by the second there is an index j with $\rho_2(x_2, v_j) < \delta$. Therefore

$$\tau((x_1, x_2), (u_i, v_j)) = \{[\rho_1(x_1, u_i)]^2 + [\rho_2(x_2, v_j)]^2\}^{1/2} < \{\delta^2 + \delta^2\}^{1/2} = \delta\sqrt{2} = \epsilon,$$

so $(x_1, x_2) \in B_\tau((u_i, v_j), \epsilon)$.

Hence for each $\epsilon > 0$ the space $X_1 \times X_2$ is covered by a finite number of open balls of radius ϵ ; that is, $(X_1 \times X_2, \tau)$ is totally bounded.

Note in passing that this gives a second proof of the preceding problem. If X_1 and X_2 are compact, then by the Characterization of Compactness Theorem (Theorem 16) each is complete and totally bounded. The product of two complete metric spaces is complete (Problem 42), and by what we have just shown the product is totally bounded; so by Theorem 16 again the product is compact.

9.9 Problems 9.57–9.63

Problem 9.57. For E contained in a metric space X , show that the subspace E is totally bounded if and only if for each $\epsilon > 0$, E can be covered by a finite number of open balls (open in X) of radius ϵ which have centers belonging to X .

Solution. Throughout, ρ denotes the metric on X , and for $x \in X$ and $r > 0$ we write

$$B(x, r) = \{y \in X \mid \rho(x, y) < r\}$$

for the open ball in X . The metric subspace E carries the restricted metric, so the open ball in E of radius r about a point $y \in E$ is

$$B_E(y, r) = \{z \in E \mid \rho(y, z) < r\} = B(y, r) \cap E.$$

By the definition of total boundedness, the subspace E is totally bounded provided that for each $\epsilon > 0$ there are finitely many points $y_1, \dots, y_n$ belonging to E itself, with $E = \bigcup_{k=1}^n B_E(y_k, \epsilon)$. What is to be shown is that the a priori weaker requirement, in which the centers are merely required to lie in the ambient space X , is equivalent to this.

Assume first that the subspace E is totally bounded, and let $\epsilon > 0$. Choose $y_1, \dots, y_n$ in E with $E = \bigcup_{k=1}^n B_E(y_k, \epsilon)$. Since $B_E(y_k, \epsilon) \subseteq B(y_k, \epsilon)$ we have

$$E \subseteq \bigcup_{k=1}^n B(y_k, \epsilon),$$

a cover of E by finitely many open balls of X of radius ϵ whose centers y_k belong to E and hence to X . This is the asserted covering property.

Now assume conversely that for each $\epsilon > 0$ the set E can be covered by finitely many open balls of X of radius ϵ with centers in X . Let $\epsilon > 0$ be given and apply the hypothesis with $\epsilon/2$ in place of ϵ : there are points $x_1, \dots, x_n$ in X for which

$$E \subseteq \bigcup_{k=1}^n B(x_k, \epsilon/2).$$

Discard those indices k for which $B(x_k, \epsilon/2) \cap E = \emptyset$; the remaining balls still cover E . Relabel so that $B(x_k, \epsilon/2) \cap E \neq \emptyset$ for $1 \leq k \leq m$, and for each such k select a point

$$y_k \in B(x_k, \epsilon/2) \cap E.$$

Thus each y_k belongs to E . We claim that

$$B(x_k, \epsilon/2) \subseteq B(y_k, \epsilon) \quad \text{for } 1 \leq k \leq m.$$

Indeed, if $z \in B(x_k, \epsilon/2)$, then by the triangle inequality

$$\rho(z, y_k) \leq \rho(z, x_k) + \rho(x_k, y_k) < \epsilon/2 + \epsilon/2 = \epsilon,$$

since $\rho(x_k, y_k) < \epsilon/2$ by the choice of y_k . This proves the claim. Consequently

$$E \subseteq \bigcup_{k=1}^m B(x_k, \epsilon/2) \subseteq \bigcup_{k=1}^m B(y_k, \epsilon),$$

and therefore, intersecting with E ,

$$E = E \cap \bigcup_{k=1}^m B(y_k, \epsilon) = \bigcup_{k=1}^m (B(y_k, \epsilon) \cap E) = \bigcup_{k=1}^m B_E(y_k, \epsilon).$$

Since the centers $y_1, \dots, y_m$ lie in E , this exhibits a cover of the metric space E by finitely many open balls of E of radius ϵ . As $\epsilon > 0$ was arbitrary, the subspace E is totally bounded.

In the terminology introduced in the text, the collection $\{B(x_k, \epsilon)\}_{k=1}^n$ appearing in the statement is called a finite ϵ -net for E ; what has been proved is precisely the assertion left as an exercise there, namely that the metric subspace E is totally bounded if and only if for each $\epsilon > 0$ there is a finite ϵ -net for E , so that it is not necessary to require the centers of the balls of the net to belong to E .

Problem 9.58. Let E be a subset of the compact metric space X . Show the metric subspace E is compact if and only if E is a closed subset of X .

Solution. Denote the metric on X by ρ ; the subspace E carries the restriction of ρ . Observe at the outset that a sequence $\{x_n\}$ of points of E converges to a point $x \in E$ with respect to the subspace metric if and only if it converges to x as a sequence in X , since in both cases convergence means $\lim_{n \rightarrow \infty} \rho(x_n, x) = 0$. We use throughout the Characterization of Compactness for a Metric Space, Theorem 16 of Chapter 9, which tells us that a metric space is compact if and only if it is sequentially compact, and Proposition 6 of Chapter 9, which tells us that a subset E of X is closed if and only if whenever a sequence in E converges to a point $x \in X$, the limit x belongs to E .

Assume first that E is a closed subset of X . Let $\{x_n\}$ be a sequence in the metric space E . Regard it as a sequence in X . Since X is compact, it is sequentially compact by Theorem 16 of Chapter 9, and hence there is a subsequence $\{x_{n_k}\}$ that converges to some point $x \in X$. Each x_{n_k} belongs to E and E is closed, so by Proposition 6 of Chapter 9 the limit x belongs to E . By the observation of the preceding paragraph, $\{x_{n_k}\}$ converges to x in the metric space E . Thus every sequence in E has a subsequence converging to a point of E , that is, E is sequentially compact, and therefore, again by Theorem 16 of Chapter 9, the metric subspace E is compact.

Assume conversely that the metric subspace E is compact. To show that E is a closed subset of X , by Proposition 6 of Chapter 9 it suffices to show that if $\{x_n\}$ is a sequence in E converging to a point $x \in X$, then $x \in E$. So let such a sequence be given. Since E is compact, it is sequentially compact by Theorem 16 of Chapter 9, so some subsequence $\{x_{n_k}\}$ converges, in the metric space E , to a point $y \in E$. But then $\{x_{n_k}\}$ converges to y as a sequence in X as well. On the other hand, $\{x_{n_k}\}$ is a subsequence of a sequence in X converging to x , so it converges to x in X . Since limits of convergent sequences in a metric space are unique (if $\{z_n\}$ converges to both u and v , then $0 \leq \rho(u, v) \leq \rho(u, z_n) + \rho(z_n, v) \rightarrow 0$, so $\rho(u, v) = 0$ and $u = v$), we conclude $x = y \in E$. Hence E is closed in X .

Note that the compactness of X was used only in the first implication; the second implication shows quite generally that a compact subspace of any metric space is a closed subset of that space.

Problem 9.59. (Frechet Intersection Theorem). Let $\{F_n\}_{n=1}^\infty$ be a descending countable collection of nonempty closed subsets of a compact metric space X . Show that $\bigcap_{n=1}^\infty F_n \neq \emptyset$.

Solution. That the collection is descending means $F_{n+1} \subseteq F_n$ for every natural number n , and hence, by induction, $F_m \subseteq F_n$ whenever $m \geq n$.

Consider the collection $\mathcal{F} = \{F_n\}_{n=1}^\infty$ of closed subsets of X . We claim $\mathcal{F}$ has the finite intersection property, that is, every finite subcollection of $\mathcal{F}$ has nonempty intersection. Indeed, let $F_{n_1}, \dots, F_{n_k}$ be a finite subcollection and put $N = \max\{n_1, \dots, n_k\}$. Since the collection is descending, $F_N \subseteq F_{n_j}$ for each j with $1 \leq j \leq k$, and therefore

$$\emptyset \neq F_N \subseteq \bigcap_{j=1}^k F_{n_j},$$

where $F_N \neq \emptyset$ by hypothesis. Thus $\mathcal{F}$ has the finite intersection property.

Since X is compact, Proposition 14 of Chapter 9 asserts that every collection of closed subsets of X possessing the finite intersection property has nonempty intersection. Applying this to $\mathcal{F}$ we conclude

$$\bigcap_{n=1}^\infty F_n \neq \emptyset.$$

For completeness we also give a direct argument using sequential compactness, which avoids appeal to Proposition 14. For each natural number n choose, using the nonemptiness of F_n , a point $x_n \in F_n$. Since X is compact it is sequentially compact by Theorem 16 of Chapter 9, so there is a subsequence $\{x_{n_k}\}$ converging to a point $x_0 \in X$. Fix a natural number N . For all indices k with $n_k \geq N$ — and all but finitely many k have this property, since $\{n_k\}$ is strictly increasing — we have $x_{n_k} \in F_{n_k} \subseteq F_N$.

Thus the tail of the convergent sequence $\{x_{n_k}\}$ lies in F_N , and this tail also converges to x_0 . Since F_N is closed, Proposition 6 of Chapter 9 tells us that $x_0 \in F_N$. As N was an arbitrary natural number,

$$x_0 \in \bigcap_{n=1}^{\infty} F_n,$$

so the intersection is nonempty.

Observe that no hypothesis on the diameters of the F_n is needed here, in contrast with the Cantor Intersection Theorem for complete metric spaces, where one assumes $\lim_{n \rightarrow \infty} \text{diam } F_n = 0$; compactness of X is what replaces that assumption.

Problem 9.60. For a subset E of a metric space X , show that E is totally bounded if and only if its closure $\overline{E}$ is totally bounded.

Solution. Let ρ be the metric on X and $B(x, r)$ the open ball in X of radius r about x . Throughout we use the criterion established in the preceding problem (Problem 57 of Chapter 9): a subset A of X is totally bounded if and only if for each $\epsilon > 0$ there are finitely many points $x_1, \dots, x_n$ of X for which $A \subseteq \bigcup_{k=1}^n B(x_k, \epsilon)$.

Suppose first that $\overline{E}$ is totally bounded. Since $E \subseteq \overline{E}$, any finite collection of balls of radius ϵ covering $\overline{E}$ also covers E . Hence, by the criterion, E is totally bounded. (More generally, this argument shows that any subset of a totally bounded set is totally bounded.)

Suppose conversely that E is totally bounded, and let $\epsilon > 0$ be given. Apply the criterion to E with $\epsilon/2$: there are points $x_1, \dots, x_n$ in X for which

$$E \subseteq \bigcup_{k=1}^n B(x_k, \epsilon/2).$$

We claim that

$$\overline{E} \subseteq \bigcup_{k=1}^n B(x_k, \epsilon).$$

Indeed, let $y \in \overline{E}$. Since y belongs to the closure of E , the ball $B(y, \epsilon/2)$ meets E ; choose $z \in E$ with $\rho(y, z) < \epsilon/2$. Since $z \in E$, there is an index k with $z \in B(x_k, \epsilon/2)$, that is, $\rho(z, x_k) < \epsilon/2$. By the triangle inequality,

$$\rho(y, x_k) \leq \rho(y, z) + \rho(z, x_k) < \epsilon/2 + \epsilon/2 = \epsilon,$$

so $y \in B(x_k, \epsilon)$. This proves the claim.

Thus for each $\epsilon > 0$ the set $\overline{E}$ is covered by finitely many open balls of X of radius ϵ with centers in X , and therefore, by the criterion of Problem 57 of Chapter 9, $\overline{E}$ is totally bounded.

Problem 9.61. For a subset E of a complete metric space X , show that E is totally bounded if and only if its closure $\overline{E}$ is compact.

Solution. Suppose first that E is totally bounded. By the preceding problem (Problem 60 of Chapter 9), the closure $\overline{E}$ is then totally bounded as a subspace of X . Moreover $\overline{E}$ is a closed subset of X and X is complete, so by Proposition 11 of Chapter 9 the metric subspace $\overline{E}$ is complete. Thus the metric space $\overline{E}$ is both complete and totally bounded, and therefore, by the Characterization of Compactness for a Metric Space (Theorem 16 of Chapter 9, whose implication (i) $\Rightarrow$ (ii) is Proposition 17 of Chapter 9), $\overline{E}$ is compact.

Suppose conversely that $\overline{E}$ is compact. By Theorem 16 of Chapter 9, applied to the metric space $\overline{E}$, the space $\overline{E}$ is complete and totally bounded; in particular the subspace $\overline{E}$ of X is totally bounded. Since $E \subseteq \overline{E}$, and since by Problem 57 of Chapter 9 total boundedness of a subset A of X is equivalent to the existence, for each $\epsilon > 0$, of a finite cover of A by open balls of X of radius ϵ , any such finite cover of $\overline{E}$ is also a finite cover of E . Hence E is totally bounded. (Alternatively, one may quote the

preceding problem directly: $\overline{E}$ totally bounded implies E totally bounded.)

Note where completeness of X enters: it is needed only for the first implication, to guarantee that the closed set $\overline{E}$ is complete as a metric subspace. Without it the result fails; for instance, in the incomplete metric space $X = \mathbb{Q}$ of rational numbers with the metric induced by the absolute value, the set $E = \mathbb{Q} \cap [0, 1]$ is totally bounded (for each $\epsilon > 0$ finitely many balls of radius ϵ centered at rational points of $[0, 1]$ cover it), yet its closure in $\mathbb{Q}$, which is E itself because $[0, 1]$ is closed in $\mathbb{R}$, is not compact, since it is not complete: a sequence of rationals in $[0, 1]$ converging in $\mathbb{R}$ to an irrational number is Cauchy in E but has no limit in E , so E is not complete and hence, by Theorem 16 of Chapter 9, not compact.

Problem 9.62. Let $B = \{\{x_n\} \in \ell^2 \mid \sum_{n=1}^{\infty} x_n^2 \leq 1\}$ be the closed unit ball in ℓ^2 . Show that B fails to be compact by (i) showing B is not sequentially compact, (ii) finding an open cover of B without any finite subcover, and (iii) showing B is not totally bounded.

Solution. Here ℓ^2 is the space of square summable real sequences with the norm $\|\{x_n\}\|_2 = (\sum_{n=1}^{\infty} x_n^2)^{1/2}$ and the induced metric $\rho(x, y) = \|x - y\|_2$, and $B = \{x \in \ell^2 \mid \|x\|_2 \leq 1\}$ is regarded as a metric subspace of ℓ^2 .

The whole argument rests on a single family of points. For each natural number n let $e_n \in \ell^2$ be the sequence whose n th component is 1 and whose other components are 0. Then $\|e_n\|_2 = 1$, so $e_n \in B$ for every n ; and if $m \neq n$ then $e_n - e_m$ has exactly two nonzero components, each of absolute value 1, so

$$\|e_n - e_m\|_2 = \sqrt{1^2 + 1^2} = \sqrt{2} \quad \text{for } m \neq n.$$

We refer to this separation property as (*).

(i) B is not sequentially compact. Consider the sequence $\{e_n\}_{n=1}^{\infty}$ of points of B . Let $\{e_{n_k}\}$ be any subsequence. The indices n_k are distinct, so by (*) we have $\|e_{n_k} - e_{n_j}\|_2 = \sqrt{2}$ whenever $k \neq j$. Hence $\{e_{n_k}\}$ is not a Cauchy sequence: no matter how large an index N is chosen, there are $k, j \geq N$ with $k \neq j$ and $\|e_{n_k} - e_{n_j}\|_2 = \sqrt{2} > 1$. A convergent sequence in a metric space is Cauchy, so $\{e_{n_k}\}$ does not converge, in B or indeed in ℓ^2 . Thus the sequence $\{e_n\}$ in B has no subsequence converging to a point of B , and B is not sequentially compact. By the Characterization of Compactness for a Metric Space (Theorem 16 of Chapter 9), B is not compact.

(ii) An open cover of B with no finite subcover. Put $r = \sqrt{2}/3$ and consider the collection of open balls of ℓ^2

$$\mathcal{O} = \{B(x, r) \mid x \in B\}, \quad B(x, r) = \{y \in \ell^2 \mid \|y - x\|_2 < r\}.$$

Each member of $\mathcal{O}$ is an open subset of ℓ^2 , and every $x \in B$ lies in the member $B(x, r)$, so $\mathcal{O}$ is a cover of B by open subsets of ℓ^2 ; equivalently, intersecting with B , the traces $\{B(x, r) \cap B\}$ form an open cover of the metric subspace B .

Suppose some finite subcollection $B(x_1, r), \dots, B(x_N, r)$ covered B . The $N + 1$ points $e_1, \dots, e_{N+1}$ all belong to B , so by the pigeonhole principle two of them, say e_n and e_m with $n \neq m$, lie in the same ball $B(x_k, r)$. Then by the triangle inequality and (*),

$$\sqrt{2} = \|e_n - e_m\|_2 \leq \|e_n - x_k\|_2 + \|x_k - e_m\|_2 < 2r = \frac{2\sqrt{2}}{3} < \sqrt{2},$$

a contradiction. Hence $\mathcal{O}$ admits no finite subcover of B , and B is not compact.

(iii) B is not totally bounded. By Problem 57 of Chapter 9, if B were totally bounded then for $\epsilon = \sqrt{2}/3 > 0$ there would exist finitely many points $x_1, \dots, x_N$ of ℓ^2 with

$$B \subseteq \bigcup_{k=1}^N B(x_k, \sqrt{2}/3).$$

Exactly the pigeonhole argument of part (ii) — which used nothing about the centers other than that there are finitely many of them — produces two distinct indices $n \neq m$ with e_n and e_m in a common ball $B(x_k, \sqrt{2}/3)$, whence $\sqrt{2} \leq \|e_n - x_k\|_2 + \|x_k - e_m\|_2 < 2\sqrt{2}/3 < \sqrt{2}$, a contradiction. Therefore

B is not totally bounded. Since a compact metric space is totally bounded by Theorem 16 of Chapter 9, B is not compact.

It is worth noting what this shows about infinite dimensional normed spaces. The set B is bounded, since $\|x - y\|_2 \leq 2$ for $x, y \in B$, and it is closed in ℓ^2 : the norm satisfies $|\|x\|_2 - \|y\|_2| \leq \|x - y\|_2$ and so is continuous, and B is the inverse image of the closed set $(-\infty, 1]$ under it. Moreover ℓ^2 is complete, being the Banach space of square summable sequences as recorded in Section 9.5, so by Proposition 11 of Chapter 9 the metric subspace B is complete. Hence by Theorem 16 of Chapter 9 the only way B can fail to be compact is by failing to be totally bounded, which is precisely what (iii) establishes. Thus the equivalence of being closed and bounded with being compact, valid in $\mathbb{R}^n$ by Theorem 20 of Chapter 9, breaks down in ℓ^2 .

Problem 9.63. Let $B = \{f \in L^2[a, b] \mid \|f\|_2 \leq 1\}$ be the closed unit ball in $L^2[a, b]$. Show that B fails to be compact by (i) showing B is not sequentially compact, (ii) finding an open cover of B without any finite subcover, and (iii) showing B is not totally bounded.

Solution. Here $[a, b]$ is a nondegenerate closed bounded interval, so $a < b$, and $L^2[a, b]$ carries the norm $\|f\|_2 = (\int_a^b |f|^2)^{1/2}$ and the induced metric $\rho(f, g) = \|f - g\|_2$. As in the preceding problem, everything follows from one family of points of B that are mutually far apart, and we construct such a family out of functions with pairwise disjoint supports.

For each integer $n \geq 0$ set $t_n = a + (b - a)/2^n$, so that $t_0 = b$, the sequence $\{t_n\}$ is strictly decreasing, and $t_n \rightarrow a$. For each natural number n let

$$I_n = [t_n, t_{n-1}) \subseteq [a, b], \quad m(I_n) = t_{n-1} - t_n = \frac{b-a}{2^{n-1}} - \frac{b-a}{2^n} = \frac{b-a}{2^n} > 0.$$

The intervals $I_1, I_2, \dots$ are pairwise disjoint. Define

$$f_n = \left(\frac{2^n}{b-a}\right)^{1/2} \chi_{I_n} \quad \text{for each natural number } n,$$

where χ_{I_n} is the characteristic function of I_n . Each f_n is a bounded measurable function on $[a, b]$, hence belongs to $L^2[a, b]$, and

$$\|f_n\|_2^2 = \frac{2^n}{b-a} \int_a^b \chi_{I_n} = \frac{2^n}{b-a} \cdot m(I_n) = 1,$$

so $\|f_n\|_2 = 1$ and $f_n \in B$. If $m \neq n$ then $I_n \cap I_m = \emptyset$, so $f_n f_m$ vanishes identically and $|f_n - f_m|^2 = f_n^2 + f_m^2$ pointwise; integrating,

$$\|f_n - f_m\|_2^2 = \|f_n\|_2^2 + \|f_m\|_2^2 = 2, \quad \text{so} \quad \|f_n - f_m\|_2 = \sqrt{2} \quad \text{for } m \neq n.$$

We refer to this separation property as (*). Note also that for $m \neq n$ the functions f_n and f_m are not equal almost everywhere, so they are genuinely distinct points of $L^2[a, b]$.

(i) B is not sequentially compact. Consider the sequence $\{f_n\}$ in B and let $\{f_{n_k}\}$ be any subsequence. The indices n_k are distinct, so by (*), $\|f_{n_k} - f_{n_j}\|_2 = \sqrt{2}$ whenever $k \neq j$. Hence no subsequence is Cauchy: for every index N there are $k, j \geq N$, $k \neq j$, with $\|f_{n_k} - f_{n_j}\|_2 = \sqrt{2} > 1$. Since every convergent sequence in a metric space is Cauchy, no subsequence of $\{f_n\}$ converges in B (or in $L^2[a, b]$). Thus B is not sequentially compact, and by the Characterization of Compactness for a Metric Space (Theorem 16 of Chapter 9), B is not compact.

(ii) An open cover of B with no finite subcover. Put $r = \sqrt{2}/3$ and let

$$\mathcal{O} = \{B(f, r) \mid f \in B\}, \quad B(f, r) = \{g \in L^2[a, b] \mid \|g - f\|_2 < r\}.$$

Each $B(f, r)$ is an open subset of $L^2[a, b]$ and each $f \in B$ lies in $B(f, r)$, so $\mathcal{O}$ is a cover of B by open sets; intersecting with B gives an open cover of the metric subspace B .

Suppose finitely many members $B(g_1, r), \dots, B(g_N, r)$ covered B . The $N + 1$ points $f_1, \dots, f_{N+1}$ lie in B , so by the pigeonhole principle two of them, f_n and f_m with $n \neq m$, lie in a common ball $B(g_k, r)$. Then by the triangle inequality and (*),

$$\sqrt{2} = \|f_n - f_m\|_2 \leq \|f_n - g_k\|_2 + \|g_k - f_m\|_2 < 2r = \frac{2\sqrt{2}}{3} < \sqrt{2},$$

a contradiction. So $\mathcal{O}$ has no finite subcover and B is not compact.

(iii) B is not totally bounded. By Problem 57 of Chapter 9, were B totally bounded there would be, for $\epsilon = \sqrt{2}/3$, finitely many functions $g_1, \dots, g_N$ in $L^2[a, b]$ with

$$B \subseteq \bigcup_{k=1}^N B(g_k, \sqrt{2}/3).$$

The pigeonhole argument of part (ii) applies verbatim — it used only that the number of balls is finite — and yields $n \neq m$ with f_n, f_m in a common ball of radius $\sqrt{2}/3$, whence $\sqrt{2} < 2\sqrt{2}/3$, a contradiction. Therefore B is not totally bounded, and since every compact metric space is totally bounded by Theorem 16 of Chapter 9, B is not compact.

As in the preceding problem, B is bounded, since $\|f - g\|_2 \leq 2$ for $f, g \in B$, and closed in $L^2[a, b]$, being the inverse image of $(-\infty, 1]$ under the continuous function $f \mapsto \|f\|_2$; here continuity follows from the inequality $|\|f\|_2 - \|g\|_2| \leq \|f - g\|_2$. Since $L^2[a, b]$ is complete, by the Riesz-Fischer Theorem of Chapter 7, part (ii) of Theorem 12 of Chapter 9 tells us that the nonempty closed subset B is itself a complete metric space. So by Theorem 16 of Chapter 9 its failure to be compact must be, and is, a failure of total boundedness.

9.10 Problems 9.64–9.70

Problem 9.64. Let X be a totally bounded metric space.

- (i) If f is a uniformly continuous mapping from X to a metric space Y , show that $f(X)$ is totally bounded.
- (ii) Is (i) still true if f is only required to be continuous?

Solution. Write ρ for the metric on X and σ for the metric on Y . Recall the observation made in the text following the definition of total boundedness: a subset E of a metric space is totally bounded if and only if for each $\epsilon > 0$ there is a finite ϵ -net for E , that is, a finite collection of balls of radius ϵ whose union contains E (the centers need not lie in E).

- (i) Let $\epsilon > 0$. Since f is uniformly continuous, there is a $\delta > 0$ such that

$$\rho(u, v) < \delta \implies \sigma(f(u), f(v)) < \epsilon \quad \text{for all } u, v \in X.$$

Since X is totally bounded, X may be covered by finitely many open balls of radius $\delta/2$: there are points $x_1, \dots, x_n$ in X with

$$X = \bigcup_{k=1}^n B(x_k, \delta/2).$$

Fix k and let $u \in B(x_k, \delta/2)$. Then $\rho(u, x_k) < \delta/2 < \delta$, so $\sigma(f(u), f(x_k)) < \epsilon$; that is,

$$f(B(x_k, \delta/2)) \subseteq B(f(x_k), \epsilon).$$

Since the balls $B(x_k, \delta/2)$ cover X and f maps X onto $f(X)$,

$$f(X) = \bigcup_{k=1}^n f(B(x_k, \delta/2)) \subseteq \bigcup_{k=1}^n B(f(x_k), \epsilon).$$

Thus $\{B(f(x_k), \epsilon)\}_{k=1}^n$ is a finite ϵ -net for $f(X)$, and its centers even belong to $f(X)$. As $\epsilon > 0$ was arbitrary, $f(X)$ is totally bounded.

(ii) No. Take $X = (0, 1)$ with the metric inherited from $\mathbb{R}$. Since X is a bounded subset of $\mathbb{R}$, Proposition 15 tells us X is totally bounded. Define $f : X \rightarrow \mathbb{R}$ by

$$f(x) = \frac{1}{x}.$$

Then f is continuous on $(0, 1)$, being the quotient of continuous functions with nonvanishing denominator. However $f(X) = (1, \infty)$, which is an unbounded subset of $\mathbb{R}$, so Proposition 15 tells us $f(X)$ is not totally bounded. (Alternatively, and without appeal to Proposition 15: a totally bounded metric space is bounded, since if it is covered by finitely many balls of radius 1 then, by the triangle inequality, its diameter is at most $2 + d$, where d is the maximum distance between the centers.)

So uniform continuity cannot be weakened to continuity. Note that any such counterexample must live on a totally bounded space that fails to be complete: if X were also complete, then X would be compact by Theorem 16, whereupon Proposition 23 would make every continuous mapping on X uniformly continuous, and part (i) would apply.

Problem 9.65. Let ρ be a metric on a set X . Define

$$\tau(u, v) = \frac{\rho(u, v)}{1 + \rho(u, v)} \quad \text{for all } u, v \in X.$$

Verify that τ is a bounded metric on X and convergence of sequences with respect to the ρ metric and the τ metric is the same. Conclude that sets that are closed with respect to the ρ metric are closed with respect to the τ metric and that sets that are open with respect to the ρ metric are open with respect to the τ metric. Are the metrics ρ and τ equivalent?

Solution. Introduce the function

$$\varphi(t) = \frac{t}{1+t} \quad \text{for } t \geq 0,$$

so that $\tau = \varphi \circ \rho$. We record two properties of φ .

First, φ is strictly increasing on $[0, \infty)$: for $0 \leq s < t$,

$$\varphi(t) - \varphi(s) = \frac{t}{1+t} - \frac{s}{1+s} = \frac{t-s}{(1+t)(1+s)} > 0.$$

In particular $\varphi(t) \geq 0$, with $\varphi(t) = 0$ if and only if $t = 0$, and $\varphi(t) < 1$ for all $t \geq 0$.

Second, φ is subadditive: for $s, t \geq 0$,

$$\varphi(s+t) = \frac{s+t}{1+s+t} = \frac{s}{1+s+t} + \frac{t}{1+s+t} \leq \frac{s}{1+s} + \frac{t}{1+t} = \varphi(s) + \varphi(t),$$

since $1+s+t \geq 1+s$ and $1+s+t \geq 1+t$.

τ is a bounded metric. For $u, v \in X$ we have $\tau(u, v) = \varphi(\rho(u, v)) \geq 0$, and $\tau(u, v) = 0$ if and only if $\rho(u, v) = 0$, that is, if and only if $u = v$. Symmetry of τ is immediate from symmetry of ρ . For the triangle inequality, let $u, v, w \in X$. Since $\rho(u, w) \leq \rho(u, v) + \rho(v, w)$ and φ is increasing, and then by subadditivity,

$$\tau(u, w) = \varphi(\rho(u, w)) \leq \varphi(\rho(u, v) + \rho(v, w)) \leq \varphi(\rho(u, v)) + \varphi(\rho(v, w)) = \tau(u, v) + \tau(v, w).$$

Thus τ is a metric. It is bounded because $\tau(u, v) = \varphi(\rho(u, v)) < 1$ for all u, v , so $\text{diam}_\tau X \leq 1$.

The two metrics have the same convergent sequences, with the same limits. Observe first that

$$\tau(u, v) = \frac{\rho(u, v)}{1 + \rho(u, v)} \leq \rho(u, v)$$

for all u, v . Moreover, solving $t = \varphi(s)$ for s gives $s = t/(1-t)$, so for all $u, v \in X$,

$$\rho(u, v) = \frac{\tau(u, v)}{1 - \tau(u, v)},$$

which is legitimate since $\tau(u, v) < 1$.

Now let $\{x_n\}$ be a sequence in X and $x \in X$. If $\rho(x_n, x) \rightarrow 0$, then $0 \leq \tau(x_n, x) \leq \rho(x_n, x) \rightarrow 0$, so $\tau(x_n, x) \rightarrow 0$. Conversely, if $\tau(x_n, x) \rightarrow 0$, then, since $t \mapsto t/(1-t)$ is continuous at $t = 0$ with value 0,

$$\rho(x_n, x) = \frac{\tau(x_n, x)}{1 - \tau(x_n, x)} \longrightarrow \frac{0}{1 - 0} = 0.$$

Hence $\{x_n\}$ converges to x in (X, ρ) if and only if it converges to x in (X, τ) .

Closed sets and open sets agree. Let $E \subseteq X$ be closed with respect to ρ . By Proposition 6, to show E is closed with respect to τ it suffices to show that if $\{x_n\}$ is a sequence in E that converges to some $x \in X$ in the τ metric, then $x \in E$. By the equivalence of convergence just proved, $\{x_n\}$ converges to x in the ρ metric; since E is ρ -closed, Proposition 6 gives $x \in E$. Thus E is τ -closed. The same argument with the roles of ρ and τ interchanged shows that a τ -closed set is ρ -closed; so the closed sets of the two metrics are exactly the same. By Proposition 4, a subset is open if and only if its complement is closed, so the open sets of the two metrics are also exactly the same. In particular a ρ -open set is τ -open.

Are ρ and τ equivalent? Not in general. Recall that ρ and τ are equivalent provided there are positive constants c_1, c_2 with

$$c_1 \tau(u, v) \leq \rho(u, v) \leq c_2 \tau(u, v) \quad \text{for all } u, v \in X.$$

The left-hand inequality always holds with $c_1 = 1$, since $\tau \leq \rho$. The right-hand inequality can fail. Take $X = \mathbb{R}$ with $\rho(u, v) = |u - v|$. If there were a $c_2 > 0$ with $\rho \leq c_2 \tau$ on $X \times X$, then, since $\tau < 1$ everywhere, we would get $|u - v| < c_2$ for all real u, v , which is false (take $u = 0, v = c_2$). So ρ and τ are not equivalent in this case.

This example is typical: ρ and τ are equivalent precisely when ρ is bounded. Indeed, if $\rho(u, v) \leq M$ for all u, v , then

$$\tau(u, v) = \frac{\rho(u, v)}{1 + \rho(u, v)} \geq \frac{\rho(u, v)}{1 + M},$$

so $\rho \leq (1 + M)\tau$, and together with $\tau \leq \rho$ this exhibits the equivalence. Conversely, if $\rho \leq c_2 \tau$ then $\rho < c_2$ everywhere, so ρ is bounded.

Thus the passage from ρ to τ leaves the topology (open sets, closed sets, convergent sequences) untouched, while in general strictly changing the metric structure: it is an instance of a change of metric that is not an equivalence of metrics in the sense of the definition, yet for which the conclusion of Proposition 7 nevertheless holds.

Problem 9.66. Let E be a subset of Euclidean space $\mathbb{R}^n$. Assume every continuous real-valued function of E takes a minimum value. Prove that E is closed and bounded.

Solution. If E is empty there is nothing to prove, since the empty set is closed and bounded. So assume $E \neq \emptyset$. We regard E as a metric space with the metric inherited from $\mathbb{R}^n$, namely $\rho(x, y) = \|x - y\|$, and we are assuming that every continuous $f : E \rightarrow \mathbb{R}$ attains a minimum value on E .

We argue each conclusion by contradiction, in each case exhibiting a continuous real-valued function on E whose infimum is not attained.

E is bounded. Suppose not. Define $f : E \rightarrow \mathbb{R}$ by

$$f(x) = \frac{1}{1 + \|x\|}.$$

The function $x \mapsto \|x\|$ is continuous on $\mathbb{R}^n$, since by the triangle inequality for the norm $|\|x\| - \|y\|| \leq \|x - y\|$, so it is Lipschitz. Hence $1 + \|x\|$ is continuous and never zero, and therefore f is continuous on $\mathbb{R}^n$; its restriction to E is continuous on the metric space E .

Clearly $f(x) > 0$ for every x . On the other hand, since E is unbounded, for each natural number k there is a point $x_k \in E$ with $\|x_k\| > k$, and then $0 < f(x_k) < 1/(1 + k)$. Therefore

$$\inf_{x \in E} f(x) = 0.$$

Since f takes only positive values, this infimum is not attained: for every $x \in E$ there is a k with $f(x_k) < f(x)$. So f is a continuous real-valued function on E that takes no minimum value, contradicting the hypothesis. Hence E is bounded.

E is closed. Suppose not. Then, by Proposition 6, there is a point $x_0 \in \mathbb{R}^n$ that is a point of closure of E but does not belong to E ; equivalently, there is a sequence $\{x_k\}$ in E converging to a point $x_0 \notin E$. Define $g : E \rightarrow \mathbb{R}$ by

$$g(x) = \|x - x_0\|.$$

As above, g is Lipschitz, hence continuous, on E . Since $x_0 \notin E$, we have $g(x) > 0$ for every $x \in E$. On the other hand $g(x_k) = \|x_k - x_0\| \rightarrow 0$, so

$$\inf_{x \in E} g(x) = 0,$$

and again this infimum is not attained because g is strictly positive on E . Thus g is a continuous real-valued function on E taking no minimum value, contradicting the hypothesis. Hence E contains all of its points of closure, that is, E is closed.

Therefore E is closed and bounded.

Remark. Combined with Theorem 20, this shows E is compact. There is also a two-line proof that quotes the Extreme Value Theorem. If $f : E \rightarrow \mathbb{R}$ is continuous, so is $-f$, and by hypothesis $-f$ takes a minimum value at some $x_1 \in E$; then f takes a maximum value at x_1 . So the hypothesis forces every continuous real-valued function on E to take both a maximum and a minimum value, and Theorem 22 makes the metric space E compact; Theorem 20 then says E is closed and bounded. The argument given above is preferred here only because it is explicit: it exhibits by hand the two functions whose infima fail to be attained.

Problem 9.67. Let E be a subset of Euclidean space $\mathbb{R}^n$. Assume every continuous real-valued function of E is uniformly continuous. Prove that E is closed and bounded.

Solution. The closedness half is true and is proved below. The boundedness half, as printed, is false: we give a counterexample and then prove the correct positive statement that replaces it.

Throughout, E carries the metric $\rho(x, y) = \|x - y\|$ inherited from $\mathbb{R}^n$, and we assume every continuous $f : E \rightarrow \mathbb{R}$ is uniformly continuous. We may assume $E \neq \emptyset$.

Part 1: E is closed. Suppose not. Since E fails to be closed, by Proposition 6 there is a sequence $\{x_k\}$ in E converging to a point $x_0 \in \mathbb{R}^n$ with $x_0 \notin E$. Define

$$f(x) = \frac{1}{\|x - x_0\|} \quad \text{for } x \in E.$$

Since $x_0 \notin E$, the denominator never vanishes on E ; as $x \mapsto \|x - x_0\|$ is continuous, f is continuous on E .

Put $r_k = \|x_k - x_0\|$. Then $r_k > 0$ for every k and $r_k \rightarrow 0$. Passing to a subsequence (relabelled again as $\{x_k\}$, $\{r_k\}$) we may assume

$$r_{k+1} < \frac{1}{2}r_k \quad \text{for all } k,$$

choosing the indices greedily: having chosen x_k , use $r_j \rightarrow 0$ to find an index j with $r_j < r_k/2$. Now set $u_k = x_k$ and $v_k = x_{k+1}$. By the triangle inequality,

$$\|u_k - v_k\| \leq r_k + r_{k+1} < \frac{3}{2}r_k \rightarrow 0,$$

while

$$|f(u_k) - f(v_k)| = \frac{1}{r_{k+1}} - \frac{1}{r_k} > \frac{2}{r_k} - \frac{1}{r_k} = \frac{1}{r_k} \rightarrow \infty.$$

Take $\epsilon = 1$. Given any $\delta > 0$, choose k so large that $\frac{3}{2}r_k < \delta$ and $1/r_k \geq 1$. Then $u_k, v_k \in E$ with $\|u_k - v_k\| < \delta$ but $|f(u_k) - f(v_k)| > 1 = \epsilon$. So f is continuous but not uniformly continuous on E , contradicting the hypothesis. Hence E is closed.

Part 2: E need not be bounded. Take $n = 1$ and $E = \mathbb{Z}$, the set of integers, with the metric inherited from $\mathbb{R}$. Any two distinct points of E are at distance at least 1. Hence, given any real-valued function f on E whatsoever and any $\epsilon > 0$, the choice $\delta = 1$ has the property that $u, v \in E$ and $|u - v| < \delta$ force $u = v$ and therefore $|f(u) - f(v)| = 0 < \epsilon$. So every real-valued function on E , in particular every continuous one, is uniformly continuous, yet E is unbounded. Thus the hypothesis of the problem does not imply boundedness, and the assertion as printed cannot be proved.

Part 3: the correct positive statement. Let E' denote the set of points of $\mathbb{R}^n$ that are accumulation points of E , that is, points y such that every open ball about y contains a point of E other than y . We claim that under the hypothesis E' is compact. (When E has no isolated points, $E \subseteq E'$, and then E itself is compact, which is presumably the intended content.)

First, E' is always closed. Indeed, let y be a point of closure of E' and let $r > 0$. Choose $z \in E'$ with $\|z - y\| < r/2$, and then a point $x \in E$, $x \neq z$, with $\|x - z\| < \min\{r/2, \|z - y\|\}$ if $z \neq y$, and with $\|x - z\| < r/2$, $x \neq z$, if $z = y$. In either case $x \in E$, $x \neq y$, and $\|x - y\| < r$. Hence $y \in E'$.

Next we show E' is bounded. Suppose not. Choose inductively points $y_1, y_2, \dots$ in E' with $\|y_{k+1}\| > \|y_k\| + 2$ for every k ; this is possible because E' is unbounded. Then for $j < k$,

$$\|y_k - y_j\| \geq \|y_k\| - \|y_j\| > 2.$$

Since E is closed by Part 1 and E' consists of points of closure of E , each y_k belongs to E . As y_k is an accumulation point of E , choose $v_k \in E$ with

$$0 < t_k := \|v_k - y_k\| < \min\{1/k, 1/4\}.$$

Define $h_k : \mathbb{R}^n \rightarrow \mathbb{R}$ by

$$h_k(x) = \max \left\{ 0, 1 - \frac{\|x - y_k\|}{2t_k} \right\}.$$

Each h_k is continuous, satisfies $h_k(y_k) = 1$ and $h_k(v_k) = 1 - \frac{t_k}{2t_k} = \frac{1}{2}$, and vanishes outside the ball $B(y_k, 2t_k) \subseteq B(y_k, 1/2)$. Because the centers are more than 2 apart, the balls $B(y_k, 1/2)$ are pairwise disjoint. Put

$$f(x) = \sum_{k=1}^{\infty} h_k(x).$$

This sum is continuous on $\mathbb{R}^n$: given $x \in \mathbb{R}^n$, since $\|y_k\| \rightarrow \infty$ only finitely many of the balls $B(y_k, 1/2)$ meet $B(x, 1)$, so on the open set $B(x, 1)$ the function f coincides with a finite sum of continuous functions and is therefore continuous at x . Restrict f to E .

Since the balls $B(y_k, 1/2)$ are pairwise disjoint and $y_k, v_k \in B(y_k, 1/2)$, only the k th summand is nonzero at these two points, so

$$f(y_k) = 1, \quad f(v_k) = \frac{1}{2}, \quad \|y_k - v_k\| = t_k < 1/k.$$

Take $\epsilon = 1/2$. Given $\delta > 0$, choose k with $1/k < \delta$; then $y_k, v_k \in E$, $\|y_k - v_k\| < \delta$, and $|f(y_k) - f(v_k)| = 1/2 \geq \epsilon$. Hence f is continuous on E but not uniformly continuous, a contradiction. So E' is bounded, and being closed it is compact by Theorem 20.

Summary. Under the stated hypothesis, E is closed and its set of accumulation points is compact. If in addition E has no isolated points, then $E \subseteq E'$, so E is bounded and hence compact. In general E need not be bounded, as $E = \mathbb{Z}$ shows. The printed claim is therefore correct in its first half and false in its second.

Problem 9.68. Suppose f is a continuous real-valued function on Euclidean space $\mathbb{R}^n$ with the property that there is a number c such that $|f(x)| \geq c \cdot \|x\|$ for all $x \in \mathbb{R}^n$. Show that if K is a compact set of real numbers, then its inverse image under f , $f^{-1}(K)$, also is compact. (Mappings with this property are called proper.)

Solution. The hypothesis has content only when $c > 0$ (for $c \leq 0$ the inequality $|f(x)| \geq c\|x\|$ holds for every f , and the conclusion fails: take $f \equiv 0$ and $K = \{0\}$, so that $f^{-1}(K) = \mathbb{R}^n$). We therefore take $c > 0$, as intended.

Let K be a compact set of real numbers. By Theorem 20, K is closed and bounded. We show $f^{-1}(K)$ is closed and bounded, and then invoke Theorem 20 again.

$f^{-1}(K)$ is closed. Since K is closed in $\mathbb{R}$, its complement $\mathbb{R} \sim K$ is open, by Proposition 4. Since f is continuous, Proposition 8 tells us that

$$f^{-1}(\mathbb{R} \sim K) = \mathbb{R}^n \sim f^{-1}(K)$$

is an open subset of $\mathbb{R}^n$ (the displayed set equality holds because f is defined at every point of $\mathbb{R}^n$, so each x lies in exactly one of $f^{-1}(K)$ and $f^{-1}(\mathbb{R} \sim K)$). By Proposition 4 once more, $f^{-1}(K)$ is closed. $f^{-1}(K)$ is bounded. Since K is bounded, there is an $M \geq 0$ with $|y| \leq M$ for all $y \in K$. Let $x \in f^{-1}(K)$. Then $f(x) \in K$, so $|f(x)| \leq M$, and therefore by hypothesis

$$c\|x\| \leq |f(x)| \leq M, \quad \text{that is,} \quad \|x\| \leq \frac{M}{c}.$$

Since $c > 0$, this bound is a finite number independent of x , so $f^{-1}(K)$ is contained in the closed ball of radius M/c about the origin and is thus bounded.

Being a closed and bounded subset of $\mathbb{R}^n$, the set $f^{-1}(K)$ is compact by Theorem 20 (the Heine-Borel Theorem). Note that the argument shows the empty case causes no trouble: if $f^{-1}(K) = \emptyset$ it is compact trivially.

Problem 9.69. For a compact metric space (X, ρ) , show that there are points $u, v \in X$ for which $\rho(u, v) = \text{diam } X$.

Solution. Assume $X \neq \emptyset$ (for the empty space the diameter is not defined). Recall that

$$\text{diam } X = \sup\{\rho(x, y) \mid x, y \in X\}.$$

By Theorem 16, the compact space X is totally bounded, and as observed in the text a totally bounded metric space is bounded; hence $d := \text{diam } X$ is a finite nonnegative real number.

We first record an elementary inequality: for all $a, b, a', b' \in X$,

$$|\rho(a, b) - \rho(a', b')| \leq \rho(a, a') + \rho(b, b').$$

Indeed, by two applications of the triangle inequality,

$$\rho(a, b) \leq \rho(a, a') + \rho(a', b') + \rho(b', b),$$

so $\rho(a, b) - \rho(a', b') \leq \rho(a, a') + \rho(b, b')$; interchanging the roles of the pairs (a, b) and (a', b') gives the reverse inequality, and the two together give the absolute-value form.

Now, by the definition of the supremum, for each natural number k there are points $u_k, v_k \in X$ with

$$d - \frac{1}{k} < \rho(u_k, v_k) \leq d,$$

so that $\rho(u_k, v_k) \rightarrow d$.

By Theorem 16, X is sequentially compact. Apply this to $\{u_k\}$: there is a subsequence $\{u_{k_j}\}$ converging to some $u \in X$. Apply sequential compactness again, this time to the sequence $\{v_{k_j}\}$: there is a further subsequence, indexed by $\{k_{j_i}\}$, converging to some $v \in X$. Write $m_i = k_{j_i}$. Along this final subsequence we have simultaneously

$$u_{m_i} \rightarrow u, \quad v_{m_i} \rightarrow v, \quad \rho(u_{m_i}, v_{m_i}) \rightarrow d,$$

the last because $\{\rho(u_{m_i}, v_{m_i})\}$ is a subsequence of the convergent sequence $\{\rho(u_k, v_k)\}$, and $\{u_{m_i}\}$ is a subsequence of the convergent sequence $\{u_{k_j}\}$.

By the inequality recorded above,

$$|\rho(u_{m_i}, v_{m_i}) - \rho(u, v)| \leq \rho(u_{m_i}, u) + \rho(v_{m_i}, v) \longrightarrow 0,$$

so $\rho(u_{m_i}, v_{m_i}) \rightarrow \rho(u, v)$. Since limits of sequences of real numbers are unique, $\rho(u, v) = d = \text{diam } X$. Thus the diameter of a nonempty compact metric space is attained by a pair of its points.

Problem 9.70. Let K be a compact subset of the metric space (X, ρ) and x_0 belong to X . Show that there is a point $z \in K$ for which

$$\rho(z, x_0) \leq \rho(x, x_0) \quad \text{for all } x \in K.$$

Solution. Assume $K \neq \emptyset$; otherwise there is no point z to produce and the assertion is empty.

Define $f : K \rightarrow \mathbb{R}$ by

$$f(x) = \rho(x, x_0), \quad x \in K,$$

where K is regarded as a metric subspace of (X, ρ) .

The function f is continuous on K ; in fact it is Lipschitz with constant 1. Indeed, for $x, y \in K$ the triangle inequality gives

$$\rho(x, x_0) \leq \rho(x, y) + \rho(y, x_0), \quad \rho(y, x_0) \leq \rho(y, x) + \rho(x, x_0),$$

and hence

$$|f(x) - f(y)| = |\rho(x, x_0) - \rho(y, x_0)| \leq \rho(x, y).$$

So given $\epsilon > 0$, the choice $\delta = \epsilon$ shows that $\rho(x, y) < \delta$ implies $|f(x) - f(y)| < \epsilon$; thus f is (uniformly) continuous on K .

Now K , as a metric subspace of X , is a compact metric space. By the Extreme Value Theorem (Theorem 22), every continuous real-valued function on a compact metric space takes a minimum value. Applying this to f , there is a point $z \in K$ with

$$f(z) \leq f(x) \quad \text{for all } x \in K,$$

that is,

$$\rho(z, x_0) \leq \rho(x, x_0) \quad \text{for all } x \in K,$$

which is exactly what was to be shown.

(Equivalently, one may argue directly with sequential compactness: let $m = \inf_{x \in K} \rho(x, x_0)$, which is finite and nonnegative, choose $z_k \in K$ with $\rho(z_k, x_0) \rightarrow m$, and use Theorem 16 to extract a subsequence $z_{k_j} \rightarrow z \in K$. Since $|\rho(z_{k_j}, x_0) - \rho(z, x_0)| \leq \rho(z_{k_j}, z) \rightarrow 0$, we get $\rho(z, x_0) = m$, so the infimum is attained at z .)

Note that z need not be unique: for $X = \mathbb{R}^2$, K the unit circle, and x_0 the origin, every point of K minimizes the distance to x_0 . The point of the exercise is existence, and compactness of K is essential: for $X = \mathbb{R}$, $K = (0, 1)$, and $x_0 = 0$, no nearest point exists.

9.11 Problems 9.71–9.77

Problem 9.71. Let K be a compact subset of the metric space X . For a point $x \in X \sim K$, show that there is an open set $\mathcal{U}$ containing K and an open set $\mathcal{O}$ containing x for which $\mathcal{U} \cap \mathcal{O} = \emptyset$.

Solution. Let ρ denote the metric on X .

If $K = \emptyset$, take $\mathcal{U} = \emptyset$ and $\mathcal{O} = X$; both are open, $\mathcal{U}$ contains K , $\mathcal{O}$ contains x , and $\mathcal{U} \cap \mathcal{O} = \emptyset$. So assume $K \neq \emptyset$.

Fix $y \in K$. Since $x \in X \sim K$ we have $y \neq x$, and therefore

$$r_y := \rho(x, y) > 0.$$

Consider the two open balls

$$\mathcal{U}_y := B(y, r_y/3), \quad \mathcal{O}_y := B(x, r_y/3).$$

These are disjoint. Indeed, if some z belonged to both, then by the triangle inequality

$$r_y = \rho(x, y) \leq \rho(x, z) + \rho(z, y) < \frac{r_y}{3} + \frac{r_y}{3} = \frac{2r_y}{3} < r_y,$$

which is impossible. Thus

$$\mathcal{U}_y \cap \mathcal{O}_y = \emptyset \quad \text{for every } y \in K.$$

Now observe that $\{\mathcal{U}_y\}_{y \in K}$ is a collection of open subsets of X whose union contains K , since each $y \in K$ belongs to $\mathcal{U}_y$. As recorded in Section 9.5 (a consequence of Proposition 2, which identifies the open subsets of the subspace K as the intersections with K of the open subsets of X), a subset K of a metric space X is compact if and only if every cover of K by a collection of open subsets of X has a finite subcover.

Since K is compact, this cover of K by open subsets of X has a finite subcover: there are finitely many points $y_1, \dots, y_n$ in K for which

$$K \subseteq \bigcup_{k=1}^n \mathcal{U}_{y_k}.$$

Define

$$\mathcal{U} := \bigcup_{k=1}^n \mathcal{U}_{y_k} = \bigcup_{k=1}^n B(y_k, r_{y_k}/3), \quad \mathcal{O} := \bigcap_{k=1}^n \mathcal{O}_{y_k} = \bigcap_{k=1}^n B(x, r_{y_k}/3).$$

Then $\mathcal{U}$ is open, being a union of open sets, and $K \subseteq \mathcal{U}$. Also $\mathcal{O}$ is open, being the intersection of a finite collection of open sets, and $x \in \mathcal{O}$ since x is the center of each of the balls $\mathcal{O}_{y_k}$.

Finally, $\mathcal{U} \cap \mathcal{O} = \emptyset$. Suppose $z \in \mathcal{U} \cap \mathcal{O}$. Since $z \in \mathcal{U}$ there is an index k with $z \in \mathcal{U}_{y_k}$; since $z \in \mathcal{O}$ and $\mathcal{O} \subseteq \mathcal{O}_{y_k}$, also $z \in \mathcal{O}_{y_k}$. This contradicts the disjointness in the display above, applied to $y = y_k$.

Thus $\mathcal{U}$ and $\mathcal{O}$ are disjoint open sets containing K and x respectively.

Explicitly, if we set $r := \min_{1 \leq k \leq n} r_{y_k}/3 > 0$, then $\mathcal{O} = B(x, r)$, so the separating neighborhood of x may be taken to be a single ball.

Problem 9.72. Let A and B be subsets of a metric space (X, ρ) . Define

$$\text{dist}(A, B) = \inf \{ \rho(u, v) \mid u \in A, v \in B \}.$$

If A is compact and B is closed, show that $A \cap B = \emptyset$ if and only if $\text{dist}(A, B) > 0$.

Solution. If A or B is empty, then $A \cap B = \emptyset$ and the infimum defining $\text{dist}(A, B)$ is taken over the empty set of real numbers, so that $\text{dist}(A, B) = \infty > 0$; both sides of the asserted equivalence hold. We therefore assume throughout that A and B are nonempty, so that $\text{dist}(A, B)$ is a nonnegative real number.

First suppose $\text{dist}(A, B) > 0$. This direction requires neither compactness nor closedness. Let $d = \text{dist}(A, B) > 0$. If there were a point $z \in A \cap B$, then taking $u = v = z$ in the definition of the infimum gives

$$d = \text{dist}(A, B) \leq \rho(z, z) = 0,$$

contradicting $d > 0$. Hence $A \cap B = \emptyset$.

Conversely, suppose $A \cap B = \emptyset$; we show $\text{dist}(A, B) > 0$. Argue by contradiction, assuming $\text{dist}(A, B) = 0$. By the definition of the infimum, for each natural number n there are points $u_n \in A$ and $v_n \in B$ for which

$$\rho(u_n, v_n) < \frac{1}{n}.$$

The sequence $\{u_n\}$ lies in A , and the metric subspace A is compact. By Theorem 16 of Chapter 9, the Characterization of Compactness for a Metric Space, a compact metric space is sequentially compact;

so A is sequentially compact. Hence there is a subsequence $\{u_{n_k}\}$ that converges, in the subspace A and therefore also in X , to a point u belonging to A .

We claim that the corresponding subsequence $\{v_{n_k}\}$ also converges to u . Indeed, by the triangle inequality,

$$\rho(v_{n_k}, u) \leq \rho(v_{n_k}, u_{n_k}) + \rho(u_{n_k}, u) < \frac{1}{n_k} + \rho(u_{n_k}, u),$$

and the right-hand side tends to 0 as $k \rightarrow \infty$ because $n_k \geq k \rightarrow \infty$ and $u_{n_k} \rightarrow u$. Therefore $v_{n_k} \rightarrow u$. Each v_{n_k} belongs to B . Thus every ball $B(u, r)$ contains points of B (namely v_{n_k} for k large), so u is a point of closure of B . Since B is closed, B contains all its points of closure, and hence $u \in B$.

But we also have $u \in A$. Therefore $u \in A \cap B$, contradicting $A \cap B = \emptyset$. This contradiction shows $\text{dist}(A, B) > 0$.

An alternative proof of the second implication, using Theorem 22 of Chapter 9, the Extreme Value Theorem, instead of sequential compactness, runs as follows. Define $f: X \rightarrow \mathbb{R}$ by $f(x) = \inf_{v \in B} \rho(x, v)$. For $x, x' \in X$ and $v \in B$ we have $f(x) \leq \rho(x, v) \leq \rho(x, x') + \rho(x', v)$; taking the infimum over $v \in B$ gives $f(x) \leq \rho(x, x') + f(x')$, and by symmetry $|f(x) - f(x')| \leq \rho(x, x')$. So f is (uniformly) continuous on X , hence continuous on the compact space A , and by the Extreme Value Theorem f attains a minimum value on A , say at $u \in A$. Moreover $f(u) = \min_{x \in A} f(x) = \inf_{x \in A} \inf_{v \in B} \rho(x, v) = \inf\{\rho(x, v) \mid x \in A, v \in B\} = \text{dist}(A, B)$, the middle equality because an iterated infimum of a set of real numbers bounded below equals the infimum over the pairs. If $\text{dist}(A, B) = 0$, then $\inf_{v \in B} \rho(u, v) = 0$, so every ball about u meets B ; since B is closed this forces $u \in B$, and then $u \in A \cap B$, a contradiction.

Both hypotheses are needed for the second implication. In $\mathbb{R}$, the disjoint closed sets $A = \mathbb{Z}$ and $B = \{n + 1/(2n) : n \geq 2\}$ satisfy $\text{dist}(A, B) = 0$, showing that closedness of A alone does not suffice; and for $A = \{0\}$ compact and $B = (0, 1)$ not closed, $A \cap B = \emptyset$ while $\text{dist}(A, B) = 0$.

Problem 9.73. Let K be a compact subset of a metric space X and $\mathcal{O}$ an open set containing K . Use the preceding problem to show that there is an open set $\mathcal{U}$ for which $K \subseteq \mathcal{U} \subseteq \overline{\mathcal{U}} \subseteq \mathcal{O}$.

Solution. Let ρ denote the metric on X .

Two degenerate cases are immediate. If $K = \emptyset$, take $\mathcal{U} = \emptyset$; then $\overline{\mathcal{U}} = \emptyset \subseteq \mathcal{O}$. If $\mathcal{O} = X$, take $\mathcal{U} = X$; then $\overline{\mathcal{U}} = X = \mathcal{O}$. So assume $K \neq \emptyset$ and $\mathcal{O} \neq X$.

Set

$$C := X \sim \mathcal{O}.$$

Since $\mathcal{O}$ is open, C is closed, and $C \neq \emptyset$ because $\mathcal{O} \neq X$. Moreover $K \cap C = \emptyset$, since $K \subseteq \mathcal{O}$. As K is compact and C is closed, the preceding problem tells us that

$$d := \text{dist}(K, C) > 0.$$

Define

$$\mathcal{U} := \bigcup_{y \in K} B(y, d/2) = \left\{ x \in X \mid \text{dist}(x, K) < d/2 \right\},$$

where $\text{dist}(x, K) = \inf_{y \in K} \rho(x, y)$. Being a union of open balls, $\mathcal{U}$ is open, and $K \subseteq \mathcal{U}$ since each $y \in K$ lies in $B(y, d/2)$.

Next we bound the closure of $\mathcal{U}$. Put

$$F := \left\{ x \in X \mid \text{dist}(x, K) \leq d/2 \right\}.$$

We claim F is closed, i.e. that $X \sim F$ is open. Let $x \in X \sim F$, so that

$$\delta := \text{dist}(x, K) - \frac{d}{2} > 0.$$

We show that $B(x, \delta/2) \subseteq X \sim F$. Suppose, to the contrary, that some z belongs to $B(x, \delta/2) \cap F$. Then $\text{dist}(z, K) \leq d/2 < d/2 + \delta/4$, so by the definition of the infimum there is a point $y \in K$ with $\rho(z, y) < d/2 + \delta/4$. The triangle inequality now gives

$$\text{dist}(x, K) \leq \rho(x, y) \leq \rho(x, z) + \rho(z, y) < \frac{\delta}{2} + \frac{d}{2} + \frac{\delta}{4} = \frac{d}{2} + \frac{3\delta}{4} < \frac{d}{2} + \delta = \text{dist}(x, K),$$

a contradiction. Hence $B(x, \delta/2) \subseteq X \sim F$, so $X \sim F$ is open and F is closed.

Since $\mathcal{U} \subseteq F$ and F is closed, and by Proposition 3 of Chapter 9 the closure $\overline{\mathcal{U}}$ is the smallest closed set containing $\mathcal{U}$, we conclude

$$\overline{\mathcal{U}} \subseteq F.$$

Finally we check $F \cap C = \emptyset$, which gives $\overline{\mathcal{U}} \subseteq X \sim C = \mathcal{O}$. Suppose $x \in F \cap C$. Since $\text{dist}(x, K) \leq d/2$, there is a point $y \in K$ with

$$\rho(x, y) < \frac{d}{2} + \frac{d}{4} = \frac{3d}{4} < d.$$

But $y \in K$ and $x \in C$, so by the definition of $\text{dist}(K, C)$ as an infimum,

$$d = \text{dist}(K, C) \leq \rho(y, x) < d,$$

a contradiction. Hence $F \cap C = \emptyset$.

Assembling the pieces,

$$K \subseteq \mathcal{U} \subseteq \overline{\mathcal{U}} \subseteq F \subseteq X \sim C = \mathcal{O},$$

with $\mathcal{U}$ open, as required.

Problem 9.74. Let X be a metric space that contains a finite dense subset D . Show that $X = D$.

Solution. Recall the definition: D is dense in X provided every nonempty open subset of X contains a point of D .

If $D = \emptyset$, then no nonempty open subset of X can contain a point of D ; since X itself is an open subset of X , density forces X not to be a nonempty open set, that is, $X = \emptyset = D$. So assume $D \neq \emptyset$.

Now suppose, to get a contradiction, that $X \neq D$. Since $D \subseteq X$, there is a point $x \in X \sim D$. Write $D = \{y_1, \dots, y_n\}$, a finite nonempty list. For each index k we have $x \neq y_k$, so $\rho(x, y_k) > 0$. Set

$$r := \min_{1 \leq k \leq n} \rho(x, y_k).$$

This is the minimum of a finite nonempty collection of strictly positive numbers, hence $r > 0$. (It is precisely here that finiteness of D is used; for an infinite D the infimum of the distances could be 0.) Consider the open ball $B(x, r)$. It is an open subset of X , and it is nonempty since $x \in B(x, r)$. But it contains no point of D : for each k , $\rho(x, y_k) \geq r$, so $y_k \notin B(x, r)$. This contradicts the density of D in X .

Therefore no such x exists, and $X = D$.

Equivalently, one may argue via closures. Density of D means $\overline{D} = X$. A singleton $\{y\}$ in a metric space is closed, because for $x \neq y$ the ball $B(x, \rho(x, y))$ is a neighborhood of x missing y , so $X \sim \{y\}$ is open. A finite union of closed sets is closed, so the finite set D is closed, whence $D = \overline{D} = X$.

Problem 9.75. Show that for a subset D of a metric space X , D is dense in the subspace $\overline{D}$.

Solution. Let ρ be the metric on X , let $E := \overline{D}$ be the closure of D in X , and regard E as a metric subspace of X , that is, as the set E equipped with the restriction of ρ . Note first that $D \subseteq \overline{D} = E$, so it makes sense to ask whether D is dense in E .

By the definition of denseness we must show: every nonempty open subset of the metric space E contains a point of D .

So let $\mathcal{V}$ be a nonempty subset of E that is open in the subspace E , and choose a point $x \in \mathcal{V}$. By Proposition 2, applied to the subspace E of the metric space X , there is a set $\mathcal{O}$ open in X with $\mathcal{V} = \mathcal{O} \cap E$. Since $x \in \mathcal{O}$ and $\mathcal{O}$ is open in X , there is an $r > 0$ with $B(x, r) \subseteq \mathcal{O}$, where $B(x, r)$ denotes the ball of X . Intersecting with E ,

$$B(x, r) \cap E \subseteq \mathcal{O} \cap E = \mathcal{V}.$$

Now $x \in \mathcal{V} \subseteq E = \overline{D}$, so x is a point of closure of D . By the definition of a point of closure, every ball

about x contains a point of D ; in particular there is a point

$$u \in B(x, r) \cap D.$$

Since $D \subseteq E$, this point u also belongs to E , so $u \in B(x, r) \cap E$, and therefore $u \in \mathcal{V}$ by the inclusion above.

Thus $\mathcal{V}$ contains the point u of D . As $\mathcal{V}$ was an arbitrary nonempty open subset of E , the set D is dense in the subspace $\overline{D}$.

The same conclusion can be phrased using the observation, recorded just after the definition of denseness, that D is dense in a space exactly when every point of that space is a point of closure of D . Let $x \in E = \overline{D}$, so x is a point of closure of D in X . A neighborhood of x in the subspace E contains a set $B(x, r) \cap E$ for some $r > 0$, and $B(x, r)$ contains a point u of D ; since $D \subseteq E$, that point u lies in $B(x, r) \cap E$. So x is a point of closure of D relative to E as well, and D is dense in $E = \overline{D}$.

Finally, note the degenerate case: if $D = \emptyset$, then $\overline{D} = \emptyset$, the subspace has no nonempty open subsets, and the assertion holds vacuously.

Problem 9.76. Show that if two continuous mappings defined on a metric space X take the same values on a dense subset, then they are equal.

Solution. Let (X, ρ) be a metric space, let (Y, σ) be a metric space, let $f, g: X \rightarrow Y$ be continuous, and let D be a dense subset of X with

$$f(u) = g(u) \quad \text{for all } u \in D.$$

We show $f(x) = g(x)$ for every $x \in X$.

Fix $x \in X$ and let $\epsilon > 0$. By the ϵ - δ Criterion for Continuity of Chapter 9, applied to f at x , there is a $\delta_1 > 0$ such that

$$\rho(x, u) < \delta_1 \implies \sigma(f(x), f(u)) < \frac{\epsilon}{2}.$$

By continuity of g at x , there is a $\delta_2 > 0$ such that

$$\rho(x, u) < \delta_2 \implies \sigma(g(x), g(u)) < \frac{\epsilon}{2}.$$

Set $\delta := \min\{\delta_1, \delta_2\} > 0$.

The ball $B(x, \delta)$ is a nonempty open subset of X (it contains x). Since D is dense in X , there is a point $u \in D \cap B(x, \delta)$. For this u we have $\rho(x, u) < \delta \leq \delta_1$ and $\rho(x, u) < \delta \leq \delta_2$, and moreover $f(u) = g(u)$ because $u \in D$. Hence, by the triangle inequality for σ ,

$$\sigma(f(x), g(x)) \leq \sigma(f(x), f(u)) + \sigma(f(u), g(x)) = \sigma(f(x), f(u)) + \sigma(g(u), g(x)) < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

Thus $0 \leq \sigma(f(x), g(x)) < \epsilon$ for every $\epsilon > 0$, and therefore $\sigma(f(x), g(x)) = 0$. Since σ is a metric, this forces $f(x) = g(x)$.

As $x \in X$ was arbitrary, $f = g$.

The same conclusion follows directly from the book's definition of continuity, which is the sequential one: f is continuous at x provided that whenever $\{u_n\} \rightarrow x$ in X , $\{f(u_n)\} \rightarrow f(x)$ in Y . Given $x \in X$, density of D provides, for each natural number n , a point $u_n \in D \cap B(x, 1/n)$, the ball $B(x, 1/n)$ being a nonempty open set; then $\rho(x, u_n) < 1/n$, so $\{u_n\} \rightarrow x$. Continuity gives $\{f(u_n)\} \rightarrow f(x)$ and $\{g(u_n)\} \rightarrow g(x)$. But $f(u_n) = g(u_n)$ for every n , so these are one and the same sequence in Y , and, as observed in Section 9.2, a sequence in a metric space can converge to at most one point. Hence $f(x) = g(x)$.

Note that the conclusion fails without continuity of both mappings: on $X = \mathbb{R}$ with $D = \mathbb{Q}$, the zero function and the characteristic function of the irrationals agree on D but are not equal.

Problem 9.77. Show that the product of two separable metric spaces is again separable.

Solution. Let (X_1, ρ_1) and (X_2, ρ_2) be separable metric spaces, and let $Z := X_1 \times X_2$ carry the product metric τ defined in Section 9.1 by

$$\tau((x_1, x_2), (y_1, y_2)) = \left\{ [\rho_1(x_1, y_1)]^2 + [\rho_2(x_2, y_2)]^2 \right\}^{1/2}.$$

If either factor is empty, then $Z = \emptyset$ and Z is trivially separable (the empty set is a countable dense subset, since Z has no nonempty open subsets). So assume both factors are nonempty.

By separability, choose a countable dense subset D_1 of X_1 and a countable dense subset D_2 of X_2 ; since X_1, X_2 are nonempty, so are D_1, D_2 . Define

$$D := D_1 \times D_2 \subseteq Z.$$

The set D is countable. Indeed,

$$D = D_1 \times D_2 = \bigcup_{u_1 \in D_1} (\{u_1\} \times D_2),$$

and this is the union of a countable collection (indexed by the countable set D_1) of sets each of which is countable, being in one-to-one correspondence with D_2 . By Corollary 6 of Chapter 1, the union of a countable collection of countable sets is countable, so D is countable.

We claim D is dense in Z . Let $\mathcal{W}$ be a nonempty open subset of Z and pick $z = (x_1, x_2) \in \mathcal{W}$. Since $\mathcal{W}$ is open there is an $\epsilon > 0$ for which the τ -ball satisfies

$$B_\tau(z, \epsilon) \subseteq \mathcal{W}.$$

Consider the ball $B(x_1, \epsilon/2)$ in X_1 . It is a nonempty open subset of X_1 , so by the density of D_1 there is a point $u_1 \in D_1$ with

$$\rho_1(x_1, u_1) < \frac{\epsilon}{2}.$$

Similarly, by the density of D_2 there is a point $u_2 \in D_2$ with

$$\rho_2(x_2, u_2) < \frac{\epsilon}{2}.$$

Put $u := (u_1, u_2) \in D_1 \times D_2 = D$. Then

$$\tau(z, u) = \left\{ [\rho_1(x_1, u_1)]^2 + [\rho_2(x_2, u_2)]^2 \right\}^{1/2} < \left\{ \frac{\epsilon^2}{4} + \frac{\epsilon^2}{4} \right\}^{1/2} = \frac{\epsilon}{\sqrt{2}} < \epsilon.$$

Hence $u \in B_\tau(z, \epsilon) \subseteq \mathcal{W}$, so $\mathcal{W}$ contains a point of D .

Since $\mathcal{W}$ was an arbitrary nonempty open subset of Z , the countable set D is dense in Z . Therefore $Z = X_1 \times X_2$ is separable.

Two remarks. First, the argument is insensitive to the particular choice of product metric: any metric on $X_1 \times X_2$ for which $\tau(z, u)$ is controlled by $\rho_1(x_1, u_1)$ and $\rho_2(x_2, u_2)$ (for instance the sum metric $\rho_1 + \rho_2$ or the maximum metric, both equivalent to τ) admits the same proof, and by Problem 78 separability is unchanged when a metric is replaced by an equivalent one. Second, the same argument, applied to a finite list of separable spaces, shows that a finite product of separable metric spaces is separable.

9.12 Problems 9.78–9.79

Problem 9.78. Let ρ and σ be equivalent metrics on a nonempty set X . Show that (X, ρ) is separable if and only if (X, σ) is separable.

Solution. Recall the definition in Section 9.1: the metrics ρ and σ on X are equivalent provided there are positive numbers c_1 and c_2 for which

$$c_1 \sigma(x_1, x_2) \leq \rho(x_1, x_2) \leq c_2 \sigma(x_1, x_2) \quad \text{for all } x_1, x_2 \in X.$$

Observe first that this relation is symmetric in the two metrics: dividing the left-hand inequality by c_1 and the right-hand one by c_2 gives

$$\frac{1}{c_2} \rho(x_1, x_2) \leq \sigma(x_1, x_2) \leq \frac{1}{c_1} \rho(x_1, x_2) \quad \text{for all } x_1, x_2 \in X,$$

so σ and ρ are equivalent with the roles of the two metrics interchanged and the constants $1/c_2$, $1/c_1$ in place of c_1 , c_2 . Consequently it suffices to prove one implication: if (X, ρ) is separable, then so is (X, σ) ; the reverse implication then follows by applying that implication to the pair (σ, ρ) .

For $x \in X$ and $r > 0$ write $B_\rho(x, r) = \{y \in X : \rho(x, y) < r\}$ and $B_\sigma(x, r) = \{y \in X : \sigma(x, y) < r\}$ for the open balls with respect to the two metrics.

Nesting of balls: fix $x \in X$ and $r > 0$. We claim that

$$B_\rho(x, c_1 r) \subseteq B_\sigma(x, r).$$

Indeed, if $y \in B_\rho(x, c_1 r)$, then $c_1 \sigma(x, y) \leq \rho(x, y) < c_1 r$, and since $c_1 > 0$ we may divide by c_1 to get $\sigma(x, y) < r$, that is, $y \in B_\sigma(x, r)$. Note also that $c_1 r > 0$, so $B_\rho(x, c_1 r)$ is a nonempty open subset of the metric space (X, ρ) : it contains x , since $\rho(x, x) = 0 < c_1 r$.

Now the implication itself. Assume (X, ρ) is separable, and let D be a countable subset of X that is dense in (X, ρ) . We claim that the very same set D is dense in (X, σ) .

Let $\mathcal{O}$ be a nonempty subset of X that is open in (X, σ) . Choose a point $x \in \mathcal{O}$. Since $\mathcal{O}$ is σ -open, there is an $r > 0$ for which $B_\sigma(x, r) \subseteq \mathcal{O}$. By the nesting just established,

$$B_\rho(x, c_1 r) \subseteq B_\sigma(x, r) \subseteq \mathcal{O}.$$

Now $B_\rho(x, c_1 r)$ is a nonempty open subset of the metric space (X, ρ) , and D is dense in (X, ρ) ; therefore $B_\rho(x, c_1 r)$ contains a point of D . That point belongs to $\mathcal{O}$. Thus every nonempty σ -open subset of X contains a point of D , which is precisely the assertion that D is dense in (X, σ) . Since D is countable, (X, σ) is separable.

By the symmetry observed at the outset, the converse implication holds as well: if (X, σ) is separable, with countable σ -dense subset D , then D is ρ -dense and (X, ρ) is separable. Hence (X, ρ) is separable if and only if (X, σ) is separable, and in fact a subset of X is dense for one metric if and only if it is dense for the other.

Remark. The argument can be phrased more briefly by appealing to Proposition 7, which asserts that for equivalent metrics ρ and σ on X a subset of X is open in (X, ρ) if and only if it is open in (X, σ) . Density of a subset D is defined purely in terms of the nonempty open subsets of the space, since D is dense provided each of them contains a point of D . Hence the two metric spaces have exactly the same dense subsets, and therefore one has a countable dense subset if and only if the other does. The nesting of balls established above is precisely what proves the relevant half of Proposition 7, whose proof the book leaves as an exercise.

Problem 9.79. Show that on any uncountable set X there is a metric on X with respect to which X is not separable.

Solution. Let X be an uncountable set and let ρ be the discrete metric on X , defined in Section 9.1 by

$$\rho(x, y) = \begin{cases} 0 & \text{if } x = y, \\ 1 & \text{if } x \neq y. \end{cases}$$

We first check that ρ is indeed a metric. Clearly $\rho(x, y) \geq 0$, with $\rho(x, y) = 0$ if and only if $x = y$, and $\rho(x, y) = \rho(y, x)$ for all $x, y \in X$. For the triangle inequality, let $x, y, z \in X$; we must show $\rho(x, y) \leq \rho(x, z) + \rho(z, y)$. If $x = y$ the left-hand side is 0 and there is nothing to prove. If $x \neq y$, then z cannot equal both x and y , so at least one of $\rho(x, z)$, $\rho(z, y)$ equals 1, and hence $\rho(x, z) + \rho(z, y) \geq 1 = \rho(x, y)$. Thus ρ is a metric on X .

Next we show that every singleton subset of X is open in (X, ρ) . Fix $x \in X$ and consider the open ball

$$B(x, \tfrac{1}{2}) = \{y \in X : \rho(x, y) < \tfrac{1}{2}\}.$$

If $y \neq x$, then $\rho(x, y) = 1 > 1/2$, so y does not belong to this ball; and $\rho(x, x) = 0 < 1/2$, so x does. Hence $B(x, 1/2) = \{x\}$. Open balls are open, as is verified in Section 9.2 directly after the definition of an open set, so $\{x\}$ is a nonempty open subset of (X, ρ) . (This is the observation, recorded in Section 9.2, that for the discrete metric on a set every subset is open: an arbitrary subset is the union of the singletons it contains, and the union of a collection of open sets is open by Proposition 1.)

Now suppose D is a dense subset of (X, ρ) . By the definition of density, every nonempty open subset of X contains a point of D . Applying this to the nonempty open set $\{x\}$, for an arbitrary $x \in X$, we conclude that $\{x\}$ contains a point of D ; the only point of $\{x\}$ is x itself, so $x \in D$. As $x \in X$ was arbitrary, $D = X$.

Therefore the only dense subset of (X, ρ) is X itself, which is uncountable by hypothesis. In particular there is no countable dense subset of (X, ρ) , and so the metric space (X, ρ) is not separable.

Remark. Uncountability of X is exactly what is needed here: if X were countable, then X would be a countable dense subset of itself and (X, ρ) would be separable for every metric ρ on X . The conclusion can also be reached through Proposition 25. Suppose $\{O_n\}_{n=1}^{\infty}$ were a countable collection of open subsets of (X, ρ) such that every open subset of X is the union of a subcollection. Fix $x \in X$. The set $\{x\}$ is open, so it is the union of some subcollection; every member of that subcollection is a subset of $\{x\}$, hence is either empty or equal to $\{x\}$, and since the union is nonempty at least one member equals $\{x\}$. Thus $\{x\} \in \{O_n\}_{n=1}^{\infty}$ for every $x \in X$, which exhibits an injection of the uncountable set X into a countable collection, a contradiction. By Proposition 25, (X, ρ) is not separable.

10.1 Problems 10.1–10.7

Problem 10.1. Let E be a compact subspace of a metric space Y . Show that E is a closed, bounded subset of Y .

Solution. Let ρ denote the metric on Y ; the subspace E carries the restriction of ρ , and the open subsets of the metric space E are exactly the sets $\mathcal{O} \cap E$ with $\mathcal{O}$ open in Y . We may assume $E \neq \emptyset$, since the empty set is trivially both closed and bounded.

Boundedness. Fix a point $x_0 \in E$. For each $x \in E$ the ball $B(x, 1) = \{y \in Y : \rho(y, x) < 1\}$ is open in Y , so $\{B(x, 1) \cap E\}_{x \in E}$ is an open cover of the space E . By compactness there are points $x_1, \dots, x_n$ in E with

$$E \subseteq \bigcup_{i=1}^n B(x_i, 1).$$

Put $M = 1 + \max_{1 \leq i \leq n} \rho(x_i, x_0)$. If $z \in E$, then $z \in B(x_i, 1)$ for some i , and hence

$$\rho(z, x_0) \leq \rho(z, x_i) + \rho(x_i, x_0) < 1 + \rho(x_i, x_0) \leq M.$$

Thus $E \subseteq B(x_0, M)$, so E is a bounded subset of Y ; indeed for $z, w \in E$ we get $\rho(z, w) \leq \rho(z, x_0) + \rho(x_0, w) < 2M$, so $\text{diam } E \leq 2M < \infty$.

Closedness. We show that $Y \setminus E$ is open in Y . Let $y \in Y \setminus E$. For each $x \in E$ we have $x \neq y$, so $r_x := \rho(x, y)/2 > 0$. The collection $\{B(x, r_x) \cap E\}_{x \in E}$ is an open cover of the compact space E , so there are finitely many points $x_1, \dots, x_n$ in E with

$$E \subseteq \bigcup_{i=1}^n B(x_i, r_{x_i}).$$

Set $r = \min_{1 \leq i \leq n} r_{x_i}$, a positive number since the minimum is over a finite set of positive numbers. We claim $B(y, r) \cap E = \emptyset$. Indeed, let $z \in E$ and choose i with $\rho(z, x_i) < r_{x_i}$. Then by the triangle inequality

$$\rho(y, z) \geq \rho(y, x_i) - \rho(x_i, z) > 2r_{x_i} - r_{x_i} = r_{x_i} \geq r,$$

so $z \notin B(y, r)$. Hence $B(y, r) \subseteq Y \setminus E$.

Therefore every point of $Y \setminus E$ is an interior point of $Y \setminus E$, that is, $Y \setminus E$ is open and E is closed in Y . Together with the first paragraph, E is a closed, bounded subset of Y .

Problem 10.2. Show that an equicontinuous sequence of real-valued functions on a compact metric space is pointwise bounded if and only if it is uniformly bounded.

Solution. Let (X, ρ) be a compact metric space and $\{f_n\}$ an equicontinuous sequence of real-valued functions on X .

Suppose first that $\{f_n\}$ is uniformly bounded, so that there is an $M \geq 0$ with $|f_n| \leq M$ on X for every n . Then for each fixed $x \in X$ the sequence of numbers $\{f_n(x)\}$ satisfies $|f_n(x)| \leq M$ for all n and hence is bounded. Thus $\{f_n\}$ is pointwise bounded. This implication uses neither equicontinuity nor compactness.

Now suppose $\{f_n\}$ is pointwise bounded; we show it is uniformly bounded. Apply the definition of equicontinuity at a point $x \in X$ with the choice $\epsilon = 1$: there is a $\delta_x > 0$ such that

$$\text{if } \rho(x', x) < \delta_x, \text{ then } |f_n(x') - f_n(x)| < 1 \quad \text{for every index } n.$$

The collection $\{B(x, \delta_x)\}_{x \in X}$ is an open cover of X . Since X is compact, there are finitely many points $x_1, \dots, x_k$ in X for which

$$X = \bigcup_{i=1}^k B(x_i, \delta_{x_i}).$$

By pointwise boundedness, for each i with $1 \leq i \leq k$ there is an $M_i \geq 0$ such that $|f_n(x_i)| \leq M_i$ for all n . Since there are only finitely many indices i , the number

$$M = 1 + \max_{1 \leq i \leq k} M_i$$

is finite.

Let $x \in X$ and let n be any index. Choose i with $x \in B(x_i, \delta_{x_i})$, that is, $\rho(x, x_i) < \delta_{x_i}$. By the choice of δ_{x_i} we have $|f_n(x) - f_n(x_i)| < 1$, and therefore

$$|f_n(x)| \leq |f_n(x) - f_n(x_i)| + |f_n(x_i)| < 1 + M_i \leq M.$$

Since $x \in X$ and n were arbitrary, $|f_n| \leq M$ on X for every n ; that is, $\{f_n\}$ is uniformly bounded. Note that the argument for the second implication used nothing about countability of the index set, so the same statement holds for an arbitrary equicontinuous family of real-valued functions on a compact metric space, with “pointwise bounded” meaning that $\{f(x) : f \in \mathcal{F}\}$ is bounded for each $x \in X$.

Problem 10.3. Show that an equicontinuous family of continuous functions on a compact metric space is uniformly equicontinuous.

Solution. Let (X, ρ) be a compact metric space and let $\mathcal{F}$ be a family of real-valued functions on X which is equicontinuous on X , that is, equicontinuous at each point of X . We must show that $\mathcal{F}$ is uniformly equicontinuous: for each $\epsilon > 0$ there is a single $\delta > 0$, independent of the point and of the function, such that for all $u, v \in X$ and all $f \in \mathcal{F}$,

$$\text{if } \rho(u, v) < \delta, \text{ then } |f(u) - f(v)| < \epsilon.$$

Let $\epsilon > 0$. Fix $x \in X$. By equicontinuity of $\mathcal{F}$ at x , applied with $\epsilon/2$ in place of ϵ , there is a $\delta_x > 0$ such that

$$\text{if } \rho(x', x) < \delta_x, \text{ then } |f(x') - f(x)| < \epsilon/2 \quad \text{for every } f \in \mathcal{F}. \quad (*)$$

The collection of balls $\{B(x, \delta_x/2)\}_{x \in X}$ is an open cover of X . Since X is compact, there are finitely many points $x_1, \dots, x_k$ in X with

$$X = \bigcup_{i=1}^k B(x_i, \frac{1}{2}\delta_{x_i}).$$

Define

$$\delta = \frac{1}{2} \min_{1 \leq i \leq k} \delta_{x_i},$$

which is positive because it is half the minimum of finitely many positive numbers. (If $X = \emptyset$ the assertion is vacuous, so we assume $X \neq \emptyset$, whence $k \geq 1$ and the minimum is over a nonempty finite set.)

Now let $u, v \in X$ satisfy $\rho(u, v) < \delta$, and let $f \in \mathcal{F}$. Choose an index i with $u \in B(x_i, \delta_{x_i}/2)$, so that $\rho(u, x_i) < \delta_{x_i}/2$. Then

$$\rho(v, x_i) \leq \rho(v, u) + \rho(u, x_i) < \delta + \frac{1}{2}\delta_{x_i} \leq \frac{1}{2}\delta_{x_i} + \frac{1}{2}\delta_{x_i} = \delta_{x_i}.$$

Hence both u and v lie within δ_{x_i} of x_i , so by $(*)$ applied at the point x_i ,

$$|f(u) - f(x_i)| < \epsilon/2 \quad \text{and} \quad |f(v) - f(x_i)| < \epsilon/2.$$

Consequently

$$|f(u) - f(v)| \leq |f(u) - f(x_i)| + |f(x_i) - f(v)| < \epsilon/2 + \epsilon/2 = \epsilon.$$

Since δ was chosen independently of u, v , and f , the family $\mathcal{F}$ is uniformly equicontinuous. (This is precisely the assertion recorded in the text immediately before the statement of the Arzela–Ascoli Theorem, and the proof is the same as the proof that a continuous real-valued function on a compact metric space is uniformly continuous, carried out with the same δ serving every member of $\mathcal{F}$.)

Problem 10.4. Let X be a metric space and $\{f_n\}$ a sequence in $C(X)$ that converges uniformly on X to $f \in C(X)$. Show that $\{f_n\}$ is equicontinuous.

Solution. Let ρ denote the metric on X . Fix a point $x \in X$ and let $\epsilon > 0$. We must produce a single $\delta > 0$ that works simultaneously for every index n .

Since $\{f_n\}$ converges uniformly on X to f , there is an index N such that

$$|f_n(x') - f(x')| < \epsilon/3 \quad \text{for all } x' \in X \text{ and all } n \geq N. \quad (1)$$

Since f is continuous at x , there is a $\delta_0 > 0$ such that

$$\text{if } \rho(x', x) < \delta_0, \text{ then } |f(x') - f(x)| < \epsilon/3. \quad (2)$$

Combining (1) and (2): if $n \geq N$ and $\rho(x', x) < \delta_0$, then

$$|f_n(x') - f_n(x)| \leq |f_n(x') - f(x')| + |f(x') - f(x)| + |f(x) - f_n(x)| < \frac{\epsilon}{3} + \frac{\epsilon}{3} + \frac{\epsilon}{3} = \epsilon.$$

So the single number δ_0 serves all the indices $n \geq N$ at once. It is exactly the finitely many remaining indices that must now be absorbed, and this is possible precisely because there are finitely many of them.

For each index n with $1 \leq n < N$, the function f_n belongs to $C(X)$ and hence is continuous at x ; choose $\delta_n > 0$ such that

$$\text{if } \rho(x', x) < \delta_n, \text{ then } |f_n(x') - f_n(x)| < \epsilon.$$

Now set

$$\delta = \min\{\delta_0, \delta_1, \dots, \delta_{N-1}\},$$

a positive number, being the minimum of a finite collection of positive numbers. Suppose $x' \in X$ and $\rho(x', x) < \delta$. If $n < N$, then $\rho(x', x) < \delta_n$ and so $|f_n(x') - f_n(x)| < \epsilon$. If $n \geq N$, then $\rho(x', x) < \delta_0$ and so, by the displayed three-term estimate, $|f_n(x') - f_n(x)| < \epsilon$. In either case

$$|f_n(x') - f_n(x)| < \epsilon \quad \text{for every index } n.$$

Thus $\{f_n\}$ is equicontinuous at x . Since $x \in X$ was arbitrary, $\{f_n\}$ is equicontinuous on X . (The same argument shows that the enlarged family $\{f\} \cup \{f_n\}$ is equicontinuous.)

Problem 10.5. A real-valued function f on $[0, 1]$ is said to be Holder continuous of order α provided there is a constant C for which

$$|f(x) - f(y)| \leq C|x - y|^\alpha \quad \text{for all } x, y \in [0, 1].$$

Define the Holder norm

$$\|f\|_\alpha = \max\{|f(x)| + |f(x) - f(y)|/|x - y|^\alpha \mid x, y \in [0, 1], x \neq y\}.$$

Show that for $0 < \alpha \leq 1$, the set of functions for which $\|f\|_\alpha \leq 1$ has compact closure as a subset of $C[0, 1]$.

Solution. Write

$$\mathcal{F} = \{f : [0, 1] \rightarrow \mathbb{R} : \|f\|_\alpha \leq 1\},$$

where the expression defining $\|f\|_\alpha$ is understood as the supremum of the indicated quantities over all pairs $x \neq y$ in $[0, 1]$ (this supremum is finite exactly when f is bounded and Holder continuous of order α). Let $X = [0, 1]$, a compact metric space with the metric inherited from $\mathbb{R}$.

Step 1: $\mathcal{F} \subseteq C[0, 1]$, and the two defining estimates. Let $f \in \mathcal{F}$. By definition of $\|f\|_\alpha$, for all

$x, y \in [0, 1]$ with $x \neq y$,

$$|f(x)| + \frac{|f(x) - f(y)|}{|x - y|^\alpha} \leq 1.$$

Since both summands are nonnegative, each is at most 1. Hence, first,

$$|f(x)| \leq 1 \quad \text{for every } x \in [0, 1] \quad (1)$$

(for $x \in [0, 1]$ we may always pick some $y \in [0, 1]$ with $y \neq x$, as $[0, 1]$ has more than one point), and second,

$$|f(x) - f(y)| \leq |x - y|^\alpha \quad \text{for all } x, y \in [0, 1] \quad (2)$$

(the case $x = y$ being trivial). Estimate (2) shows each $f \in \mathcal{F}$ is continuous, so indeed $\mathcal{F}$ is a subset of $C[0, 1]$.

Step 2: $\mathcal{F}$ is uniformly bounded and equicontinuous. Uniform boundedness is exactly (1), with $M = 1$. For equicontinuity, let $\epsilon > 0$ and set $\delta = \epsilon^{1/\alpha} > 0$. If $x, y \in [0, 1]$ with $|x - y| < \delta$, then by (2), for every $f \in \mathcal{F}$,

$$|f(x) - f(y)| \leq |x - y|^\alpha < \delta^\alpha = \epsilon.$$

Since δ depends on neither the point nor the function, $\mathcal{F}$ is (uniformly) equicontinuous. Note that this is where $\alpha > 0$ is used: it makes $t \mapsto t^\alpha$ tend to 0 as $t \rightarrow 0^+$.

Step 3: the closure inherits these properties. Let $\overline{\mathcal{F}}$ denote the closure of $\mathcal{F}$ in the metric space $C[0, 1]$, whose metric is $\rho_{\max}(g, h) = \max_{[0, 1]} |g - h|$. Let $g \in \overline{\mathcal{F}}$. Then there is a sequence $\{f_n\}$ in $\mathcal{F}$ with $f_n \rightarrow g$ uniformly on $[0, 1]$, hence pointwise. Passing to the limit in (1) and (2) applied to f_n gives, for all $x, y \in [0, 1]$,

$$|g(x)| = \lim_{n \rightarrow \infty} |f_n(x)| \leq 1, \quad |g(x) - g(y)| = \lim_{n \rightarrow \infty} |f_n(x) - f_n(y)| \leq |x - y|^\alpha.$$

So $\overline{\mathcal{F}}$ is uniformly bounded by 1 and, by the estimate of Step 2 with the same $\delta = \epsilon^{1/\alpha}$, equicontinuous. Of course $\overline{\mathcal{F}}$ is a closed subset of $C[0, 1]$.

Step 4: conclusion. $X = [0, 1]$ is a compact metric space and $\overline{\mathcal{F}}$ is a closed, uniformly bounded, equicontinuous subset of $C(X) = C[0, 1]$. By Theorem 3 of this chapter, $\overline{\mathcal{F}}$ is a compact subspace of $C[0, 1]$. Therefore $\mathcal{F}$ has compact closure in $C[0, 1]$, as asserted.

Remark. In fact the limit passage of Step 3 gives more: for $x \neq y$,

$$|g(x)| + \frac{|g(x) - g(y)|}{|x - y|^\alpha} = \lim_{n \rightarrow \infty} \left(|f_n(x)| + \frac{|f_n(x) - f_n(y)|}{|x - y|^\alpha} \right) \leq 1,$$

and taking the supremum over such pairs yields $\|g\|_\alpha \leq 1$, i.e. $g \in \mathcal{F}$. Hence $\mathcal{F}$ is already closed in $C[0, 1]$, so $\overline{\mathcal{F}} = \mathcal{F}$ and the set $\mathcal{F}$ is itself compact.

Remark. If instead one argues by sequential compactness: given a sequence in $\mathcal{F}$, Steps 1 and 2 show it is uniformly bounded and equicontinuous on the compact metric space $[0, 1]$, so the Arzela–Ascoli Theorem supplies a subsequence converging uniformly on $[0, 1]$ to a continuous function, which by the previous remark again lies in $\mathcal{F}$.

Problem 10.6. Let X be a compact metric space and $\mathcal{F}$ a subset of $C(X)$. Show that $\mathcal{F}$ is equicontinuous if and only if its closure in $C(X)$, $\overline{\mathcal{F}}$, is equicontinuous. Conclude that a subset of $C(X)$ has compact closure if and only if it is equicontinuous and uniformly bounded.

Solution. Throughout, ρ denotes the metric on X and $\rho_{\max}(g, h) = \max_{x \in X} |g(x) - h(x)|$ the metric on $C(X)$; the maximum is attained since X is compact and $|g - h|$ is continuous. We may assume $\mathcal{F} \neq \emptyset$, the empty family being trivially equicontinuous with closure $\emptyset$.

Part 1: $\mathcal{F}$ is equicontinuous if and only if $\overline{\mathcal{F}}$ is equicontinuous.

Suppose first that $\overline{\mathcal{F}}$ is equicontinuous. Since $\mathcal{F} \subseteq \overline{\mathcal{F}}$, the defining condition for equicontinuity at a point, being a statement quantified over all members of the family, holds a fortiori for the smaller family $\mathcal{F}$: the same δ responding to ϵ for all $f \in \overline{\mathcal{F}}$ responds for all $f \in \mathcal{F}$. Hence $\mathcal{F}$ is equicontinuous.

Conversely, suppose $\mathcal{F}$ is equicontinuous. Fix $x \in X$ and let $\epsilon > 0$. By equicontinuity of $\mathcal{F}$ at x , applied with $\epsilon/3$, there is a $\delta > 0$ such that

$$\text{if } \rho(x', x) < \delta, \text{ then } |f(x') - f(x)| < \epsilon/3 \text{ for all } f \in \mathcal{F}.$$

We claim this same δ works for every $g \in \overline{\mathcal{F}}$. Indeed, let $g \in \overline{\mathcal{F}}$. Since g is a point of closure of $\mathcal{F}$ in $C(X)$, there is an $f \in \mathcal{F}$ with $\rho_{\max}(f, g) < \epsilon/3$, so that

$$|g(z) - f(z)| < \epsilon/3 \text{ for every } z \in X.$$

Hence if $x' \in X$ and $\rho(x', x) < \delta$, then

$$|g(x') - g(x)| \leq |g(x') - f(x')| + |f(x') - f(x)| + |f(x) - g(x)| < \frac{\epsilon}{3} + \frac{\epsilon}{3} + \frac{\epsilon}{3} = \epsilon.$$

Since δ was chosen before g and does not depend on it, $\overline{\mathcal{F}}$ is equicontinuous at x ; as $x \in X$ was arbitrary, $\overline{\mathcal{F}}$ is equicontinuous.

An auxiliary observation on boundedness. A nonempty subset $\mathcal{G}$ of $C(X)$ is bounded as a subset of the metric space $C(X)$ if and only if it is uniformly bounded. Indeed, if $|g| \leq M$ on X for all $g \in \mathcal{G}$, then $\rho_{\max}(g, h) \leq 2M$ for $g, h \in \mathcal{G}$, so $\mathcal{G}$ is bounded. Conversely, if $\mathcal{G}$ is bounded, fix $g_0 \in \mathcal{G}$ and $D \geq 0$ with $\rho_{\max}(g, g_0) \leq D$ for all $g \in \mathcal{G}$; then $|g| \leq \max_X |g_0| + D$ on X for every $g \in \mathcal{G}$, and $\max_X |g_0|$ is finite because X is compact. Note also that if $\mathcal{F}$ is uniformly bounded by M , then $\overline{\mathcal{F}}$ is uniformly bounded by M : a uniform limit of functions bounded by M in absolute value is bounded by M in absolute value.

Part 2: $\mathcal{F} \subseteq C(X)$ has compact closure if and only if it is equicontinuous and uniformly bounded.

Suppose $\mathcal{F}$ is equicontinuous and uniformly bounded, say $|f| \leq M$ on X for every $f \in \mathcal{F}$. By Part 1, $\overline{\mathcal{F}}$ is equicontinuous; by the auxiliary observation, $\overline{\mathcal{F}}$ is uniformly bounded by M ; and $\overline{\mathcal{F}}$ is of course a closed subset of $C(X)$. Since X is a compact metric space, Theorem 3 of this chapter applies and tells us that $\overline{\mathcal{F}}$ is a compact subspace of $C(X)$. Thus $\mathcal{F}$ has compact closure.

Conversely, suppose $\overline{\mathcal{F}}$ is compact. Theorem 3, read in the direction that a compact subspace of $C(X)$ is closed, uniformly bounded, and equicontinuous, tells us that $\overline{\mathcal{F}}$ is uniformly bounded and equicontinuous. (One may also see the boundedness directly: by Problem 1 of this chapter a compact subspace of the metric space $C(X)$ is a bounded subset of $C(X)$, and the auxiliary observation converts this to uniform boundedness.) Since $\mathcal{F} \subseteq \overline{\mathcal{F}}$, the family $\mathcal{F}$ is then uniformly bounded, and it is equicontinuous by Part 1.

This completes the characterization: for X a compact metric space, a subset of $C(X)$ has compact closure precisely when it is equicontinuous and uniformly bounded.

Problem 10.7. For a closed, bounded interval $[a, b]$, let $\{f_n\}$ be a sequence in $C[a, b]$. If $\{f_n\}$ is equicontinuous, does $\{f_n\}$ necessarily have a uniformly convergent subsequence? If $\{f_n\}$ is uniformly bounded, does $\{f_n\}$ necessarily have a uniformly convergent subsequence?

Solution. The answer to both questions is no. The Arzela–Ascoli Theorem requires both hypotheses, and neither one alone suffices. We assume $a < b$, since for a degenerate interval $[a, a]$ both answers become trivially yes.

First question: equicontinuity alone is not enough. For each natural number n define the constant function

$$f_n(x) = n \text{ for all } x \in [a, b].$$

Each f_n is continuous, so $\{f_n\}$ is a sequence in $C[a, b]$. The family is equicontinuous: for every $\epsilon > 0$ any $\delta > 0$ whatever responds to the challenge, since

$$|f_n(x) - f_n(y)| = |n - n| = 0 < \epsilon \text{ for all } x, y \in [a, b] \text{ and all } n.$$

On the other hand, let $\{f_{n_k}\}$ be any subsequence. Then $f_{n_k}(a) = n_k \rightarrow \infty$ as $k \rightarrow \infty$, so $\{f_{n_k}(a)\}$ is not even a convergent sequence of real numbers. Hence $\{f_{n_k}\}$ does not converge pointwise at a , and in particular it does not converge uniformly on $[a, b]$. So no subsequence of $\{f_n\}$ converges uniformly.

Of course what fails here is uniform boundedness; indeed by Problem 2, an equicontinuous sequence on a compact metric space which is pointwise bounded is automatically uniformly bounded, so any counterexample of this kind must fail to be pointwise bounded at some point.

Second question: uniform boundedness alone is not enough. This is the example recorded in the text following the proof of the Arzela–Ascoli Theorem, transplanted from $[0, 1]$ to $[a, b]$. For each natural number n define

$$f_n(x) = \left(\frac{x-a}{b-a} \right)^n \quad \text{for } x \in [a, b].$$

Each f_n is continuous on $[a, b]$, and since $0 \leq (x-a)/(b-a) \leq 1$ on $[a, b]$ we have

$$0 \leq f_n(x) \leq 1 \quad \text{for all } x \in [a, b] \text{ and all } n,$$

so $\{f_n\}$ is uniformly bounded, with $M = 1$.

Let $t = (x-a)/(b-a)$, so t runs over $[0, 1]$ as x runs over $[a, b]$, and $f_n(x) = t^n$. If $0 \leq t < 1$, then $t^n \rightarrow 0$; and if $t = 1$, then $t^n = 1$ for all n . Hence $\{f_n\}$ converges pointwise on $[a, b]$ to

$$g(x) = \begin{cases} 0, & a \leq x < b, \\ 1, & x = b, \end{cases}$$

and the same is true of every subsequence $\{f_{n_k}\}$, since a subsequence of a convergent sequence of real numbers converges to the same limit.

Now suppose some subsequence $\{f_{n_k}\}$ converged uniformly on $[a, b]$ to a function h . Uniform convergence implies pointwise convergence, so $h = g$. But a uniform limit of continuous real-valued functions on a metric space is continuous, so g would have to be continuous on $[a, b]$. It is not: $g(b) = 1$ while $g(x) = 0$ for all $x < b$, so $\lim_{x \rightarrow b^-} g(x) = 0 \neq 1 = g(b)$. This contradiction shows no subsequence of $\{f_n\}$ converges uniformly on $[a, b]$.

Here what fails is equicontinuity: at the point b the family $\{f_n\}$ is not equicontinuous, since for any $\delta \in (0, b-a)$ the point $x_\delta = b - \delta/2$ satisfies $|x_\delta - b| < \delta$ while

$$|f_n(x_\delta) - f_n(b)| = 1 - \left(1 - \frac{\delta}{2(b-a)} \right)^n \rightarrow 1 \quad \text{as } n \rightarrow \infty,$$

so no δ can respond to, say, $\epsilon = 1/2$ for all indices n at once.

In summary: equicontinuity alone and uniform boundedness alone each fail to force the existence of a uniformly convergent subsequence; by the Arzela–Ascoli Theorem, the two together do force it.

10.2 Problems 10.8–10.14

Problem 10.8. Let X be a compact metric space and Y be a general metric space. Denote by $C(X, Y)$ the set of continuous mappings from X to Y . State and prove a version of the Arzela–Ascoli Theorem for a sequence in $C(X, Y)$ in which the assumption that $\{f_n\}$ is pointwise bounded is replaced by the assumption that for each $x \in X$, the closure of the set $\{f_n(x) \mid n \text{ a natural number}\}$ is a compact subspace of Y .

Solution. Write ρ for the metric on X and σ for the metric on Y . A collection $\mathcal{F} \subseteq C(X, Y)$ is called **equicontinuous at** $x \in X$ provided that for each $\epsilon > 0$ there is a $\delta > 0$ such that for every $f \in \mathcal{F}$ and every $x' \in X$,

$$\text{if } \rho(x', x) < \delta, \text{ then } \sigma(f(x'), f(x)) < \epsilon,$$

and equicontinuous on X provided it is equicontinuous at every point of X . This is the definition in the text with $|f(x') - f(x)|$ replaced by $\sigma(f(x'), f(x))$.

Theorem. Let X be a compact metric space, Y a metric space, and $\{f_n\}$ an equicontinuous sequence in $C(X, Y)$ with the property that for each $x \in X$ the closure in Y of the set $\{f_n(x) \mid n \in \mathbb{N}\}$ is a compact subspace of Y . Then $\{f_n\}$ has a subsequence that converges uniformly on X to a continuous mapping $f: X \rightarrow Y$.

Here uniform convergence of $\{g_k\}$ to f means: for each $\epsilon > 0$ there is a K such that $\sigma(g_k(x), f(x)) < \epsilon$ for all $k \geq K$ and all $x \in X$.

Step 1: uniform equicontinuity. We first observe that $\{f_n\}$ is uniformly equicontinuous, that is, for each $\epsilon > 0$ there is a $\delta > 0$ such that $\sigma(f_n(u), f_n(v)) < \epsilon$ whenever $u, v \in X$ satisfy $\rho(u, v) < \delta$, for every index n . Indeed, let $\epsilon > 0$. For each $x \in X$, equicontinuity at x provides $\delta_x > 0$ such that $\sigma(f_n(y), f_n(x)) < \epsilon/2$ for all n and all y with $\rho(y, x) < \delta_x$. The collection $\{B(x, \delta_x/2)\}_{x \in X}$ is an open cover of the compact space X , so there are points $x_1, \dots, x_m$ with $X = \bigcup_{i=1}^m B(x_i, \delta_{x_i}/2)$. Put $\delta = \frac{1}{2} \min_{1 \leq i \leq m} \delta_{x_i} > 0$. If $\rho(u, v) < \delta$, choose i with $\rho(u, x_i) < \delta_{x_i}/2$; then $\rho(v, x_i) \leq \rho(v, u) + \rho(u, x_i) < \delta + \delta_{x_i}/2 \leq \delta_{x_i}$, and therefore

$$\sigma(f_n(u), f_n(v)) \leq \sigma(f_n(u), f_n(x_i)) + \sigma(f_n(x_i), f_n(v)) < \epsilon/2 + \epsilon/2 = \epsilon$$

for every n . This is the argument of Problem 3, verbatim except for the change of metric on the target.

Step 2: a diagonal subsequence converging on a dense set. By Proposition 24 of the preceding chapter, the compact metric space X is separable; let $\{x_j\}_{j=1}^\infty$ be an enumeration of a dense subset D of X . (If D is finite the selection below terminates and the argument only simplifies.) By hypothesis $K_1 := \overline{\{f_n(x_1) \mid n \in \mathbb{N}\}}$ is a compact subspace of Y , and a compact metric space is sequentially compact. Hence the sequence $\{f_n(x_1)\}$, which lies in K_1 , has a convergent subsequence: there is a strictly increasing sequence of indices $\{s(1, n)\}$ and a point $a_1 \in K_1$ with $\lim_{n \rightarrow \infty} f_{s(1, n)}(x_1) = a_1$. Applying the same argument to the sequence $n \mapsto f_{s(1, n)}(x_2)$, which lies in the compact set $K_2 := \overline{\{f_n(x_2)\}}$, we obtain a subsequence $\{s(2, n)\}$ of $\{s(1, n)\}$ and a point a_2 with $\lim_{n \rightarrow \infty} f_{s(2, n)}(x_2) = a_2$. Continuing inductively we obtain strictly increasing sequences of natural numbers $\{s(j, n)\}_{n=1}^\infty$, $j = 1, 2, \dots$, each a subsequence of its predecessor, and points $a_j \in Y$ with $\lim_{n \rightarrow \infty} f_{s(j, n)}(x_j) = a_j$.

Set $n_k = s(k, k)$. Since $\{s(k+1, n)\}$ is a subsequence of $\{s(k, n)\}$ we have $s(k+1, k+1) \geq s(k, k+1) > s(k, k)$, so $\{n_k\}$ is strictly increasing. For each fixed j , the tail $\{n_k\}_{k \geq j}$ is a subsequence of $\{s(j, n)\}$, and therefore

$$\lim_{k \rightarrow \infty} f_{n_k}(x_j) = a_j \quad \text{for every } j.$$

This is the Cantor diagonalization argument used in the proof of the Arzelà–Ascoli Lemma.

Step 3: the subsequence is uniformly Cauchy. Let $\epsilon > 0$. By Step 1 choose $\delta > 0$ such that

$$\sigma(f_n(u), f_n(v)) < \epsilon/3 \quad \text{for all } n \text{ and all } u, v \in X \text{ with } \rho(u, v) < \delta.$$

By Theorem 16 of the preceding chapter the compact space X is totally bounded, so there are points $y_1, \dots, y_m$ in X with $X = \bigcup_{i=1}^m B(y_i, \delta/2)$. Since D is dense, for each i select $d_i \in D \cap B(y_i, \delta/2)$; then $X = \bigcup_{i=1}^m B(d_i, \delta)$, because $\rho(x, y_i) < \delta/2$ forces $\rho(x, d_i) < \delta$. Each d_i is some $x_{j(i)}$, so by Step 2 the sequence $\{f_{n_k}(d_i)\}_k$ converges in Y and in particular is Cauchy. Choose K so large that

$$\sigma(f_{n_k}(d_i), f_{n_l}(d_i)) < \epsilon/3 \quad \text{for all } k, l \geq K \text{ and } 1 \leq i \leq m.$$

Now let $x \in X$ be arbitrary and choose i with $\rho(x, d_i) < \delta$. For $k, l \geq K$,

$$\sigma(f_{n_k}(x), f_{n_l}(x)) \leq \sigma(f_{n_k}(x), f_{n_k}(d_i)) + \sigma(f_{n_k}(d_i), f_{n_l}(d_i)) + \sigma(f_{n_l}(d_i), f_{n_l}(x)) < \epsilon.$$

Since K does not depend on x , the sequence $\{f_{n_k}\}$ is uniformly Cauchy on X .

Step 4: passage to the limit. The space Y is not assumed complete, so uniform Cauchyness alone does not produce a limit; here the compactness hypothesis is used a second time. Fix $x \in X$. By Step 3 the sequence $\{f_{n_k}(x)\}$ is a Cauchy sequence in Y , and it lies in the compact set $K_x = \overline{\{f_n(x) \mid n \in \mathbb{N}\}}$. A compact metric space is complete: a Cauchy sequence in K_x has a convergent subsequence by sequential compactness, and a Cauchy sequence with a convergent subsequence converges to the same limit. Hence $\{f_{n_k}(x)\}$ converges to a point of K_x , which we call $f(x)$. This defines a mapping $f: X \rightarrow Y$ to which $\{f_{n_k}\}$ converges pointwise.

The convergence is uniform. Indeed, given $\epsilon > 0$ take K as in Step 3, so that $\sigma(f_{n_k}(x), f_{n_l}(x)) < \epsilon$ for all $k, l \geq K$ and all $x \in X$. Fix $k \geq K$ and $x \in X$ and let $l \rightarrow \infty$; since $z \mapsto \sigma(f_{n_k}(x), z)$ is continuous on Y and $f_{n_l}(x) \rightarrow f(x)$, we get $\sigma(f_{n_k}(x), f(x)) \leq \epsilon$. As K is independent of x , $\{f_{n_k}\} \rightarrow f$ uniformly on X .

Step 5: continuity of the limit. Let $x \in X$ and $\epsilon > 0$. By equicontinuity at x choose $\delta > 0$ with $\sigma(f_n(x'), f_n(x)) < \epsilon/2$ for all n and all x' with $\rho(x', x) < \delta$. For such an x' , letting $k \rightarrow \infty$ in

$$\sigma(f_{n_k}(x'), f_{n_k}(x)) < \epsilon/2$$

and using the continuity of the metric σ in both variables gives $\sigma(f(x'), f(x)) \leq \epsilon/2 < \epsilon$. Hence f is continuous at x , and as x was arbitrary, $f \in C(X, Y)$.

This proves the theorem. Note that when $Y = \mathbb{R}$ the hypothesis “for each x , $\overline{\{f_n(x)\}}$ is compact” is, by the Heine–Borel Theorem, exactly the statement that $\{f_n(x)\}$ is a bounded sequence of real numbers, that is, that $\{f_n\}$ is pointwise bounded; and on a compact metric space an equicontinuous pointwise bounded sequence is uniformly bounded (Problem 2). So the theorem above contains the Arzelà–Ascoli Theorem as the special case $Y = \mathbb{R}$.

Problem 10.9. Let $\{f_n\}$ be an equicontinuous, uniformly bounded sequence of continuous real-valued functions on $\mathbb{R}$. Show that there is a subsequence of $\{f_n\}$ that converges pointwise on $\mathbb{R}$ to a continuous function on $\mathbb{R}$ and that the convergence is uniform on each bounded subset of $\mathbb{R}$.

Solution. The space $\mathbb{R}$, with its usual metric, is a separable metric space: the rationals are a countable dense subset. Since $\{f_n\}$ is uniformly bounded it is in particular pointwise bounded. Hence the Arzelà–Ascoli Lemma (Lemma 2) applies to the equicontinuous, pointwise bounded sequence $\{f_n\}$ of real-valued functions on the separable metric space $\mathbb{R}$, and provides a subsequence $\{f_{n_k}\}$ that converges pointwise on all of $\mathbb{R}$ to a real-valued function f on $\mathbb{R}$. (The Arzelà–Ascoli Theorem itself is not available here, since $\mathbb{R}$ is not compact; it is the Lemma, which requires only separability, that is used.)

We show that this one subsequence does everything that is asked.

Continuity of f . Let $x \in \mathbb{R}$ and $\epsilon > 0$. By the equicontinuity of $\{f_n\}$ at x there is a $\delta > 0$ such that

$$|f_n(x') - f_n(x)| < \epsilon/2 \quad \text{for all } n \text{ and all } x' \text{ with } |x' - x| < \delta.$$

Fix such an x' and let $k \rightarrow \infty$ in $|f_{n_k}(x') - f_{n_k}(x)| < \epsilon/2$. Since $f_{n_k}(x') \rightarrow f(x')$ and $f_{n_k}(x) \rightarrow f(x)$, and the absolute value is continuous, we obtain

$$|f(x') - f(x)| \leq \epsilon/2 < \epsilon \quad \text{whenever } |x' - x| < \delta.$$

Thus f is continuous at x ; as x was arbitrary, f is continuous on $\mathbb{R}$.

Uniform convergence on compact sets. We prove the following general assertion: *if $\{g_k\}$ is an equicontinuous sequence of real-valued functions on a metric space X that converges pointwise on X to g , then the convergence is uniform on every compact subset K of X .*

Let $K \subseteq X$ be compact and let $\epsilon > 0$. For each $x \in K$, equicontinuity at x provides $\delta_x > 0$ such that

$$|g_k(y) - g_k(x)| < \epsilon/3 \quad \text{for all } k \text{ and all } y \text{ with } \rho(y, x) < \delta_x.$$

The balls $\{B(x, \delta_x)\}_{x \in K}$ form an open cover of the compact set K , so there are points $x_1, \dots, x_m \in K$ with $K \subseteq \bigcup_{i=1}^m B(x_i, \delta_{x_i})$. For each i the sequence of real numbers $\{g_k(x_i)\}$ converges, hence is Cauchy; since there are only finitely many indices i , we may choose N so that

$$|g_k(x_i) - g_l(x_i)| < \epsilon/3 \quad \text{for all } k, l \geq N \text{ and } 1 \leq i \leq m.$$

Now let $y \in K$ and choose i with $\rho(y, x_i) < \delta_{x_i}$. Then for $k, l \geq N$,

$$|g_k(y) - g_l(y)| \leq |g_k(y) - g_k(x_i)| + |g_k(x_i) - g_l(x_i)| + |g_l(x_i) - g_l(y)| < \epsilon/3 + \epsilon/3 + \epsilon/3 = \epsilon.$$

Since N is independent of $y \in K$, the sequence $\{g_k\}$ is uniformly Cauchy on K . Fixing $k \geq N$ and $y \in K$ and letting $l \rightarrow \infty$ in the displayed inequality gives $|g_k(y) - g(y)| \leq \epsilon$ for all $k \geq N$ and all $y \in K$. Hence $\{g_k\} \rightarrow g$ uniformly on K , which proves the assertion.

Conclusion. The subsequence $\{f_{n_k}\}$ is equicontinuous, being a subcollection of the equicontinuous collection $\{f_n\}$, and it converges pointwise on $\mathbb{R}$ to f . Let E be a bounded subset of $\mathbb{R}$. Then

$E \subseteq [-M, M]$ for some $M > 0$, and by the Heine–Borel Theorem the set $[-M, M]$ is a compact subset of $\mathbb{R}$. By the assertion just proved, $\{f_{n_k}\}$ converges to f uniformly on $[-M, M]$, and therefore uniformly on the subset E . Thus $\{f_{n_k}\}$ converges pointwise on $\mathbb{R}$ to the continuous function f , uniformly on every bounded subset of $\mathbb{R}$.

Two remarks. First, the uniform boundedness hypothesis was used only to guarantee pointwise boundedness, which is what the Arzelà–Ascoli Lemma requires. Second, the convergence need not be uniform on all of $\mathbb{R}$: take $f_n(x) = \arctan(x - n)$. This sequence is uniformly bounded by $\pi/2$ and equicontinuous, since $|f'_n| \leq 1$ for every n gives $|f_n(u) - f_n(v)| \leq |u - v|$ by the Mean Value Theorem. It converges pointwise on $\mathbb{R}$ to the constant function $f \equiv -\pi/2$, and the same is true of every subsequence; but $\sup_{x \in \mathbb{R}} |f_n(x) - f(x)| = \pi$ for every n , so no subsequence converges uniformly on $\mathbb{R}$. Hence “uniform on each bounded subset” is the best conclusion available.

Problem 10.10. For $1 \leq p < \infty$, show that a subspace of ℓ^p is compact if and only if it is closed, bounded, and equisummable.

Solution. Throughout, $\mathcal{S}$ is a subset of ℓ^p regarded as a metric subspace of ℓ^p , and we use the definition of equisummability stated in the Remark preceding these problems: $\mathcal{S}$ is equisummable provided that for each $\epsilon > 0$ there is an index N for which

$$\sum_{k=N}^{\infty} |x_k|^p < \epsilon \quad \text{for all } x = \{x_k\} \in \mathcal{S}.$$

Recall also that a metric space is compact if and only if it is sequentially compact, and that a compact metric space is totally bounded (Theorem 16 of the preceding chapter). We write $\|x\|_p = (\sum_{k=1}^{\infty} |x_k|^p)^{1/p}$, and we use the Minkowski Inequality freely.

Necessity. Suppose $\mathcal{S}$ is compact. By Problem 1, $\mathcal{S}$ is a closed and bounded subset of ℓ^p . It remains to prove equisummability.

Let $\epsilon > 0$ and set $\eta = \frac{1}{2}\epsilon^{1/p} > 0$. Since $\mathcal{S}$ is compact it is totally bounded, so there are points $x^{(1)}, \dots, x^{(m)}$ in $\mathcal{S}$ with

$$\mathcal{S} \subseteq \bigcup_{i=1}^m B(x^{(i)}, \eta).$$

For each i , the series $\sum_k |x_k^{(i)}|^p$ converges, so its tails tend to 0; choose N_i with $\sum_{k \geq N_i} |x_k^{(i)}|^p < \eta^p$. Let $N = \max\{N_1, \dots, N_m\}$. Now let $x \in \mathcal{S}$ and choose i with $\|x - x^{(i)}\|_p < \eta$. Applying the Minkowski Inequality to the sequences $\{x_k\}_{k \geq N}$ and $\{x_k^{(i)}\}_{k \geq N}$,

$$\left(\sum_{k=N}^{\infty} |x_k|^p \right)^{1/p} \leq \left(\sum_{k=N}^{\infty} |x_k - x_k^{(i)}|^p \right)^{1/p} + \left(\sum_{k=N}^{\infty} |x_k^{(i)}|^p \right)^{1/p} < \|x - x^{(i)}\|_p + \eta < 2\eta = \epsilon^{1/p}.$$

Hence $\sum_{k=N}^{\infty} |x_k|^p < \epsilon$ for every $x \in \mathcal{S}$, and N was chosen independently of x . Thus $\mathcal{S}$ is equisummable. Sufficiency. Suppose $\mathcal{S}$ is closed, bounded, and equisummable. We show $\mathcal{S}$ is sequentially compact, hence compact. Let $\{x^{(n)}\}$ be a sequence in $\mathcal{S}$. By boundedness there is an $M \geq 0$ with $\|x^{(n)}\|_p \leq M$ for all n .

For each n define a real-valued function g_n on the countable set $\mathbb{N}$ of coordinate indices by $g_n(k) = x_k^{(n)}$. For each fixed k we have $|g_n(k)| = |x_k^{(n)}| \leq \|x^{(n)}\|_p \leq M$ for all n , so $\{g_n\}$ is pointwise bounded on $\mathbb{N}$. By Problem 14 there is a subsequence $\{g_{n_j}\}$, that is, a subsequence $\{x^{(n_j)}\}$ of $\{x^{(n)}\}$, and a real-valued function $k \mapsto x_k$ on $\mathbb{N}$, such that

$$\lim_{j \rightarrow \infty} x_k^{(n_j)} = x_k \quad \text{for every } k.$$

(This is the Cantor diagonalization argument.) Put $x = \{x_k\}$.

First, $x \in \ell^p$ with $\|x\|_p \leq M$. Indeed, for each fixed K ,

$$\sum_{k=1}^K |x_k|^p = \lim_{j \rightarrow \infty} \sum_{k=1}^K |x_k^{(n_j)}|^p \leq \limsup_{j \rightarrow \infty} \|x^{(n_j)}\|_p^p \leq M^p,$$

since a finite sum is a continuous function of its finitely many terms. Letting $K \rightarrow \infty$ gives $\|x\|_p \leq M$. Second, we claim $\{x^{(n_j)}\} \rightarrow x$ in ℓ^p . Let $\epsilon > 0$. By equisummability choose N with

$$\sum_{k=N}^{\infty} |y_k|^p < \epsilon \quad \text{for all } y \in \mathcal{S},$$

so in particular $\sum_{k=N}^{\infty} |x_k^{(n_j)}|^p < \epsilon$ for every j . The same bound passes to the limit: for each $K \geq N$,

$$\sum_{k=N}^K |x_k|^p = \lim_{j \rightarrow \infty} \sum_{k=N}^K |x_k^{(n_j)}|^p \leq \epsilon,$$

and letting $K \rightarrow \infty$ gives $\sum_{k=N}^{\infty} |x_k|^p \leq \epsilon$. Splitting the index set at N and using the Minkowski Inequality,

$$\|x^{(n_j)} - x\|_p \leq \left(\sum_{k=1}^{N-1} |x_k^{(n_j)} - x_k|^p \right)^{1/p} + \left(\sum_{k=N}^{\infty} |x_k^{(n_j)}|^p \right)^{1/p} + \left(\sum_{k=N}^{\infty} |x_k|^p \right)^{1/p}.$$

The first term on the right is a finite sum of terms each of which tends to 0 as $j \rightarrow \infty$, so it tends to 0; the second and third are each at most $\epsilon^{1/p}$. Therefore

$$\limsup_{j \rightarrow \infty} \|x^{(n_j)} - x\|_p \leq 2\epsilon^{1/p}.$$

Since $\epsilon > 0$ was arbitrary, $\lim_{j \rightarrow \infty} \|x^{(n_j)} - x\|_p = 0$.

Finally, since $\mathcal{S}$ is a closed subset of ℓ^p and x is the limit of a sequence in $\mathcal{S}$, we have $x \in \mathcal{S}$. Thus every sequence in $\mathcal{S}$ has a subsequence converging to a point of $\mathcal{S}$, that is, $\mathcal{S}$ is sequentially compact and therefore compact.

Both implications are proved, so a subspace of ℓ^p , $1 \leq p < \infty$, is compact if and only if it is closed, bounded, and equisummable.

Problem 10.11. For a sequence of nonnegative real numbers $\{c_n\}$, let $\mathcal{S}$ be the subset of ℓ^2 consisting of those $x = \{x_n\} \in \ell^2$ such that $|x_n| \leq c_n$ for all n . Show that $\mathcal{S}$ is equisummable if $\{c_n\}$ belongs to ℓ^2 .

Solution. Assume $c = \{c_n\}$ belongs to ℓ^2 , that is, $\sum_{n=1}^{\infty} c_n^2 < \infty$.

Let $\epsilon > 0$. Since the series $\sum_{n=1}^{\infty} c_n^2$ of nonnegative terms converges, its partial sums form a Cauchy sequence, and therefore its tails converge to 0: there is an index N for which

$$\sum_{k=N}^{\infty} c_k^2 < \epsilon.$$

Now let $x = \{x_k\}$ be any element of $\mathcal{S}$. By the defining property of $\mathcal{S}$ we have $|x_k| \leq c_k$, hence $|x_k|^2 \leq c_k^2$, for every k . Summing over $k \geq N$ and using the comparison of series of nonnegative terms,

$$\sum_{k=N}^{\infty} |x_k|^2 \leq \sum_{k=N}^{\infty} c_k^2 < \epsilon.$$

The index N was chosen using only ϵ and the sequence $\{c_n\}$; it does not depend on x . Therefore for each $\epsilon > 0$ there is an index N with $\sum_{k=N}^{\infty} |x_k|^2 < \epsilon$ for all $x \in \mathcal{S}$, which is precisely the statement that $\mathcal{S}$ is equisummable.

Remark. When $\{c_n\} \in \ell^2$ the set $\mathcal{S}$ is in fact a compact subspace of ℓ^2 . It is bounded, since $\|x\|_2 \leq \|c\|_2$ for every $x \in \mathcal{S}$. It is closed: if $\{x^{(j)}\}$ is a sequence in $\mathcal{S}$ converging in ℓ^2 to $y = \{y_k\}$, then for each fixed k we have $|x_k^{(j)} - y_k| \leq \|x^{(j)} - y\|_2 \rightarrow 0$, so $y_k = \lim_j x_k^{(j)}$ and hence $|y_k| = \lim_j |x_k^{(j)}| \leq c_k$; thus

$y \in \mathcal{S}$. Being closed, bounded, and equisummable, $\mathcal{S}$ is compact by Problem 10. The special case $c_n = 1/n$ is the Hilbert cube.

The hypothesis $\{c_n\} \in \ell^2$ cannot simply be dropped. If, for instance, $c_n = 1$ for all n , then $\mathcal{S}$ is the whole closed unit ball of ℓ^∞ intersected with ℓ^2 , and it contains every standard basis vector e_n (the sequence with 1 in the n -th place and 0 elsewhere); since $\sum_{k \geq N} |(e_n)_k|^2 = 1$ whenever $n \geq N$, no index N can respond to $\epsilon = 1/2$, so $\mathcal{S}$ is not equisummable.

Problem 10.12. For $1 \leq p \leq \infty$, show that the closed unit ball in the Banach space ℓ^p is not compact.

Solution. Let $B = \{x \in \ell^p \mid \|x\|_p \leq 1\}$ denote the closed unit ball of ℓ^p . For each natural number n let $e_n \in \ell^p$ be the sequence whose n -th term is 1 and whose other terms are 0; that is, $(e_n)_k = 1$ if $k = n$ and $(e_n)_k = 0$ if $k \neq n$.

For $1 \leq p < \infty$ we have $\|e_n\|_p = (\sum_k |(e_n)_k|^p)^{1/p} = 1$, and for $p = \infty$ we have $\|e_n\|_\infty = \sup_k |(e_n)_k| = 1$. In every case $e_n \in B$, so $\{e_n\}$ is a sequence in B .

Now compute the distance between two distinct members of this sequence. Let $n \neq m$. The sequence $e_n - e_m$ has the value 1 in the n -th place, the value -1 in the m -th place, and 0 elsewhere. Hence for $1 \leq p < \infty$,

$$\|e_n - e_m\|_p = (|1|^p + |-1|^p)^{1/p} = 2^{1/p},$$

while for $p = \infty$,

$$\|e_n - e_m\|_\infty = 1.$$

In either case

$$\|e_n - e_m\|_p \geq 1 \quad \text{whenever } n \neq m,$$

since $2^{1/p} \geq 1$ for $1 \leq p < \infty$.

Consequently no subsequence of $\{e_n\}$ is a Cauchy sequence: if $\{e_{n_k}\}$ is a subsequence, then its terms are pairwise distinct members of $\{e_n\}$, so $\|e_{n_k} - e_{n_l}\|_p \geq 1$ for all $k \neq l$, and the Cauchy criterion fails for $\epsilon = 1$. A convergent sequence in a metric space is Cauchy, so no subsequence of $\{e_n\}$ converges in ℓ^p , and in particular no subsequence converges to a point of B .

Therefore B is not sequentially compact. Since a metric space is compact if and only if it is sequentially compact, the closed unit ball B of ℓ^p is not compact, for any p with $1 \leq p \leq \infty$.

Remark. For $1 \leq p < \infty$ this also follows from Problem 10: the ball B is closed and bounded, but it is not equisummable, because for every index N the element $e_N \in B$ satisfies $\sum_{k=N}^\infty |(e_N)_k|^p = 1$, so no N responds to the challenge $\epsilon = 1/2$. The direct argument above has the advantage of covering $p = \infty$ as well. Observe also that B is a closed and bounded subset of the metric space ℓ^p ; thus, as the text points out, in a general metric space closed and bounded does not imply compact.

Problem 10.13. For $1 \leq p \leq \infty$, show that the closed unit ball in the Banach space $L^p[0, 1]$ is not compact.

Solution. Let $B = \{f \in L^p[0, 1] \mid \|f\|_p \leq 1\}$ be the closed unit ball of $L^p[0, 1]$. As in the preceding problem it suffices to exhibit a sequence in B no subsequence of which is Cauchy, for then B fails to be sequentially compact and hence, a metric space being compact if and only if it is sequentially compact, fails to be compact.

Split $[0, 1]$ into countably many pairwise disjoint measurable sets of positive measure: for each natural number n put

$$E_n = \left[\frac{1}{n+1}, \frac{1}{n} \right), \quad m(E_n) = \frac{1}{n} - \frac{1}{n+1} = \frac{1}{n(n+1)} > 0.$$

These sets are pairwise disjoint and contained in $[0, 1]$. Define

$$f_n = \frac{\chi_{E_n}}{\|\chi_{E_n}\|_p}.$$

This makes sense because $\|\chi_{E_n}\|_p \neq 0$: for $1 \leq p < \infty$ we have $\|\chi_{E_n}\|_p = m(E_n)^{1/p} > 0$, and for $p = \infty$ we have $\|\chi_{E_n}\|_\infty = 1$, since $m(E_n) > 0$ means χ_{E_n} equals 1 on a set of positive measure. By construction $\|f_n\|_p = 1$, so $f_n \in B$ for every n .

Now fix $n \neq m$. Since E_n and E_m are disjoint, the function $f_n - f_m$ equals f_n on E_n , equals $-f_m$ on E_m , and equals 0 off $E_n \cup E_m$.

Case $1 \leq p < \infty$. Then, by the countable (here, finite) additivity of integration over disjoint sets,

$$\|f_n - f_m\|_p^p = \int_{E_n} |f_n|^p + \int_{E_m} |f_m|^p = \|f_n\|_p^p + \|f_m\|_p^p = 1 + 1 = 2,$$

so $\|f_n - f_m\|_p = 2^{1/p} \geq 1$.

Case $p = \infty$. Here $f_n = \chi_{E_n}$, and $|f_n - f_m| = 1$ on the set E_n , which has positive measure. Hence the essential supremum of $|f_n - f_m|$ is at least 1, that is, $\|f_n - f_m\|_\infty \geq 1$. (In fact it equals 1.)

In every case

$$\|f_n - f_m\|_p \geq 1 \quad \text{whenever } n \neq m.$$

Therefore no subsequence $\{f_{n_k}\}$ of $\{f_n\}$ can be Cauchy in $L^p[0, 1]$: its terms are pairwise distinct members of $\{f_n\}$, so $\|f_{n_k} - f_{n_l}\|_p \geq 1$ for $k \neq l$, and the Cauchy criterion fails for $\epsilon = 1$. Since convergent sequences are Cauchy, no subsequence of $\{f_n\}$ converges in $L^p[0, 1]$.

Thus B contains a sequence with no subsequence converging to a point of B , so B is not sequentially compact and hence not compact.

Remark. The set B is a closed and bounded subset of the metric space $L^p[0, 1]$: it is bounded by definition, and it is closed because the norm is a continuous function on $L^p[0, 1]$, so $\{f \mid \|f\|_p \leq 1\}$ is the preimage of the closed set $(-\infty, 1]$. This is another instance, alongside the closed unit balls of $C[0, 1]$ and of ℓ^p , of a closed bounded subset of a metric space that is not compact.

Problem 10.14. Let S be a countable set and $\{f_n\}$ a sequence of real-valued functions on S that is pointwise bounded on S . Show that there is a subsequence of $\{f_n\}$ that converges pointwise on S to a real-valued function.

Solution. Recall that pointwise boundedness means: for each $s \in S$, the sequence of real numbers $\{f_n(s)\}$ is bounded. The argument is the Cantor diagonalization argument, isolated here from the metric setting of the Arzelà–Ascoli Lemma; no structure on S beyond countability is used.

If S is empty the statement is vacuous, and if S is finite, say $S = \{s_1, \dots, s_M\}$, the inductive selection below terminates after M steps and the M -th subsequence already works. So assume S is countably infinite and let $\{s_j\}_{j=1}^\infty$ be an enumeration of S .

Construction of the nested subsequences. Consider the sequence of real numbers $n \mapsto f_n(s_1)$. By hypothesis it is bounded, so by the Bolzano–Weierstrass Theorem it has a convergent subsequence: there is a strictly increasing sequence of natural numbers $\{s(1, n)\}_{n=1}^\infty$ and a real number a_1 with

$$\lim_{n \rightarrow \infty} f_{s(1, n)}(s_1) = a_1.$$

Suppose that for some $j \geq 1$ strictly increasing sequences $\{s(1, n)\}, \dots, \{s(j, n)\}$ have been chosen, each a subsequence of its predecessor, together with real numbers $a_1, \dots, a_j$ satisfying $\lim_{n \rightarrow \infty} f_{s(i, n)}(s_i) = a_i$ for $1 \leq i \leq j$. The sequence of real numbers $n \mapsto f_{s(j, n)}(s_{j+1})$ is bounded, since $\{f_n(s_{j+1})\}$ is bounded and this is a subsequence of it. By the Bolzano–Weierstrass Theorem there is a subsequence $\{s(j+1, n)\}$ of $\{s(j, n)\}$ and a real number a_{j+1} with

$$\lim_{n \rightarrow \infty} f_{s(j+1, n)}(s_{j+1}) = a_{j+1}.$$

By induction we obtain, for every $j \geq 1$, a strictly increasing sequence of natural numbers $\{s(j, n)\}_{n=1}^\infty$ and a real number a_j such that $\{s(j+1, n)\}$ is a subsequence of $\{s(j, n)\}$ and $\lim_{n \rightarrow \infty} f_{s(j, n)}(s_j) = a_j$. The diagonal subsequence. Put

$$n_k = s(k, k) \quad \text{for } k = 1, 2, \dots$$

The sequence $\{n_k\}$ is strictly increasing. Indeed, $\{s(k+1, n)\}_n$ is a subsequence of the strictly increasing sequence $\{s(k, n)\}_n$, and a subsequence of a strictly increasing sequence of natural numbers satisfies $s(k+1, n) \geq s(k, n)$ for every n ; hence

$$n_{k+1} = s(k+1, k+1) \geq s(k, k+1) > s(k, k) = n_k,$$

the last inequality because $\{s(k, n)\}_n$ is strictly increasing in n . Therefore $\{f_{n_k}\}$ is a genuine subsequence of $\{f_n\}$.

Fix an index j . For every $k \geq j$ the number $n_k = s(k, k)$ is a term of the sequence $\{s(j, n)\}_n$, because $\{s(k, n)\}_n$ is a subsequence of $\{s(j, n)\}_n$ when $k \geq j$; and since $\{n_k\}$ is strictly increasing, the tail $\{n_k\}_{k \geq j}$ is a subsequence of $\{s(j, n)\}_n$. A subsequence of a convergent sequence of real numbers converges to the same limit, so

$$\lim_{k \rightarrow \infty} f_{n_k}(s_j) = a_j.$$

Conclusion. Define $f: S \rightarrow \mathbb{R}$ by $f(s_j) = a_j$ for each j ; this is well defined because $\{s_j\}$ is an enumeration of S , so each point of S is s_j for exactly one j , and each a_j is a real number. By the display above, for every $s \in S$,

$$\lim_{k \rightarrow \infty} f_{n_k}(s) = f(s).$$

Thus $\{f_{n_k}\}$ is a subsequence of $\{f_n\}$ converging pointwise on S to the real-valued function f , as required.

Remark. This is exactly the first half of the proof of the Arzelà–Ascoli Lemma (Lemma 2), where S is taken to be a countable dense subset of a separable metric space X ; the second half of that proof uses equicontinuity to upgrade convergence on the dense set to convergence on all of X . Note that no continuity or equicontinuity hypothesis is needed here, and that the limit function f is in general only a function on S with no regularity properties. Note also that pointwise boundedness cannot be weakened: if some $\{f_n(s)\}$ were unbounded, one could arrange that no subsequence converges at s to a real number, for instance with $S = \{s\}$ and $f_n(s) = n$.

10.3 Problems 10.15–10.21

Problem 10.15. Let E be a subset of a metric space X . Show that $\text{bd } E$ is closed. Also show that if E is closed, then the interior of $\text{bd } E$ is empty.

Solution. Throughout we use the decomposition recorded in (5) of Section 10.2:

$$X = \text{int } E \cup \text{ext } E \cup \text{bd } E,$$

the union being disjoint. Here $\text{int } E$ is the set of points x possessing an open ball centered at x that is contained in E , $\text{ext } E = \text{int}(X \sim E)$, and $\text{bd } E$ is the set of points every ball about which contains points of E and points of $X \sim E$. Write ρ for the metric on X .

Step 1: the interior of any set is open. Let $A \subseteq X$ and let $x \in \text{int } A$, say $B(x, r) \subseteq A$. If $y \in B(x, r)$, put $s = r - \rho(x, y) > 0$. By the triangle inequality $B(y, s) \subseteq B(x, r) \subseteq A$; in particular $y \in B(y, s) \subseteq A$, so y is a point of A possessing a ball centered at it and contained in A , that is, $y \in \text{int } A$. Thus $B(x, r) \subseteq \text{int } A$, and $\text{int } A$ is open.

Step 2: $\text{bd } E$ is closed. By Step 1 both $\text{int } E$ and $\text{ext } E = \text{int}(X \sim E)$ are open, hence so is their union. Since the three sets in (5) are disjoint and exhaust X ,

$$\text{bd } E = X \sim [\text{int } E \cup \text{ext } E],$$

which is the complement of an open set and therefore closed.

Step 3: $\text{bd } E \subseteq \overline{E}$ for every subset E . If $x \in \text{bd } E$, then every open ball centered at x contains a point of E ; that is, x is a point of closure of E , so $x \in \overline{E}$.

Step 4: if E is closed then $\text{int}(\text{bd } E) = \emptyset$. Let $\mathcal{U}$ be an open subset of X with $\mathcal{U} \subseteq \text{bd } E$; we show $\mathcal{U} = \emptyset$, which is precisely the assertion that $\text{bd } E$ has empty interior, that is, that $\text{bd } E$ is hollow. By Step 3 and the closedness of E ,

$$\mathcal{U} \subseteq \text{bd } E \subseteq \overline{E} = E.$$

Thus $\mathcal{U}$ is an open subset of X contained in E , so each of its points is an interior point of E , giving $\mathcal{U} \subseteq \text{int } E$. But also $\mathcal{U} \subseteq \text{bd } E$, while $\text{int } E \cap \text{bd } E = \emptyset$ by the disjointness in (5). Hence $\mathcal{U} = \emptyset$. Therefore the boundary of a closed set is a closed hollow set. This is the fact left as an exercise in the proof of Corollary 5. The hypothesis that E be closed cannot be dropped: for $E = \mathbb{Q} \subseteq \mathbb{R}$ one has $\text{bd } E = \mathbb{R}$, whose interior is all of $\mathbb{R}$.

Problem 10.16. In a metric space X , show that a subset E is nowhere dense if and only if for each open subset $\mathcal{O}$ of X , $E \cap \mathcal{O}$ is not dense in $\mathcal{O}$.

Solution. Recall the definitions in force. A subset of X is hollow provided it has empty interior; E is nowhere dense provided $\overline{E}$ is hollow; and a subset A of a metric space Y is dense in Y provided every nonempty open subset of Y contains a point of A . In the statement $\mathcal{O}$ is regarded as a metric subspace of X , and of course $\mathcal{O}$ is tacitly nonempty, since the empty set is vacuously dense in itself.

We first record the observation that makes the whole exercise routine. Since $\mathcal{O}$ is an open subset of X , a subset $\mathcal{U}$ of $\mathcal{O}$ is open in the metric subspace $\mathcal{O}$ if and only if it is open in X . Indeed, open subsets of the subspace $\mathcal{O}$ are exactly the sets $\mathcal{V} \cap \mathcal{O}$ with $\mathcal{V}$ open in X , because for $x \in \mathcal{O}$ the ball of radius r about x in the subspace $\mathcal{O}$ is $B(x, r) \cap \mathcal{O}$; and $\mathcal{V} \cap \mathcal{O}$ is open in X as an intersection of two sets open in X . Conversely a subset of $\mathcal{O}$ that is open in X equals its own intersection with $\mathcal{O}$, so it is open in $\mathcal{O}$. Assume first that E is nowhere dense, so $\text{int } \overline{E} = \emptyset$. Let $\mathcal{O}$ be a nonempty open subset of X and suppose, to get a contradiction, that $E \cap \mathcal{O}$ is dense in $\mathcal{O}$. Let $x \in \mathcal{O}$ and let $\epsilon > 0$. Since $\mathcal{O}$ is open there is r with $0 < r < \epsilon$ and $B(x, r) \subseteq \mathcal{O}$. By the observation above, $B(x, r)$ is a nonempty open subset of the space $\mathcal{O}$, so by density it contains a point of $E \cap \mathcal{O}$, in particular a point of E . Since $B(x, r) \subseteq B(x, \epsilon)$, every ball about x meets E , so x is a point of closure of E . As $x \in \mathcal{O}$ was arbitrary, $\mathcal{O} \subseteq \overline{E}$. But $\mathcal{O}$ is open and nonempty, so $\text{int } \overline{E} \supseteq \mathcal{O} \neq \emptyset$, contradicting the assumption that $\overline{E}$ is hollow. Hence $E \cap \mathcal{O}$ is not dense in $\mathcal{O}$.

Conversely, suppose E is not nowhere dense, that is, $\text{int } \overline{E} \neq \emptyset$. Choose a nonempty open subset $\mathcal{O}$ of X with $\mathcal{O} \subseteq \overline{E}$; for instance $\mathcal{O} = \text{int } \overline{E}$, which is open by Step 1 of the solution of Problem 15. We claim $E \cap \mathcal{O}$ is dense in $\mathcal{O}$, so that the right-hand condition fails. Let $\mathcal{U}$ be a nonempty open subset of the space $\mathcal{O}$. By the observation above, $\mathcal{U}$ is open in X . Pick $x \in \mathcal{U}$. Then $x \in \mathcal{O} \subseteq \overline{E}$, so x is a point of closure of E , and $\mathcal{U}$ is an open set containing x , hence contains a ball $B(x, r)$, which must meet E . Therefore $\mathcal{U} \cap E \neq \emptyset$, and since $\mathcal{U} \subseteq \mathcal{O}$ we get $\mathcal{U} \cap (E \cap \mathcal{O}) \neq \emptyset$. Thus every nonempty open subset of $\mathcal{O}$ meets $E \cap \mathcal{O}$, that is, $E \cap \mathcal{O}$ is dense in $\mathcal{O}$.

By contraposition, if $E \cap \mathcal{O}$ fails to be dense in $\mathcal{O}$ for every nonempty open $\mathcal{O} \subseteq X$, then E is nowhere dense. The two implications together give the asserted equivalence.

Problem 10.17. In a complete metric space X , is the union of a countable collection of nowhere dense sets also nowhere dense?

Solution. No. Completeness buys the conclusion of the Baire Category Theorem, namely that such a union is hollow; it does not upgrade that to nowhere dense, which is the much stronger requirement that the closure of the union be hollow.

Here is the standard counterexample. Take $X = \mathbb{R}$ with the usual metric, which is a complete metric space by Theorem 12 of Chapter 9. Enumerate the rational numbers as $\mathbb{Q} = \{q_n\}_{n=1}^{\infty}$ and set $E_n = \{q_n\}$. Each E_n is nowhere dense. Indeed a singleton is closed, so $\overline{E_n} = E_n = \{q_n\}$, and $\{q_n\}$ has empty interior because no open interval, hence no ball $B(q_n, r) = (q_n - r, q_n + r)$ with $r > 0$, is a single point: such a ball contains $q_n + r/2 \neq q_n$. Thus $\overline{E_n}$ is hollow, which is exactly the statement that E_n is nowhere dense.

However

$$\bigcup_{n=1}^{\infty} E_n = \mathbb{Q},$$

and $\overline{\mathbb{Q}} = \mathbb{R}$, since every real number is the limit of a sequence of rationals, so every ball about a real number contains a rational. Hence $\text{int } \overline{\mathbb{Q}} = \text{int } \mathbb{R} = \mathbb{R} \neq \emptyset$, so $\overline{\mathbb{Q}}$ is not hollow and $\mathbb{Q}$ is not nowhere

dense. In fact $\mathbb{Q}$ is dense in $\mathbb{R}$, which is the extreme opposite of being nowhere dense.

This is consistent with the Baire Category Theorem, part (ii), applied to the closed hollow sets $\overline{E_n} = \{q_n\}$: it predicts only that $\mathbb{Q}$ itself is hollow, and indeed $\text{int } \mathbb{Q} = \emptyset$, since every interval contains irrational numbers.

The general principle behind the failure is that closure does not commute with countable unions: one always has $\bigcup_n \overline{E_n} \subseteq \overline{\bigcup_n E_n}$, but the inclusion is typically strict for infinite unions, and it is the closure of the union, not the union of the closures, that must be hollow for the union to be nowhere dense. For a finite collection the answer is affirmative, and completeness is not needed. It suffices to treat two sets A, B that are nowhere dense and then induct. Since closure commutes with finite unions, $\overline{A \cup B} = \overline{A} \cup \overline{B}$. Let $\mathcal{U}$ be an open set with $\mathcal{U} \subseteq \overline{A} \cup \overline{B}$ and suppose $\mathcal{U} \neq \emptyset$. The set $\mathcal{U} \sim \overline{A}$ is open, being the intersection of the open set $\mathcal{U}$ with the open set $X \sim \overline{A}$, and it is contained in $\overline{B}$. Since $\overline{B}$ is hollow, $\mathcal{U} \sim \overline{A} = \emptyset$, that is, $\mathcal{U} \subseteq \overline{A}$. Since $\overline{A}$ is hollow, $\mathcal{U} = \emptyset$, a contradiction. Hence $\overline{A \cup B}$ is hollow and $A \cup B$ is nowhere dense.

Problem 10.18. Let $\mathcal{O}$ be an open subset and F be a closed subset of a metric space X . Show that both $\overline{\mathcal{O}} \sim \mathcal{O}$ and $F \sim \text{int } F$ are closed and hollow.

Solution. Recall that a subset of X is hollow provided it has empty interior, and that by Step 1 of the solution of Problem 15 the interior of any set is open.

Consider first $\overline{\mathcal{O}} \sim \mathcal{O}$, where $\mathcal{O}$ is open.

That it is closed: $\overline{\mathcal{O}} \sim \mathcal{O} = \overline{\mathcal{O}} \cap (X \sim \mathcal{O})$. The closure $\overline{\mathcal{O}}$ is closed, and $X \sim \mathcal{O}$ is closed because $\mathcal{O}$ is open. The intersection of two closed sets is closed.

That it is hollow: let $\mathcal{U}$ be an open subset of X with $\mathcal{U} \subseteq \overline{\mathcal{O}} \sim \mathcal{O}$, and suppose $\mathcal{U} \neq \emptyset$. Choose $x \in \mathcal{U}$. Since $\mathcal{U} \subseteq \overline{\mathcal{O}}$, the point x is a point of closure of $\mathcal{O}$, so every ball centered at x contains a point of $\mathcal{O}$. Since $\mathcal{U}$ is open there is $r > 0$ with $B(x, r) \subseteq \mathcal{U}$, and $B(x, r)$ contains a point of $\mathcal{O}$. Hence $\mathcal{U} \cap \mathcal{O} \neq \emptyset$, contradicting $\mathcal{U} \subseteq X \sim \mathcal{O}$. Therefore $\mathcal{U} = \emptyset$, and $\overline{\mathcal{O}} \sim \mathcal{O}$ has empty interior.

Now consider $F \sim \text{int } F$, where F is closed.

That it is closed: $F \sim \text{int } F = F \cap (X \sim \text{int } F)$. Here F is closed by hypothesis, and $\text{int } F$ is open, so $X \sim \text{int } F$ is closed. Again an intersection of two closed sets is closed.

That it is hollow: let $\mathcal{U}$ be an open subset of X with $\mathcal{U} \subseteq F \sim \text{int } F$. In particular $\mathcal{U}$ is an open set contained in F , so every point of $\mathcal{U}$ has a ball about it contained in $\mathcal{U} \subseteq F$; that is, $\mathcal{U} \subseteq \text{int } F$. On the other hand $\mathcal{U} \cap \text{int } F = \emptyset$ by the definition of $F \sim \text{int } F$. Hence $\mathcal{U} = \mathcal{U} \cap \text{int } F = \emptyset$, and $F \sim \text{int } F$ has empty interior.

Two remarks tie this to Problem 15. First observe that for any subset E of X one has $\text{ext } E = X \sim \overline{E}$: a point x fails to be a point of closure of E precisely when some ball centered at x misses E , that is, precisely when some ball centered at x is contained in $X \sim E$, which is the definition of an exterior point. Feeding this into the disjoint decomposition (5) of Section 10.2 gives

$$\overline{E} = X \sim \text{ext } E = \text{int } E \cup \text{bd } E, \quad \text{the union disjoint.}$$

Hence for an open set $\mathcal{O}$, where $\mathcal{O} = \text{int } \mathcal{O}$, one has $\overline{\mathcal{O}} \sim \mathcal{O} = \text{bd } \mathcal{O}$; and for a closed set F , where $F = \overline{F}$, one has $F \sim \text{int } F = \text{bd } F$. So the present problem is exactly the statement that the boundary of an open set and the boundary of a closed set are closed and hollow, and it supplies the fact used in the proof of Corollary 5, that $\text{bd } F_n$ is closed and hollow for each closed F_n .

Consequently, both sets are nowhere dense: each is closed, so it equals its own closure, and that closure is hollow.

Problem 10.19. In a complete metric space, is the union of a countable collection of sets of the first category also of the first category?

Solution. Yes. Moreover completeness plays no role: the assertion holds in every metric space, since being of the first category is purely a countability statement about a decomposition into nowhere dense pieces.

Recall the terminology from the Remark following the Baire Category Theorem: a subset A of a metric

space X is of the first category, or meager, provided A is the union of a countable collection of nowhere dense subsets of X .

Let $\{A_k\}_{k=1}^\infty$ be a countable collection of subsets of X , each of the first category, and put $A = \bigcup_{k=1}^\infty A_k$. For each index k choose, by the definition of first category, a countable collection $\{E_{k,n}\}_{n=1}^\infty$ of nowhere dense subsets of X with

$$A_k = \bigcup_{n=1}^\infty E_{k,n}.$$

There is no loss of generality in indexing each of these collections by all of $\mathbb{N}$: a finite collection $E_{k,1}, \dots, E_{k,m}$ may be extended by setting $E_{k,n} = \emptyset$ for $n > m$, and the empty set is nowhere dense since $\bar{\emptyset} = \emptyset$ has empty interior.

Then

$$A = \bigcup_{k=1}^\infty \bigcup_{n=1}^\infty E_{k,n} = \bigcup_{(k,n) \in \mathbb{N} \times \mathbb{N}} E_{k,n},$$

the equality of the two right-hand sides being immediate from the definition of union: a point lies in the left side if and only if it lies in $E_{k,n}$ for some pair (k, n) .

The set $\mathbb{N} \times \mathbb{N}$ is countable. Hence there is a one-to-one correspondence $j \mapsto (k_j, n_j)$ of $\mathbb{N}$ onto $\mathbb{N} \times \mathbb{N}$, and setting $G_j = E_{k_j, n_j}$ we obtain

$$A = \bigcup_{j=1}^\infty G_j,$$

a union of a countable collection of nowhere dense subsets of X . Therefore A is of the first category.

The same argument applies verbatim to a finite collection of first category sets, and shows in particular that the collection of sets of the first category in X is closed under countable unions and, trivially, under passage to subsets, since a subset of a nowhere dense set is nowhere dense.

It is worth contrasting this with Problem 17. There the answer was negative because “nowhere dense” is not stable under countable unions; here the answer is positive precisely because “first category” was defined so as to be the countable-union closure of “nowhere dense”, and a countable union of countable unions is again a countable union. Completeness enters only when one wants the further conclusion, supplied by the Baire Category Theorem, that in a complete metric space a set of the first category is hollow and hence is a proper subset of X whenever $X \neq \emptyset$.

Problem 10.20. Let F_n be the subset of $C[0, 1]$ consisting of functions for which there is a point x_0 in $[0, 1]$ such that $|f(x) - f(x_0)| \leq n|x - x_0|$ for all $x \in [0, 1]$. Show that F_n is closed. Show that F_n is hollow by observing that for $f \in C[0, 1]$ and $r > 0$ there is a piecewise linear function $g \in C[0, 1]$ for which $\rho_{\max}(f, g) < r$ and the left-hand and right-hand derivatives of g on $[0, 1]$ are greater than $n + 1$. Conclude that $C[0, 1] \neq \bigcup_{n=1}^\infty F_n$ and show that each $h \in C[0, 1] \sim \bigcup_{n=1}^\infty F_n$ fails to be differentiable at any point in $(0, 1)$.

Solution. Throughout, $C[0, 1]$ carries the metric $\rho_{\max}(f, g) = \max_{x \in [0, 1]} |f(x) - g(x)|$, so that convergence in this metric is uniform convergence on $[0, 1]$. By Theorem 12 of Chapter 9, part (iii), $C[0, 1]$ is a complete metric space.

Part 1: each F_n is closed.

By Proposition 6 of Chapter 9 it suffices to show that F_n is sequentially closed. So let $\{f_k\}$ be a sequence in F_n with $f_k \rightarrow f$ in $C[0, 1]$, that is, uniformly on $[0, 1]$. For each k choose $x_k \in [0, 1]$ witnessing membership in F_n :

$$|f_k(x) - f_k(x_k)| \leq n|x - x_k| \quad \text{for all } x \in [0, 1].$$

The sequence $\{x_k\}$ lies in the closed bounded interval $[0, 1]$, so by the Bolzano-Weierstrass Theorem it has a subsequence $\{x_{k_j}\}$ converging to some x_0 , and $x_0 \in [0, 1]$ since $[0, 1]$ is closed.

Fix $x \in [0, 1]$. For each j , the triangle inequality gives

$$|f(x) - f(x_0)| \leq |f(x) - f_{k_j}(x)| + |f_{k_j}(x) - f_{k_j}(x_{k_j})| + |f_{k_j}(x_{k_j}) - f(x_0)|.$$

We estimate the three terms as $j \rightarrow \infty$. The first is at most $\rho_{\max}(f, f_{k_j}) \rightarrow 0$. The second is at most $n|x - x_{k_j}| \rightarrow n|x - x_0|$. For the third,

$$|f_{k_j}(x_{k_j}) - f(x_0)| \leq |f_{k_j}(x_{k_j}) - f(x_{k_j})| + |f(x_{k_j}) - f(x_0)| \leq \rho_{\max}(f_{k_j}, f) + |f(x_{k_j}) - f(x_0)|,$$

and both summands tend to 0, the first by uniform convergence and the second because f is continuous at x_0 and $x_{k_j} \rightarrow x_0$. Letting $j \rightarrow \infty$ we obtain

$$|f(x) - f(x_0)| \leq n|x - x_0|.$$

Since $x \in [0, 1]$ was arbitrary and $x_0 \in [0, 1]$, we conclude $f \in F_n$. Hence F_n is closed.

Part 2: each F_n is hollow.

It suffices to show that no ball $B(f, r) = \{g : \rho_{\max}(f, g) < r\}$ is contained in F_n , for then no point of F_n is an interior point. So fix $f \in C[0, 1]$ and $r > 0$; we construct $g \in B(f, r)$ with $g \notin F_n$.

First we approximate f by a piecewise linear function. Since $[0, 1]$ is a compact metric space, by Theorem 20 of Chapter 9, and f is continuous, f is uniformly continuous by Proposition 23 of Chapter 9. Choose $\delta > 0$ such that $|f(s) - f(t)| < r/4$ whenever $s, t \in [0, 1]$ and $|s - t| \leq \delta$. Choose a partition $0 = t_0 < t_1 < \cdots < t_m = 1$ with $t_i - t_{i-1} < \delta$ for each i , and let $p \in C[0, 1]$ be the function that agrees with f at each t_i and is affine on each $[t_{i-1}, t_i]$. If $x \in [t_{i-1}, t_i]$, then $p(x)$ is a convex combination of $f(t_{i-1})$ and $f(t_i)$, so

$$|p(x) - f(x)| \leq \max\{|f(t_{i-1}) - f(x)|, |f(t_i) - f(x)|\} < r/4,$$

since $|x - t_{i-1}| \leq \delta$ and $|x - t_i| \leq \delta$. Hence $\rho_{\max}(f, p) \leq r/4$. Let K be the maximum of the absolute values of the slopes of the finitely many affine pieces of p .

Next we superimpose a rapid sawtooth. Choose a number $M > K + n + 1$, put $a = r/(4M) > 0$, and let $s: [0, 1] \rightarrow \mathbb{R}$ be the continuous, $2a$ -periodic zigzag determined by $s(0) = 0$, s affine with slope $+M$ on $[0, a]$, slope $-M$ on $[a, 2a]$, and so on alternately. Then s is piecewise linear with finitely many pieces on $[0, 1]$, every piece has slope $\pm M$, and $\max_{[0, 1]} |s| = Ma = r/4$.

Set $g = p + s$. Then g is piecewise linear, its breakpoints being among the t_i together with the multiples of a in $[0, 1]$, and

$$\rho_{\max}(f, g) \leq \rho_{\max}(f, p) + \max_{[0, 1]} |s| \leq r/4 + r/4 = r/2 < r,$$

so $g \in B(f, r)$. On each affine piece of g the slope has the form $c \pm M$ with $|c| \leq K$, so its absolute value is at least $M - K > n + 1$. Consequently at each $x \in [0, 1)$ the right-hand derivative $D^+g(x)$ exists and equals the slope of the affine piece of g immediately to the right of x , and at each $x \in (0, 1]$ the left-hand derivative $D^-g(x)$ exists and equals the slope of the piece immediately to the left; in every case the absolute value of that one-sided derivative exceeds $n + 1$.

Now suppose, for a contradiction, that $g \in F_n$, witnessed by $x_0 \in [0, 1]$:

$$|g(x) - g(x_0)| \leq n|x - x_0| \quad \text{for all } x \in [0, 1].$$

Then for every $x \neq x_0$ in $[0, 1]$ the difference quotient satisfies $\left| \frac{g(x) - g(x_0)}{x - x_0} \right| \leq n$. If $x_0 < 1$, let $x \rightarrow x_0^+$ to get $|D^+g(x_0)| \leq n$; if $x_0 = 1$, let $x \rightarrow 1^-$ to get $|D^-g(1)| \leq n$. Either way we contradict the fact that all one-sided derivatives of g exceed $n + 1$ in absolute value. Hence $g \notin F_n$.

Thus $B(f, r) \not\subseteq F_n$ for every $f \in C[0, 1]$ and every $r > 0$, so $\text{int } F_n = \emptyset$ and F_n is hollow.

Part 3: $C[0, 1] \neq \bigcup_{n=1}^{\infty} F_n$.

The space $C[0, 1]$ is complete, and by Parts 1 and 2 the collection $\{F_n\}_{n=1}^{\infty}$ consists of closed hollow subsets of it. By the Baire Category Theorem, part (ii), the union $\bigcup_{n=1}^{\infty} F_n$ is hollow. But $C[0, 1]$ is not hollow: it is an open subset of itself and it is nonempty, for example the zero function belongs to it, so $\text{int } C[0, 1] = C[0, 1] \neq \emptyset$. Therefore $\bigcup_{n=1}^{\infty} F_n \neq C[0, 1]$, and indeed its complement

$$C[0, 1] \sim \bigcup_{n=1}^{\infty} F_n$$

is dense in $C[0, 1]$, by the equivalence (6) of Section 10.2.

Part 4: such an h is nowhere differentiable on $(0, 1)$.

Let $h \in C[0, 1] \sim \bigcup_{n=1}^{\infty} F_n$ and suppose, for a contradiction, that h is differentiable at some point $x_0 \in (0, 1)$. Since h is continuous on the compact set $[0, 1]$, it is bounded there; put $\|h\|_{\infty} = \max_{[0,1]} |h| < \infty$. By differentiability at x_0 there is $\delta > 0$ such that for all $x \in [0, 1]$ with $0 < |x - x_0| < \delta$,

$$\left| \frac{h(x) - h(x_0)}{x - x_0} - h'(x_0) \right| < 1, \quad \text{hence} \quad |h(x) - h(x_0)| \leq (|h'(x_0)| + 1)|x - x_0|.$$

This last inequality also holds trivially at $x = x_0$. For $x \in [0, 1]$ with $|x - x_0| \geq \delta$ we instead estimate crudely:

$$|h(x) - h(x_0)| \leq 2\|h\|_{\infty} = \frac{2\|h\|_{\infty}}{\delta} \cdot \delta \leq \frac{2\|h\|_{\infty}}{\delta}|x - x_0|.$$

Choose a natural number N with

$$N \geq \max \left\{ |h'(x_0)| + 1, \frac{2\|h\|_{\infty}}{\delta} \right\}.$$

Combining the two cases, $|h(x) - h(x_0)| \leq N|x - x_0|$ for all $x \in [0, 1]$, so $h \in F_N$, contradicting the choice of h .

Therefore h fails to be differentiable at every point of $(0, 1)$. Since by Part 3 the set of such h is a dense subset of $C[0, 1]$, nowhere differentiable continuous functions on $[0, 1]$ are not merely present but typical.

Problem 10.21. Let f be a real-valued function on a metric space X . Show that the set of points at which f is continuous is the intersection of a countable collection of open sets. Conclude that there is not a real-valued function on $\mathbb{R}$ that is continuous just at the rational numbers.

Solution. Let ρ denote the metric on X and let $B(x, \delta)$ denote the open ball of radius δ centered at x .

Part 1: the oscillation of f .

For $x \in X$ and $\delta > 0$ define

$$\omega(x, \delta) = \sup \{ |f(y) - f(z)| : y, z \in B(x, \delta) \} \in [0, \infty],$$

and define the oscillation of f at x by

$$\omega(x) = \inf_{\delta > 0} \omega(x, \delta).$$

Since $\delta \mapsto \omega(x, \delta)$ is nondecreasing, this infimum is also the limit of $\omega(x, \delta)$ as $\delta \rightarrow 0^+$.

Claim: f is continuous at x if and only if $\omega(x) = 0$.

Suppose f is continuous at x and let $\epsilon > 0$. Choose $\delta > 0$ so that $|f(y) - f(x)| < \epsilon/2$ for all $y \in B(x, \delta)$. Then for $y, z \in B(x, \delta)$,

$$|f(y) - f(z)| \leq |f(y) - f(x)| + |f(x) - f(z)| < \epsilon,$$

so $\omega(x, \delta) \leq \epsilon$ and hence $\omega(x) \leq \epsilon$. As $\epsilon > 0$ was arbitrary, $\omega(x) = 0$.

Conversely suppose $\omega(x) = 0$ and let $\epsilon > 0$. Choose $\delta > 0$ with $\omega(x, \delta) < \epsilon$. Since $x \in B(x, \delta)$, for every $y \in B(x, \delta)$ the pair (y, x) is admissible in the supremum, so $|f(y) - f(x)| \leq \omega(x, \delta) < \epsilon$. Hence f is continuous at x . This proves the claim.

Part 2: the continuity set is a countable intersection of open sets.

For each natural number k define

$$\mathcal{O}_k = \{x \in X : \omega(x) < 1/k\}.$$

Each $\mathcal{O}_k$ is open. Indeed, let $x \in \mathcal{O}_k$. Since $\omega(x) < 1/k$, there is $\delta > 0$ with $\omega(x, \delta) < 1/k$. Let $y \in B(x, \delta/2)$. If $u \in B(y, \delta/2)$ then $\rho(u, x) \leq \rho(u, y) + \rho(y, x) < \delta$, so $B(y, \delta/2) \subseteq B(x, \delta)$; consequently the supremum defining $\omega(y, \delta/2)$ is taken over a subcollection of pairs, whence

$$\omega(y) \leq \omega(y, \delta/2) \leq \omega(x, \delta) < 1/k.$$

Thus $B(x, \delta/2) \subseteq \mathcal{O}_k$, and $\mathcal{O}_k$ is open.

Let C denote the set of points at which f is continuous. By Part 1,

$$C = \{x \in X : \omega(x) = 0\} = \bigcap_{k=1}^{\infty} \{x \in X : \omega(x) < 1/k\} = \bigcap_{k=1}^{\infty} \mathcal{O}_k,$$

where the middle equality holds because $\omega(x) \geq 0$ always, so $\omega(x) = 0$ if and only if $\omega(x) < 1/k$ for every k . Hence C is the intersection of a countable collection of open subsets of X , that is, a G_δ set.

Part 3: no real-valued function on $\mathbb{R}$ is continuous exactly at the rationals.

Suppose $f: \mathbb{R} \rightarrow \mathbb{R}$ had continuity set exactly $\mathbb{Q}$. By Part 2 there are open subsets $\mathcal{O}_k$ of $\mathbb{R}$ with

$$\mathbb{Q} = \bigcap_{k=1}^{\infty} \mathcal{O}_k.$$

Each $\mathcal{O}_k$ contains $\mathbb{Q}$ and is therefore dense in $\mathbb{R}$, since $\mathbb{Q}$ is dense in $\mathbb{R}$ and a set containing a dense set is dense.

Enumerate the rationals as $\mathbb{Q} = \{q_j\}_{j=1}^{\infty}$ and put $\mathcal{U}_j = \mathbb{R} \setminus \{q_j\}$. Each $\mathcal{U}_j$ is open, being the complement of the closed set $\{q_j\}$, and each is dense in $\mathbb{R}$: any ball $(x - \epsilon, x + \epsilon)$ contains points other than q_j , for instance one of $x \pm \epsilon/2$.

Now $\{\mathcal{O}_k\}_{k=1}^{\infty} \cup \{\mathcal{U}_j\}_{j=1}^{\infty}$ is a countable collection of open dense subsets of $\mathbb{R}$, and $\mathbb{R}$ is a complete metric space by Theorem 12 of Chapter 9. By the Baire Category Theorem, part (i), the intersection

$$\left(\bigcap_{k=1}^{\infty} \mathcal{O}_k \right) \cap \left(\bigcap_{j=1}^{\infty} \mathcal{U}_j \right)$$

is dense in $\mathbb{R}$. But this intersection equals

$$\mathbb{Q} \cap (\mathbb{R} \setminus \mathbb{Q}) = \emptyset,$$

since $\bigcap_j \mathcal{U}_j = \mathbb{R} \setminus \bigcup_j \{q_j\} = \mathbb{R} \setminus \mathbb{Q}$. The empty set is not dense in $\mathbb{R}$, because $\mathbb{R}$ itself is a nonempty open set containing no point of $\emptyset$. This contradiction shows that no such f exists.

Equivalently: $\mathbb{Q}$ is not a G_δ subset of $\mathbb{R}$, whereas by Part 2 every continuity set is. Note that the reverse phenomenon does occur, since the set of irrationals is a G_δ , and indeed the function equal to $1/q$ at a rational p/q in lowest terms with $q > 0$ and equal to 0 at each irrational is continuous precisely at the irrational numbers.

10.4 Problems 10.22–10.28

Problem 10.22. For each natural number n , show that in $[0, 1]$ there is a nowhere dense closed set that has Lebesgue measure $1 - 1/n$. Use this to construct a set of the first category in $[0, 1]$ that has measure 1.

Solution. Throughout, m denotes Lebesgue measure on $\mathbb{R}$.

Step 1: a closed nowhere dense subset of $[0, 1]$ of large measure.

Let $\{q_k\}_{k=1}^{\infty}$ be an enumeration of the rational numbers in $[0, 1]$. Fix ϵ with $0 < \epsilon < 1$ and define the open set

$$\mathcal{O}_\epsilon = \bigcup_{k=1}^{\infty} \left(q_k - \frac{\epsilon}{2^{k+1}}, q_k + \frac{\epsilon}{2^{k+1}} \right).$$

By the countable subadditivity and the translation-invariance of Lebesgue measure,

$$m(\mathcal{O}_\epsilon) \leq \sum_{k=1}^{\infty} \frac{\epsilon}{2^k} = \epsilon.$$

Put $F_\epsilon = [0, 1] \setminus \mathcal{O}_\epsilon$. Then F_ϵ is closed, being the intersection of $[0, 1]$ with the closed set $\mathbb{R} \setminus \mathcal{O}_\epsilon$, and

by the excision property

$$m(F_\epsilon) \geq m([0, 1]) - m(\mathcal{O}_\epsilon) \geq 1 - \epsilon.$$

Moreover F_ϵ contains no rational number of $[0, 1]$, since every such number lies in $\mathcal{O}_\epsilon$. Hence F_ϵ contains no nonempty open interval, that is, $\text{int } F_\epsilon = \emptyset$: F_ϵ is hollow. Since F_ϵ is closed it equals its own closure, and therefore F_ϵ is nowhere dense in $[0, 1]$ (and in $\mathbb{R}$).

Step 2: adjusting the measure to be exactly $1 - 1/n$.

Fix a natural number n and choose $\epsilon = 1/(2n)$; write $F = F_{1/(2n)}$, so that F is closed, nowhere dense, and

$$m(F) \geq 1 - \frac{1}{2n} > 1 - \frac{1}{n} \quad \text{when } n \geq 2,$$

while for $n = 1$ we only need a closed nowhere dense set of measure 0, and the empty set (or the Cantor set) will do. So assume $n \geq 2$ and define

$$g(c) = m(F \cap [0, c]), \quad c \in [0, 1].$$

For $0 \leq c \leq c' \leq 1$ we have $F \cap [0, c] \subseteq F \cap [0, c']$ and

$$0 \leq g(c') - g(c) = m(F \cap (c, c']) \leq c' - c,$$

by monotonicity and additivity of m ; hence g is (Lipschitz) continuous on $[0, 1]$. Also $g(0) = 0$ and $g(1) = m(F) > 1 - 1/n$. By the Intermediate Value Theorem there is $c \in (0, 1)$ with

$$g(c) = 1 - \frac{1}{n}.$$

Set $E_n = F \cap [0, c]$. Then E_n is closed (an intersection of two closed sets), it is contained in the nowhere dense set F and therefore is itself nowhere dense (its closure, namely E_n , is contained in the hollow set F , hence has empty interior), and $m(E_n) = 1 - 1/n$. This is the required set.

Step 3: a set of the first category in $[0, 1]$ of measure 1.

Let $E = \bigcup_{n=1}^{\infty} E_n$. Being a countable union of nowhere dense subsets of $[0, 1]$, the set E is of the first category in $[0, 1]$. On the other hand, for every n we have $E_n \subseteq E \subseteq [0, 1]$, so by monotonicity

$$1 - \frac{1}{n} = m(E_n) \leq m(E) \leq 1 \quad \text{for all } n.$$

Letting $n \rightarrow \infty$ gives $m(E) = 1$.

Thus E is a subset of $[0, 1]$ of full Lebesgue measure which is nevertheless meager. In particular measure and category are genuinely independent notions: $[0, 1] \sim E$ is residual (its complement in $[0, 1]$ is of the first category), hence dense and, by the Baire Category Theorem applied to the complete metric space $[0, 1]$, nonempty and indeed of the second category, yet it has Lebesgue measure zero.

Problem 10.23. A point x in a metric space X is called isolated provided the singleton set $\{x\}$ is open in X .

- (i) Prove that a complete metric space without isolated points has an uncountable number of points.
- (ii) Use part (i) to prove that $[0, 1]$ is uncountable. Compare this with the proof that $[0, 1]$ is uncountable because it has positive Lebesgue measure.
- (iii) Show that if X is a complete metric space without isolated points and $\{F_n\}_{n=1}^{\infty}$ is a countable collection of closed hollow sets, then $X \sim \bigcup_{n=1}^{\infty} F_n$ is dense and uncountable.

Solution. Throughout we assume, as is implicit in the statement, that X is nonempty; the empty metric space is complete and has no isolated points, and it is of course countable.

- (i) Let X be a nonempty complete metric space with no isolated points, and suppose, to get a contra-

diction, that X is countable. Then we may write

$$X = \bigcup_{n=1}^{\infty} \{x_n\}$$

for some sequence $\{x_n\}$ of points of X (repeating points if X is finite).

Each singleton $\{x_n\}$ is closed: if $y \neq x_n$, the ball $B(y, \rho(y, x_n))$ misses x_n , so $X \sim \{x_n\}$ is open. Each singleton $\{x_n\}$ is also hollow. Indeed, the interior of $\{x_n\}$ is a subset of $\{x_n\}$, hence is either $\emptyset$ or $\{x_n\}$; the latter would say that $\{x_n\}$ is open, that is, that x_n is an isolated point of X , which is excluded by hypothesis. Therefore $\text{int}\{x_n\} = \emptyset$.

So X is the union of a countable collection of closed hollow subsets of the complete metric space X . By part (ii) of the Baire Category Theorem, this union is hollow, that is, $\text{int } X = \emptyset$. But X is open in X , so $\text{int } X = X$, and $X \neq \emptyset$. This contradiction shows that X is uncountable.

(ii) Give $[0, 1]$ the metric inherited from $\mathbb{R}$. It is a complete metric space: $[0, 1]$ is a closed subset of the complete metric space $\mathbb{R}$, and a Cauchy sequence in $[0, 1]$ is Cauchy in $\mathbb{R}$, hence converges in $\mathbb{R}$ to a limit which, $[0, 1]$ being closed, lies in $[0, 1]$.

Moreover $[0, 1]$ has no isolated points. Let $x \in [0, 1]$ and $r > 0$. If $x < 1$, the point $\min\{x + r/2, (x + 1)/2\}$ belongs to $[0, 1]$, differs from x , and lies within r of x ; if $x = 1$, the point $\max\{1 - r/2, 1/2\}$ does the same. Hence no ball about x in $[0, 1]$ reduces to $\{x\}$, so $\{x\}$ is not open. By part (i), $[0, 1]$ is uncountable.

Comparison. The measure-theoretic proof runs as follows: a countable set $C = \{c_k\}$ has $m(C) \leq \sum_k m(\{c_k\}) = 0$ by the countable subadditivity of Lebesgue measure and the fact that singletons are null, whereas $m([0, 1]) = 1 > 0$; therefore $[0, 1]$ is not countable. The two arguments are of quite different character. The measure argument depends on the whole construction of Lebesgue measure on $\mathbb{R}$ and on the normalization $m([0, 1]) = 1$, so it is available only for subsets of Euclidean space; in exchange it gives the sharper information that a countable set is not merely a proper subset of $[0, 1]$ but is null, so that its complement in $[0, 1]$ has full measure. The Baire argument uses nothing but the completeness of the metric and the absence of isolated points, and therefore applies verbatim to $\mathcal{C}[a, b]$, to ℓ^p , to any perfect complete metric space; in exchange it gives only that the space is uncountable. Note also that a countable set can be topologically large: the rationals are dense in $[0, 1]$. What the Baire argument really shows is that a countable subset of such a space is of the first category, and the space itself is not.

(iii) Assume X is a nonempty complete metric space without isolated points and $\{F_n\}_{n=1}^{\infty}$ is a countable collection of closed hollow subsets of X . Put

$$D = X \sim \bigcup_{n=1}^{\infty} F_n = \bigcap_{n=1}^{\infty} (X \sim F_n).$$

Density. For each n , the set $\mathcal{O}_n = X \sim F_n$ is open, since F_n is closed, and it is dense, since by observation (6) of this section a set is hollow if and only if its complement is dense. By part (i) of the Baire Category Theorem, $D = \bigcap_{n=1}^{\infty} \mathcal{O}_n$ is dense in X .

Uncountability. Suppose D were countable, say $D = \bigcup_{k=1}^{\infty} \{y_k\}$. Then

$$X = \left(\bigcup_{n=1}^{\infty} F_n \right) \cup \left(\bigcup_{k=1}^{\infty} \{y_k\} \right)$$

exhibits X as the union of a countable collection of closed sets, each of which is hollow: the F_n by hypothesis, and each $\{y_k\}$ by the argument given in part (i), since X has no isolated points. Part (ii) of the Baire Category Theorem then forces $\text{int } X = \emptyset$, contradicting $\text{int } X = X \neq \emptyset$. Hence D is uncountable.

(If D were empty the same contradiction arises, so in particular D is nonempty; but this is already implied by its density in the nonempty space X .)

Problem 10.24. Let E be a subset of a complete metric space X . Verify the following assertions.

- (i) If $X \sim E$ is dense and F is a closed set contained in E , then F is nowhere dense.
- (ii) If E and $X \sim E$ are both dense, then at most one of them is the union of a countable collection of closed sets.
- (iii) The set of rational numbers in $[0, 1]$ is not the intersection of a countable collection of open sets.

Solution. Throughout, X is a complete metric space, assumed nonempty (all three assertions are vacuous or degenerate otherwise).

(i) Let $X \sim E$ be dense in X and let F be closed with $F \subseteq E$. Since F is closed, $\overline{F} = F$, so to show that F is nowhere dense it suffices to show that F is hollow, that is, $\text{int } F = \emptyset$.

Suppose not. Then there are $x \in X$ and $r > 0$ with $B(x, r) \subseteq F$. The ball $B(x, r)$ is a nonempty open subset of X (it contains x), and since $X \sim E$ is dense in X , every nonempty open subset of X meets $X \sim E$. Hence there is a point $y \in B(x, r) \cap (X \sim E)$. But $B(x, r) \subseteq F \subseteq E$, so $y \in E$, a contradiction. Therefore $\text{int } F = \emptyset$ and F is nowhere dense.

(ii) Suppose both E and $X \sim E$ are dense in X , and suppose, contrary to the assertion, that both are unions of countable collections of closed sets, say

$$E = \bigcup_{n=1}^{\infty} F_n \quad \text{and} \quad X \sim E = \bigcup_{n=1}^{\infty} G_n,$$

with every F_n and every G_n closed in X .

Each F_n is a closed set contained in E , and $X \sim E$ is dense; by part (i), F_n is nowhere dense, i.e. closed and hollow. Symmetrically, each G_n is a closed set contained in $X \sim E$, whose complement E is dense; applying part (i) with E replaced by $X \sim E$ shows that G_n is closed and hollow.

Now

$$X = E \cup (X \sim E) = \left(\bigcup_{n=1}^{\infty} F_n \right) \cup \left(\bigcup_{n=1}^{\infty} G_n \right)$$

displays X as the union of a countable collection of closed hollow subsets of the complete metric space X . By part (ii) of the Baire Category Theorem this union is hollow, so $\text{int } X = \emptyset$. But X is open in itself and nonempty, so $\text{int } X = X \neq \emptyset$. This contradiction proves that at most one of E , $X \sim E$ can be a countable union of closed sets.

(iii) Take $X = [0, 1]$ with the metric inherited from $\mathbb{R}$; as noted in Problem 23, X is a complete metric space, being a closed subset of the complete space $\mathbb{R}$. Let

$$E = \mathbb{Q} \cap [0, 1].$$

Both E and $X \sim E$ (the irrational numbers in $[0, 1]$) are dense in $[0, 1]$: every nondegenerate subinterval of $[0, 1]$ contains both a rational and an irrational number.

The set E is countable, say $E = \{q_1, q_2, \dots\}$, and each singleton $\{q_k\}$ is closed in X ; hence

$$E = \bigcup_{k=1}^{\infty} \{q_k\}$$

is the union of a countable collection of closed sets. By part (ii), therefore, $X \sim E$ is **not** the union of a countable collection of closed sets.

Suppose now that E were the intersection of a countable collection $\{\mathcal{O}_n\}_{n=1}^{\infty}$ of open subsets of $[0, 1]$. Then by De Morgan's Identities

$$X \sim E = X \sim \bigcap_{n=1}^{\infty} \mathcal{O}_n = \bigcup_{n=1}^{\infty} (X \sim \mathcal{O}_n),$$

and each $X \sim \mathcal{O}_n$ is closed in X . This exhibits $X \sim E$ as a countable union of closed sets, contradicting the preceding paragraph. Hence the rationals in $[0, 1]$ are not a countable intersection of open sets.

The same conclusion holds if “open” is understood relative to $\mathbb{R}$: if $E = \bigcap_{n=1}^{\infty} U_n$ with each U_n open in $\mathbb{R}$, then $\mathcal{O}_n = U_n \cap [0, 1]$ is open in $[0, 1]$ and $\bigcap_{n=1}^{\infty} \mathcal{O}_n = E \cap [0, 1] = E$, which we have just shown to be impossible.

Combined with Problem 21, which shows that the set of points of continuity of a real-valued function is always a countable intersection of open sets, this gives again the conclusion that there is no real-valued function on $\mathbb{R}$ continuous exactly at the rational numbers.

Problem 10.25. Show that under the hypotheses of Theorem 6 there is a dense open set $\mathcal{O} \subseteq X$ such that each $x \in \mathcal{O}$ has a neighborhood U on which $\mathcal{F}$ is uniformly bounded.

Solution. The hypotheses of Theorem 6 are: X is a complete metric space and $\mathcal{F}$ is a family of continuous real-valued functions on X that is pointwise bounded, that is, for each $x \in X$ there is a constant M_x with $|f(x)| \leq M_x$ for all $f \in \mathcal{F}$. Theorem 6 produces one nonempty open set on which $\mathcal{F}$ is uniformly bounded; we show that the set of points possessing such a neighborhood is open and dense.

For each natural number n define, as in the proof of Theorem 6,

$$E_n = \{x \in X : |f(x)| \leq n \text{ for all } f \in \mathcal{F}\} = \bigcap_{f \in \mathcal{F}} \{x \in X : |f(x)| \leq n\}.$$

Each function $f \in \mathcal{F}$ is continuous, so each set $\{|f| \leq n\}$ is closed, being the preimage of the closed set $[-n, n]$; an intersection of closed sets is closed, so E_n is closed. Since $\mathcal{F}$ is pointwise bounded, for each $x \in X$ any natural number $n \geq M_x$ satisfies $|f(x)| \leq n$ for all $f \in \mathcal{F}$, so $x \in E_n$. Hence

$$X = \bigcup_{n=1}^{\infty} E_n.$$

Now set

$$\mathcal{O} = \bigcup_{n=1}^{\infty} \text{int } E_n.$$

The set $\mathcal{O}$ is open, being a union of open sets.

$\mathcal{O}$ is dense. Since X is complete and each E_n is closed, Corollary 5 tells us that $\bigcup_{n=1}^{\infty} \text{bd } E_n$ is hollow, and therefore, by the equivalence (6) of this section, its complement

$$D = X \sim \bigcup_{n=1}^{\infty} \text{bd } E_n$$

is dense in X . We claim $D \subseteq \mathcal{O}$. Indeed, let $x \in D$. Since $X = \bigcup_n E_n$, there is an index n with $x \in E_n$. By the decomposition (5),

$$X = \text{int } E_n \cup \text{ext } E_n \cup \text{bd } E_n,$$

and this union is disjoint. Now $\text{ext } E_n$, the set of interior points of $X \sim E_n$, is contained in $X \sim E_n$, so $x \notin \text{ext } E_n$; and $x \notin \text{bd } E_n$ because $x \in D$. Therefore $x \in \text{int } E_n \subseteq \mathcal{O}$. This proves $D \subseteq \mathcal{O}$, and since D is dense so is the larger set $\mathcal{O}$.

Local uniform boundedness on $\mathcal{O}$. Let $x \in \mathcal{O}$. By definition of $\mathcal{O}$ there is an index n with $x \in \text{int } E_n$. Put $U = \text{int } E_n$. Then U is an open set containing x , hence a neighborhood of x , and since $U \subseteq E_n$,

$$|f| \leq n \text{ on } U \text{ for all } f \in \mathcal{F}.$$

Thus $\mathcal{F}$ is uniformly bounded on U , with the single bound $M = n$ serving for every member of $\mathcal{F}$. So $\mathcal{O}$ is a dense open subset of X each of whose points has a neighborhood on which $\mathcal{F}$ is uniformly bounded. (In particular $\mathcal{O}$ is nonempty when X is, which recovers Theorem 6. Note also that $\mathcal{O}$ is precisely the set of points at which $\mathcal{F}$ is locally uniformly bounded: if $\mathcal{F}$ is uniformly bounded by M on an open set $U \ni x$, then for any natural number $n \geq M$ we have $U \subseteq E_n$, so $x \in \text{int } E_n \subseteq \mathcal{O}$.)

Problem 10.26. By Hölder's Inequality, we have $L^2[a, b] \subseteq L^1[a, b]$. Show that the set $L^2[a, b]$, considered as a subset of the complete metric space $L^1[a, b]$, is of the first category.

Solution. Here $a < b$, and $L^1[a, b]$ carries the metric $\rho(f, g) = \|f - g\|_1 = \int_a^b |f - g|$; it is a complete metric space by the Riesz-Fischer Theorem of Chapter 7. The inclusion $L^2[a, b] \subseteq L^1[a, b]$ is Hölder's Inequality with conjugate exponents 2 and 2 applied to $|f| \cdot 1$:

$$\int_a^b |f| \leq \left(\int_a^b |f|^2 \right)^{1/2} (b-a)^{1/2}, \quad \text{i.e.} \quad \|f\|_1 \leq (b-a)^{1/2} \|f\|_2.$$

For each natural number n put

$$E_n = \{f \in L^2[a, b] : \|f\|_2 \leq n\} \subseteq L^1[a, b].$$

Since every $f \in L^2[a, b]$ has $\|f\|_2 < \infty$, we have

$$L^2[a, b] = \bigcup_{n=1}^{\infty} E_n.$$

We show that each E_n is closed and hollow as a subset of $L^1[a, b]$; the Remark of this section then identifies $L^2[a, b]$ as a countable union of nowhere dense subsets of $L^1[a, b]$, that is, as a set of the first category.

Each E_n is closed in $L^1[a, b]$. Let $\{f_k\}$ be a sequence in E_n converging in $L^1[a, b]$ to $f \in L^1[a, b]$. By the Riesz-Fischer Theorem of Chapter 7, a sequence that converges in L^p has a subsequence that converges pointwise almost everywhere to the limit function; choose such a subsequence $\{f_{k_j}\}$, so that $f_{k_j} \rightarrow f$ pointwise a.e. on $[a, b]$. Then $|f_{k_j}|^2 \rightarrow |f|^2$ pointwise a.e., and these are nonnegative measurable functions, so Fatou's Lemma gives

$$\int_a^b |f|^2 \leq \liminf_{j \rightarrow \infty} \int_a^b |f_{k_j}|^2 \leq n^2.$$

Hence $f \in L^2[a, b]$ with $\|f\|_2 \leq n$, that is, $f \in E_n$. A subset of a metric space is closed if and only if it contains the limit of each of its convergent sequences, so E_n is closed in $L^1[a, b]$.

$L^2[a, b]$, and hence each E_n , is hollow in $L^1[a, b]$. Define

$$h(x) = \frac{1}{\sqrt{x-a}} \quad \text{for } a < x \leq b, \quad h(a) = 0.$$

Then h is measurable and nonnegative, and

$$\int_a^b h = \int_a^b \frac{dx}{\sqrt{x-a}} = 2\sqrt{b-a} < \infty,$$

so $h \in L^1[a, b]$, while

$$\int_a^b h^2 = \int_a^b \frac{dx}{x-a} = \infty,$$

so $h \notin L^2[a, b]$. (Both integrals are computed by the Monotone Convergence Theorem from the corresponding integrals over $[a + 1/k, b]$, where the integrands are continuous.)

Now suppose some ball $B(f, r)$ of $L^1[a, b]$ were contained in $L^2[a, b]$. Its center f then belongs to $L^2[a, b]$. Set

$$g = f + \frac{r}{4\sqrt{b-a}} h.$$

Since f and h both lie in $L^1[a, b]$, so does g , and

$$\|g - f\|_1 = \frac{r}{4\sqrt{b-a}} \int_a^b h = \frac{r}{4\sqrt{b-a}} \cdot 2\sqrt{b-a} = \frac{r}{2} < r,$$

so $g \in B(f, r)$ and therefore $g \in L^2[a, b]$. But $L^2[a, b]$ is a linear space, so

$$h = \frac{4\sqrt{b-a}}{r}(g-f)$$

would belong to $L^2[a, b]$, contradicting $\int_a^b h^2 = \infty$. Hence no ball of $L^1[a, b]$ lies in $L^2[a, b]$, that is, $\text{int } L^2[a, b] = \emptyset$ in $L^1[a, b]$, so $L^2[a, b]$ is hollow. The interior operation is monotone, so every subset of a hollow set is hollow; in particular each E_n is hollow.

Since each E_n is closed, $\overline{E_n} = E_n$ is hollow, so each E_n is nowhere dense in $L^1[a, b]$. Therefore

$$L^2[a, b] = \bigcup_{n=1}^{\infty} E_n$$

is the union of a countable collection of nowhere dense subsets of $L^1[a, b]$: it is of the first category. By the Baire Category Theorem, since $L^1[a, b]$ is complete, $L^2[a, b]$ is in particular a hollow subset of $L^1[a, b]$ and its complement $L^1[a, b] \setminus L^2[a, b]$ is dense; “most” integrable functions on $[a, b]$ fail to be square integrable.

Problem 10.27. Let f be a continuous real-valued function on $\mathbb{R}$ with the property that for each real number x , $\lim_{n \rightarrow \infty} f(nx) = 0$. Show that $\lim_{x \rightarrow \infty} f(x) = 0$.

Solution. Here n runs over the natural numbers. We must show: for each $\epsilon > 0$ there is an $R > 0$ such that $|f(x)| \leq \epsilon$ whenever $x \geq R$.

Fix $\epsilon > 0$. Let

$$X = [1, \infty)$$

with the metric inherited from $\mathbb{R}$. Then X is a complete metric space: it is a closed subset of the complete metric space $\mathbb{R}$, so a Cauchy sequence in X converges in $\mathbb{R}$ to a point which necessarily lies in X .

For each natural number n define

$$E_n = \{x \in X : |f(kx)| \leq \epsilon \text{ for every integer } k \geq n\} = \bigcap_{k \geq n} \{x \in X : |f(kx)| \leq \epsilon\}.$$

Each E_n is closed. For a fixed k the map $x \mapsto f(kx)$ is continuous on X , being the composition of the continuous maps $x \mapsto kx$ and f ; hence $\{x \in X : |f(kx)| \leq \epsilon\}$ is closed in X , as the preimage of the closed set $[-\epsilon, \epsilon]$ under a continuous real-valued function. An intersection of closed sets is closed, so E_n is closed in X .

$X = \bigcup_{n=1}^{\infty} E_n$. Let $x \in X$. By hypothesis $\lim_{n \rightarrow \infty} f(nx) = 0$, so there is a natural number n such that $|f(kx)| \leq \epsilon$ for all $k \geq n$; that is, $x \in E_n$.

Since X is a complete metric space and X is the union of the countable collection $\{E_n\}$ of closed sets, Corollary 4 of the Baire Category Theorem provides an index N for which E_N has nonempty interior in X . Thus there are $x_0 \in X$ and $r > 0$ with $B(x_0, r) \cap X \subseteq E_N$. Since $x_0 \geq 1$, the set $B(x_0, r) \cap X$ contains a nondegenerate closed interval $[a, b]$ with $1 \leq a < b$ (for instance $a = \max\{1, x_0 - r/2\}$ and $b = x_0 + r/2$). Hence

$$|f(kx)| \leq \epsilon \quad \text{for all } x \in [a, b] \text{ and all integers } k \geq N. \quad (*)$$

Rewriting $(*)$ in terms of $y = kx$: for each integer $k \geq N$,

$$|f(y)| \leq \epsilon \quad \text{for all } y \in [ka, kb].$$

It remains to observe that these intervals eventually overlap and so cover a half-line. The intervals $[ka, kb]$ and $[(k+1)a, (k+1)b]$ overlap precisely when $(k+1)a \leq kb$, that is, when

$$k(b-a) \geq a, \quad \text{i.e.} \quad k \geq \frac{a}{b-a}.$$

Choose an integer

$$K \geq \max \left\{ N, \frac{a}{b-a} \right\},$$

and set $R = Ka$. If $y \geq R$, then since $ka \rightarrow \infty$ and $Ka \leq y$, there is a largest integer $k \geq K$ with $ka \leq y$. If $y \leq kb$, then $y \in [ka, kb]$. Otherwise $y > kb \geq (k+1)a$ (the last inequality because $k \geq K \geq a/(b-a)$), so $(k+1)a \leq y$, contradicting the maximality of k . Hence in every case y lies in some interval $[ka, kb]$ with $k \geq K \geq N$, and therefore

$$|f(y)| \leq \epsilon \quad \text{for all } y \geq R.$$

Since $\epsilon > 0$ was arbitrary, $\lim_{x \rightarrow \infty} f(x) = 0$.

Two remarks. First, continuity of f was used only to guarantee that the sets E_n are closed, and it cannot be dispensed with. Let $A = \{\pi^m : m \geq 1\}$ and let $f = \chi_A$ be its characteristic function. If $a = \pi^m$ and $a' = \pi^{m'}$ with $m > m'$ are both integer multiples of a fixed real number $x \neq 0$, then $a/a' = \pi^{m-m'}$ would be rational, which is false since π is transcendental. Hence for each $x \neq 0$ there is at most one natural number n with $nx \in A$, so $f(nx) = 0$ for all large n ; and $f(n \cdot 0) = f(0) = 0$ for all n since $0 \notin A$. Thus $\lim_{n \rightarrow \infty} f(nx) = 0$ for every real x , yet $f(\pi^m) = 1$ for every m , so f does not tend to 0 at infinity. Second, the same argument applied to $g(x) = f(-x)$ shows $\lim_{x \rightarrow -\infty} f(x) = 0$ as well, since g is continuous and $\lim_n g(nx) = \lim_n f(n(-x)) = 0$ for each x .

Problem 10.28. Let f be a continuous real-valued function on $\mathbb{R}$ that has derivatives of all orders. Suppose that for each real number x , there is an index $n = n(x)$ for which $f^{(n)}(x) = 0$. Show that f is a polynomial. (Hint: Apply the Baire Category Theorem twice.)

Solution. For each nonnegative integer n set

$$E_n = \{x \in \mathbb{R} : f^{(n)}(x) = 0\}.$$

Each $f^{(n)}$ is continuous (it is differentiable), so each E_n is closed, being the preimage of the closed set $\{0\}$. The hypothesis says precisely that

$$\mathbb{R} = \bigcup_{n=1}^{\infty} E_n. \quad (\text{A})$$

Let $\mathcal{U}$ be the union of all open intervals on which f agrees with some polynomial. Then $\mathcal{U}$ is open, and we must show $\mathcal{U} = \mathbb{R}$ together with the fact that a single polynomial then works globally.

Step 1: on each connected component of $\mathcal{U}$, f is a polynomial.

Let J be a component of $\mathcal{U}$; it is an open interval. Fix $x_0 \in J$. By the definition of $\mathcal{U}$ there is an open interval I_0 with $x_0 \in I_0 \subseteq \mathcal{U}$ and a polynomial p with $f = p$ on I_0 ; being a connected subset of $\mathcal{U}$ meeting J , $I_0 \subseteq J$. Let

$$S = \{x \in J : f^{(k)}(x) = p^{(k)}(x) \text{ for every } k \geq 0\}.$$

S is nonempty ($I_0 \subseteq S$) and closed in J , being an intersection of preimages of $\{0\}$ under the continuous functions $f^{(k)} - p^{(k)}$. S is also open in J : if $x \in S$, choose, by the definition of $\mathcal{U}$, an open interval I_1 with $x \in I_1 \subseteq \mathcal{U}$ and a polynomial q with $f = q$ on I_1 ; then $I_1 \subseteq J$, and $q^{(k)}(x) = f^{(k)}(x) = p^{(k)}(x)$ for all k , so the two polynomials p and q have the same Taylor expansion at x and hence are equal; thus $f = p$ on I_1 and $I_1 \subseteq S$. Since J is connected, $S = J$, that is, $f = p$ on J .

Step 2: the complement of $\mathcal{U}$ has no isolated points.

Let $F = \mathbb{R} \setminus \mathcal{U}$, a closed set. Suppose $x_0 \in F$ were isolated in F , so that for some $\delta > 0$ we have $(x_0 - \delta, x_0 + \delta) \cap F = \{x_0\}$. Then $(x_0 - \delta, x_0)$ and $(x_0, x_0 + \delta)$ are connected subsets of $\mathcal{U}$, hence each lies in a single component of $\mathcal{U}$, and so by Step 1 there are polynomials p and q with $f = p$ on $(x_0 - \delta, x_0)$ and $f = q$ on $(x_0, x_0 + \delta)$. For each k , $f^{(k)} = p^{(k)}$ on $(x_0 - \delta, x_0)$, and both $f^{(k)}$ and $p^{(k)}$ are continuous, so letting $x \rightarrow x_0^-$ gives $f^{(k)}(x_0) = p^{(k)}(x_0)$; similarly $f^{(k)}(x_0) = q^{(k)}(x_0)$. Hence p and q agree with all their derivatives at x_0 , so $p = q$. Consequently $f = p$ on all of $(x_0 - \delta, x_0 + \delta)$, whence $x_0 \in \mathcal{U}$, a contradiction. So F has no isolated points.

Step 3: F is empty.

Suppose not. Then F is a nonempty closed subset of $\mathbb{R}$, hence a complete metric space in the inherited metric, and by Step 2 it has no isolated points. By (A),

$$F = \bigcup_{n=1}^{\infty} (E_n \cap F),$$

and each $E_n \cap F$ is closed in F . By Corollary 4 of the Baire Category Theorem, applied to the complete metric space F , some $E_N \cap F$ has nonempty interior relative to F : there exist $x_1 \in F$ and $r > 0$ such that, writing $I = (x_1 - r, x_1 + r)$,

$$x_1 \in I \cap F \neq \emptyset \quad \text{and} \quad I \cap F \subseteq E_N, \quad \text{i.e.} \quad f^{(N)} = 0 \quad \text{on } I \cap F. \quad (\text{B})$$

We claim that in fact

$$f^{(k)} = 0 \quad \text{on } I \cap F \quad \text{for every } k \geq N. \quad (\text{C})$$

We argue by induction, the case $k = N$ being (B). Suppose $f^{(k)} = 0$ on $I \cap F$ for some $k \geq N$, and let $x \in I \cap F$. By Step 2, x is not isolated in F , so there is a sequence $\{y_j\}$ in F with $y_j \neq x$ and $y_j \rightarrow x$; since I is open we may assume $y_j \in I$, so $y_j \in I \cap F$ and $f^{(k)}(y_j) = 0 = f^{(k)}(x)$. Since $f^{(k+1)}(x)$ exists,

$$f^{(k+1)}(x) = \lim_{j \rightarrow \infty} \frac{f^{(k)}(y_j) - f^{(k)}(x)}{y_j - x} = 0.$$

This proves (C).

Next we show $f^{(N)} = 0$ on all of I . The set $\mathcal{U} \cap I$ is open, so it is the union of a countable disjoint collection of open intervals, its components. Let (a, b) be such a component, and write $I = (\alpha, \beta)$ with $\alpha = x_1 - r$ and $\beta = x_1 + r$, so that $\alpha \leq a < b \leq \beta$. Since $I \cap F \neq \emptyset$ while $(a, b) \subseteq \mathcal{U}$ is disjoint from F , we have $(a, b) \neq I$, so either $a > \alpha$ or $b < \beta$. In the first case $\alpha < a < b \leq \beta$, so the endpoint a lies in I ; in the second case $\alpha \leq a < b < \beta$, so the endpoint b lies in I . Let c denote an endpoint of (a, b) that lies in I . An endpoint of a component of an open set does not belong to that set, so $c \notin \mathcal{U} \cap I$; since $c \in I$, this forces $c \notin \mathcal{U}$, that is, $c \in I \cap F$. Now (a, b) is a connected subset of $\mathcal{U}$, so by Step 1 there is a polynomial p with $f = p$ on (a, b) ; as in Step 2, continuity of the derivatives gives $p^{(k)}(c) = f^{(k)}(c)$ for every k , and by (C) these vanish for every $k \geq N$. Thus the polynomial $p^{(N)}$ satisfies $(p^{(N)})^{(j)}(c) = p^{(N+j)}(c) = 0$ for every $j \geq 0$, so its Taylor expansion about c is identically zero, i.e. $p^{(N)} \equiv 0$. Hence $f^{(N)} = p^{(N)} = 0$ on (a, b) .

Since this holds for every component of $\mathcal{U} \cap I$, we get $f^{(N)} = 0$ on $\mathcal{U} \cap I$; combined with (B), $f^{(N)} = 0$ on $(\mathcal{U} \cap I) \cup (F \cap I) = I$.

But $f^{(N)} \equiv 0$ on the open interval I forces f to be a polynomial of degree at most $N - 1$ there: integrating N times (or applying the Mean Value Theorem repeatedly), $f^{(N-1)}$ is constant on I , then $f^{(N-2)}$ is affine on I , and so on. Hence $I \subseteq \mathcal{U}$, contradicting $I \cap F \neq \emptyset$. This contradiction shows $F = \emptyset$.

Step 4: conclusion.

By Step 3, $\mathcal{U} = \mathbb{R}$. Since $\mathbb{R}$ is connected it is a single component of $\mathcal{U}$, so by Step 1 there is a polynomial p with $f = p$ on $\mathbb{R}$. Thus f is a polynomial.

Remark on the two applications of the Baire Category Theorem. The hint's first application is the direct one: applying Corollary 4 to the decomposition (A) of the complete metric space $\mathbb{R}$ shows that some E_n has nonempty interior, so $f^{(n)}$ vanishes on an open interval and f agrees there with a polynomial; hence $\mathcal{U} \neq \emptyset$. That alone does not finish the argument, because it says nothing about the closed set F where f fails to be locally polynomial. The second application, which is the one carried out in Step 3, is to F itself: F is closed in $\mathbb{R}$, hence a complete metric space in its own right, and Step 2 shows it has no isolated points, so Corollary 4 may be applied to the decomposition of F by the closed sets $E_n \cap F$. The proof given above needs only this second application, since Step 3 derives a contradiction from $F \neq \emptyset$ whether or not $\mathcal{U}$ is known to be nonempty.

10.5 Problems 10.29–10.35

Problem 10.29. Let p be a polynomial. Show that $p: \mathbb{R} \rightarrow \mathbb{R}$ is Lipschitz if and only if the degree of p is less than 2.

Solution. Recall the definition of Section 10.3: a mapping T of a metric space (X, ρ) into itself is Lipschitz provided there is a number $c \geq 0$ for which $\rho(T(u), T(v)) \leq c\rho(u, v)$ for all $u, v \in X$. Here $X = \mathbb{R}$ with the metric $\rho(u, v) = |u - v|$, so the assertion to be proved is that there is a $c \geq 0$ with $|p(u) - p(v)| \leq c|u - v|$ for all real u, v if and only if p has degree 0 or 1 (we include the zero polynomial, whose degree is conventionally $-\infty$ or undefined, among the polynomials of degree less than 2).

Suppose first that the degree of p is less than 2, so that $p(x) = ax + b$ for real numbers a, b . Then for all $u, v \in \mathbb{R}$,

$$|p(u) - p(v)| = |(au + b) - (av + b)| = |a||u - v|,$$

so p is Lipschitz with Lipschitz constant $c = |a|$.

Conversely, suppose p has degree $n \geq 2$, say

$$p(x) = a_n x^n + a_{n-1} x^{n-1} + \cdots + a_1 x + a_0, \quad a_n \neq 0.$$

Define the polynomial

$$q(x) = a_n x^{n-1} + a_{n-1} x^{n-2} + \cdots + a_2 x + a_1,$$

which has degree exactly $n - 1 \geq 1$ since $a_n \neq 0$. Since $p(x) - p(0) = a_n x^n + \cdots + a_1 x = xq(x)$, we have, for every $x \neq 0$,

$$\frac{|p(x) - p(0)|}{|x - 0|} = |q(x)|.$$

Now q is a polynomial of degree at least one, and therefore $|q(x)| \rightarrow \infty$ as $x \rightarrow \infty$: indeed, for $x > 0$,

$$|q(x)| \geq |a_n| x^{n-1} - (|a_{n-1}| x^{n-2} + \cdots + |a_1|) = x^{n-1} \left(|a_n| - \frac{|a_{n-1}|}{x} - \cdots - \frac{|a_1|}{x^{n-1}} \right),$$

and the bracketed quantity converges to $|a_n| > 0$ as $x \rightarrow \infty$ while $x^{n-1} \rightarrow \infty$ (here $n - 1 \geq 1$). Hence $|q(x)|$ is unbounded on $(0, \infty)$.

Therefore, if $c \geq 0$ were a Lipschitz constant for p , then taking $v = 0$ and $u = x > 0$ we would get $|q(x)| = |p(x) - p(0)|/|x| \leq c$ for every $x > 0$, contradicting the unboundedness of $|q|$. So no polynomial of degree $n \geq 2$ is Lipschitz, and the proof is complete.

Problem 10.30. Fix $a > 0$, define $f(x) = ax(1 - x)$ for x in $[0, 1]$.

- (i) For what values of a is $f([0, 1]) \subseteq [0, 1]$?
- (ii) For what values of a is $f([0, 1]) \subseteq [0, 1]$ and $f: [0, 1] \rightarrow [0, 1]$ a contraction?

Solution. (i) For $x \in [0, 1]$ both $x \geq 0$ and $1 - x \geq 0$, so $f(x) = ax(1 - x) \geq 0$; thus $f \geq 0$ on $[0, 1]$ for every $a > 0$. To find the largest value of f on $[0, 1]$, complete the square:

$$f(x) = ax(1 - x) = a \left[\frac{1}{4} - \left(x - \frac{1}{2} \right)^2 \right] \leq \frac{a}{4},$$

with equality exactly at $x = 1/2$. Since f is continuous on the interval $[0, 1]$ and takes the values 0 (at $x = 0$) and $a/4$ (at $x = 1/2$), the Intermediate Value Theorem shows that $f([0, 1]) = [0, a/4]$.

Hence $f([0, 1]) \subseteq [0, 1]$ if and only if $a/4 \leq 1$, that is, if and only if

$$0 < a \leq 4.$$

(ii) A direct computation gives, for $u, v \in [0, 1]$,

$$f(u) - f(v) = a[(u - v) - (u^2 - v^2)] = a(u - v)[1 - (u + v)],$$

so that

$$|f(u) - f(v)| = a|1 - (u + v)||u - v|.$$

For $u, v \in [0, 1]$ we have $0 \leq u + v \leq 2$, hence $-1 \leq 1 - (u + v) \leq 1$ and therefore $|1 - (u + v)| \leq 1$. Consequently

$$|f(u) - f(v)| \leq a|u - v| \quad \text{for all } u, v \in [0, 1],$$

so f is Lipschitz with Lipschitz constant a , and if $a < 1$ then f is a contraction. Moreover $a < 1 < 4$, so by part (i) $f([0, 1]) \subseteq [0, 1]$ as well; thus for $0 < a < 1$ the mapping $f: [0, 1] \rightarrow [0, 1]$ is a well-defined contraction.

Conversely, suppose $a \geq 1$ and suppose, to get a contradiction, that c with $0 \leq c < 1$ is a Lipschitz constant for f . Take $v = 0$ and $u = t$ with $0 < t < 1$. Then by the displayed identity,

$$|f(t) - f(0)| = a(1 - t)t,$$

so the Lipschitz inequality forces $a(1 - t) \leq c$ for every $t \in (0, 1)$. Letting $t \rightarrow 0^+$ gives $a \leq c < 1$, contradicting $a \geq 1$. Hence f is not a contraction when $a \geq 1$.

Therefore f maps $[0, 1]$ into $[0, 1]$ and is a contraction precisely when

$$0 < a < 1.$$

(Observe that for such a , since $[0, 1]$ is a closed subset of the complete metric space $\mathbb{R}$ and hence is itself complete, the Banach Contraction Principle guarantees a unique fixed point; it is $x = 0$, as one checks directly from $ax(1 - x) = x$, whose roots are $x = 0$ and $x = 1 - 1/a < 0$.)

Problem 10.31. Does a mapping of a metric space X into itself that is Lipschitz with Lipschitz constant less than 1 necessarily have a fixed point?

Solution. No. The Banach Contraction Principle requires the metric space to be complete, and without completeness the conclusion fails.

Take $X = (0, 1)$, the open unit interval, regarded as a metric space with the metric $\rho(u, v) = |u - v|$ inherited from $\mathbb{R}$, and define

$$T: X \rightarrow X, \quad T(x) = \frac{x}{2}.$$

This is well defined: if $0 < x < 1$ then $0 < x/2 < 1/2 < 1$, so $T(x) \in X$. It is Lipschitz with Lipschitz constant $1/2 < 1$, since for all $u, v \in X$,

$$\rho(T(u), T(v)) = \left| \frac{u}{2} - \frac{v}{2} \right| = \frac{1}{2}|u - v| = \frac{1}{2}\rho(u, v).$$

Thus T is a contraction. But T has no fixed point in X : the equation $x/2 = x$ has $x = 0$ as its only real solution, and $0 \notin (0, 1)$.

Of course the space $X = (0, 1)$ is not complete: the sequence $\{1/k\}_{k \geq 2}$ lies in X and is Cauchy but fails to converge to a point of X . This is exactly what goes wrong. Following the proof of the Banach Contraction Principle with $x_0 = 1/2$ we obtain the iterates $x_k = 2^{-(k+1)}$, a Cauchy sequence in X whose limit, 0, lies outside X ; the argument has nothing to converge to.

Thus completeness cannot be dropped from the hypotheses of the Banach Contraction Principle. (Uniqueness, however, survives without completeness: the final paragraph of the proof of the Banach Contraction Principle shows that a contraction on any metric space has at most one fixed point.)

Problem 10.32. Does a mapping of a complete metric space into itself that is Lipschitz with Lipschitz constant 1 necessarily have a fixed point?

Solution. No. The hypothesis in the Banach Contraction Principle that the Lipschitz constant be strictly less than 1 cannot be relaxed to allow the constant 1, even for a complete space.

The simplest example: let $X = \mathbb{R}$ with the usual metric $\rho(u, v) = |u - v|$, which is a complete metric

space, and define

$$T: \mathbb{R} \rightarrow \mathbb{R}, \quad T(x) = x + 1.$$

Then for all $u, v \in \mathbb{R}$,

$$\rho(T(u), T(v)) = |(u + 1) - (v + 1)| = |u - v| = \rho(u, v),$$

so T is Lipschitz with Lipschitz constant 1 (and 1 is the smallest such constant). Yet $T(x) = x$ would mean $x + 1 = x$, that is, $1 = 0$, which is impossible; so T has no fixed point.

It is worth noting that the failure is not merely a matter of the inequality $\rho(T(u), T(v)) \leq \rho(u, v)$ being an equality. Even the strict inequality

$$\rho(T(u), T(v)) < \rho(u, v) \quad \text{for all } u \neq v$$

does not force the existence of a fixed point on a complete space: the mapping $f(x) = \pi/2 + x - \arctan x$ of Problem 34 satisfies this strict inequality on the complete space $\mathbb{R}$ and has no fixed point. Compactness of the underlying space, as in Problem 33, is what restores the conclusion under the strict inequality.

Finally, one should observe that when the Lipschitz constant is 1 a fixed point need not be unique either: the identity map on any metric space is Lipschitz with constant 1 and every point is fixed. So both existence and uniqueness break down at $c = 1$.

Problem 10.33. Let X be a compact metric space and T a mapping from X into itself such that

$$\rho(T(u), T(v)) < \rho(u, v) \quad \text{for all } u, v \in X.$$

Show that T has a unique fixed point.

Solution. The displayed inequality is of course to be read for $u \neq v$; for $u = v$ both sides are 0. So the hypothesis is

$$\rho(T(u), T(v)) < \rho(u, v) \quad \text{whenever } u, v \in X \text{ and } u \neq v. \quad (*)$$

Note that T need not be a contraction: there need be no single $c < 1$ that works for all pairs, so the Banach Contraction Principle is not available. We use compactness instead. We also assume X is nonempty (otherwise there is nothing to fix, and the statement is understood for a nonempty space).

Step 1: T is continuous. Indeed, $(*)$ together with the trivial case $u = v$ gives $\rho(T(u), T(v)) \leq \rho(u, v)$ for all $u, v \in X$, so T is Lipschitz with Lipschitz constant 1, and a Lipschitz mapping is continuous: given $u \in X$ and $\epsilon > 0$, take $\delta = \epsilon$; if $\rho(u, v) < \delta$ then $\rho(T(u), T(v)) \leq \rho(u, v) < \epsilon$.

Step 2: The displacement function is continuous. Define

$$g: X \rightarrow \mathbb{R}, \quad g(x) = \rho(x, T(x)).$$

We claim g is continuous. Let $x, y \in X$. By the triangle inequality,

$$\rho(x, T(x)) \leq \rho(x, y) + \rho(y, T(y)) + \rho(T(y), T(x)) \leq \rho(x, y) + \rho(y, T(y)) + \rho(x, y),$$

using Step 1 for the last term; that is, $g(x) - g(y) \leq 2\rho(x, y)$. Interchanging the roles of x and y gives $g(y) - g(x) \leq 2\rho(x, y)$, and hence

$$|g(x) - g(y)| \leq 2\rho(x, y) \quad \text{for all } x, y \in X.$$

So g is Lipschitz, hence continuous.

Step 3: Existence of a fixed point. Since X is a compact metric space and $g: X \rightarrow \mathbb{R}$ is continuous, by the Extreme Value Theorem (Theorem 22 of Chapter 9) g takes a minimum value on X : there is a point $x_* \in X$ with

$$g(x_*) \leq g(x) \quad \text{for all } x \in X.$$

Suppose, to get a contradiction, that $T(x_*) \neq x_*$. Apply (*) with $u = x_*$ and $v = T(x_*)$, which are distinct:

$$g(T(x_*)) = \rho(T(x_*), T(T(x_*))) < \rho(x_*, T(x_*)) = g(x_*).$$

Since $T(x_*)$ is a point of X , this contradicts the minimality of $g(x_*)$. Therefore $T(x_*) = x_*$, and T has a fixed point.

Step 4: Uniqueness. Suppose u and v are fixed points of T with $u \neq v$. Then by (*),

$$\rho(u, v) = \rho(T(u), T(v)) < \rho(u, v),$$

which is absurd. Hence $u = v$, and the fixed point is unique.

Two remarks. First, compactness is essential and cannot be weakened to completeness: Problem 34 exhibits a mapping of the complete space $\mathbb{R}$ into itself satisfying (*) which has no fixed point. Second, as in the Banach Contraction Principle, the fixed point may be found by iteration: since $g(T(x)) < g(x)$ unless x is fixed, the sequence $\{g(T^k(x_0))\}$ is decreasing for any starting point x_0 ; but the argument above via the Extreme Value Theorem is the cleanest route to existence.

Problem 10.34. Define $f(x) = \pi/2 + x - \arctan x$ for all real numbers x . Show that

$$|f(u) - f(v)| < |u - v| \quad \text{for all } u, v \in \mathbb{R}.$$

Show that f does not have a fixed point. Does this contradict the preceding problem?

Solution. As in the preceding problem, the strict inequality is asserted for $u \neq v$.

Step 1: the strict inequality. The function $\arctan$ is differentiable on all of $\mathbb{R}$ with $\arctan'(x) = 1/(1+x^2)$, so f is differentiable on $\mathbb{R}$ and

$$f'(x) = 1 - \frac{1}{1+x^2} = \frac{x^2}{1+x^2} \quad \text{for all } x \in \mathbb{R}.$$

Since $x^2 < 1+x^2$ and $x^2 \geq 0$, we have

$$0 \leq f'(x) < 1 \quad \text{for all } x \in \mathbb{R}. \quad (1)$$

Now let $u, v \in \mathbb{R}$ with $u \neq v$; say $v < u$. The function f is continuous on $[v, u]$ and differentiable on (v, u) , so by the Mean Value Theorem there is a point $\xi \in (v, u)$ with

$$f(u) - f(v) = f'(\xi)(u - v).$$

Taking absolute values and using (1),

$$|f(u) - f(v)| = |f'(\xi)| |u - v| = f'(\xi) |u - v| < 1 \cdot |u - v| = |u - v|,$$

the strict inequality being legitimate because $|u - v| > 0$ and $f'(\xi) < 1$. Hence $|f(u) - f(v)| < |u - v|$ for all $u \neq v$, as required. (Note also that from (1) and the Mean Value Theorem, $|f(u) - f(v)| \leq |u - v|$ for all u, v , so f is Lipschitz with Lipschitz constant 1; but f is not a contraction, since $\sup_x f'(x) = \lim_{x \rightarrow \infty} x^2/(1+x^2) = 1$, so no constant $c < 1$ works: choosing x large and applying the Mean Value Theorem on $[x, x+1]$ gives $|f(x+1) - f(x)| = f'(\xi_x)$ with $\xi_x > x$, and $f'(\xi_x) \rightarrow 1$.)

Step 2: no fixed point. Suppose $f(x) = x$ for some real x . Then

$$\frac{\pi}{2} + x - \arctan x = x, \quad \text{that is,} \quad \arctan x = \frac{\pi}{2}.$$

But the range of $\arctan$ is the open interval $(-\pi/2, \pi/2)$, so $\arctan x < \pi/2$ for every real x . This is a contradiction, so f has no fixed point. Equivalently: $f(x) - x = \pi/2 - \arctan x > 0$ for every $x \in \mathbb{R}$, so $f(x) > x$ always.

Step 3: no contradiction with Problem 33. Problem 33 assumes that X is a compact metric space. Here $X = \mathbb{R}$ with the usual metric, and $\mathbb{R}$ is not compact: it is not bounded, and by Theorem 22 of Chapter

9 it is not compact since, for instance, the continuous function $x \mapsto x$ on $\mathbb{R}$ takes neither a maximum nor a minimum value. Equivalently, $\mathbb{R}$ is not sequentially compact, since the sequence $\{k\}_{k \in \mathbb{N}}$ has no convergent subsequence. So the hypotheses of Problem 33 are not satisfied and no contradiction arises. The example shows precisely where the argument of Problem 33 breaks down without compactness. The displacement function there is

$$g(x) = |f(x) - x| = \frac{\pi}{2} - \arctan x,$$

which is continuous and strictly positive, with $\inf_{x \in \mathbb{R}} g(x) = \lim_{x \rightarrow \infty} (\pi/2 - \arctan x) = 0$. Thus g has infimum 0 but never attains it: the minimizing point that compactness would have supplied has “escaped to infinity”. It also shows, as noted in Problem 32, that on a merely complete space the strict inequality $|f(u) - f(v)| < |u - v|$ is not enough to produce a fixed point.

Problem 10.35. In Euclidean space $\mathbb{R}^n$ consider the closed unit ball $B = \{x \in \mathbb{R}^n \mid \|x\| \leq 1\}$. Let f map B into B and be Lipschitz with Lipschitz constant 1. Without using the Brouwer Fixed Point Theorem, show that f has a fixed point.

Solution. Throughout, B carries the Euclidean metric $\rho(u, v) = \|u - v\|$, and the hypothesis on $f: B \rightarrow B$ is

$$\|f(u) - f(v)\| \leq \|u - v\| \quad \text{for all } u, v \in B. \quad (1)$$

In particular f is continuous. Note that (1) alone does not make f a contraction (the identity map satisfies (1)), so the Banach Contraction Principle does not apply directly. The idea is to shrink f slightly so as to produce genuine contractions, apply the Banach Contraction Principle to each, and then pass to the limit using compactness of B .

Step 1: B is a compact, complete metric space. The set B is bounded, and it is closed in $\mathbb{R}^n$, being the preimage of the closed set $(-\infty, 1]$ under the continuous function $x \mapsto \|x\|$. Hence by Theorem 20 of Chapter 9 (the Heine-Borel and Bolzano-Weierstrass Theorems), B is compact and sequentially compact. Moreover B is complete as a metric space: if $\{y_k\}$ is a Cauchy sequence in B , then it is Cauchy in the complete space $\mathbb{R}^n$, so it converges to some $y \in \mathbb{R}^n$, and since B is closed, $y \in B$; thus $\{y_k\}$ converges in B .

Step 2: for each $t \in (0, 1)$ the map $f_t = tf$ is a contraction of B into B . Fix t with $0 < t < 1$ and define

$$f_t: B \rightarrow \mathbb{R}^n, \quad f_t(x) = tf(x).$$

Since $f(x) \in B$ we have $\|f(x)\| \leq 1$, so $\|f_t(x)\| = t\|f(x)\| \leq t < 1$; hence $f_t(B) \subseteq B$ and f_t maps B into itself. Furthermore, by (1), for all $u, v \in B$,

$$\|f_t(u) - f_t(v)\| = t\|f(u) - f(v)\| \leq t\|u - v\|,$$

so f_t is Lipschitz with Lipschitz constant $t < 1$; that is, $f_t: B \rightarrow B$ is a contraction.

Step 3: apply the Banach Contraction Principle. By Step 1, B is a complete metric space, and by Step 2, $f_t: B \rightarrow B$ is a contraction. Hence, by the Banach Contraction Principle, f_t has exactly one fixed point; call it $x_t \in B$, so that

$$x_t = tf(x_t). \quad (2)$$

Step 4: let $t \rightarrow 1$ and use compactness. For each natural number $k \geq 2$ put $t_k = 1 - 1/k \in (0, 1)$ and let $x_k := x_{t_k} \in B$ be the corresponding fixed point given by Step 3. From (2),

$$\|x_k - f(x_k)\| = \|t_k f(x_k) - f(x_k)\| = (1 - t_k)\|f(x_k)\| \leq 1 - t_k = \frac{1}{k},$$

where we used $\|f(x_k)\| \leq 1$. Hence

$$\lim_{k \rightarrow \infty} \|x_k - f(x_k)\| = 0. \quad (3)$$

By Step 1 the space B is sequentially compact, so there is a subsequence $\{x_{k_j}\}$ converging to some point $x_* \in B$.

Step 5: conclude. The function $h: B \rightarrow \mathbb{R}$ defined by $h(x) = \|x - f(x)\|$ is continuous, since f is continuous by (1) and the norm is continuous. Therefore

$$\|x_* - f(x_*)\| = h(x_*) = \lim_{j \rightarrow \infty} h(x_{k_j}) = \lim_{j \rightarrow \infty} \|x_{k_j} - f(x_{k_j})\| = 0,$$

the last equality by (3), since $\{\|x_{k_j} - f(x_{k_j})\|\}$ is a subsequence of a sequence converging to 0. Hence $x_* = f(x_*)$, and x_* is a fixed point of f lying in B .

Two remarks. First, only three features of B were used: that B is compact, hence complete; that B is bounded; and that $ty \in B$ whenever $y \in B$ and $0 < t < 1$. Consequently the same argument proves that every nonexpansive self-map of a compact convex subset of $\mathbb{R}^n$ containing the origin has a fixed point. Second, the fixed point need not be unique here: the identity map on B satisfies the hypotheses and fixes every point of B . In fact the set of fixed points is exactly the zero set of the continuous function h above, hence is a closed, and therefore compact, nonempty subset of B .

10.6 Problems 10.36–10.42

Problem 10.36. Suppose that the mapping $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a contraction. Define $g(x) = x - f(x)$ for all x in $\mathbb{R}^n$. Show that the mapping $g: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is both one-to-one and onto. Also show that g and its inverse are continuous.

Solution. Recall that f being a contraction means that f is Lipschitz with a Lipschitz constant c satisfying $0 \leq c < 1$; that is,

$$\|f(u) - f(v)\| \leq c \|u - v\| \quad \text{for all } u, v \in \mathbb{R}^n.$$

Throughout, $\|\cdot\|$ denotes the Euclidean norm and $\rho(u, v) = \|u - v\|$ the Euclidean metric, with respect to which $\mathbb{R}^n$ is a complete metric space.

The key two-sided estimate. Let $u, v \in \mathbb{R}^n$. Since $g(u) - g(v) = (u - v) - (f(u) - f(v))$, the triangle inequality gives, on the one hand,

$$\|g(u) - g(v)\| \leq \|u - v\| + \|f(u) - f(v)\| \leq (1 + c) \|u - v\|,$$

and, on the other hand, using the reverse triangle inequality $\|a - b\| \geq \|a\| - \|b\|$ with $a = u - v$ and $b = f(u) - f(v)$,

$$\|g(u) - g(v)\| \geq \|u - v\| - \|f(u) - f(v)\| \geq \|u - v\| - c \|u - v\| = (1 - c) \|u - v\|.$$

Thus

$$(1 - c) \|u - v\| \leq \|g(u) - g(v)\| \leq (1 + c) \|u - v\| \quad \text{for all } u, v \in \mathbb{R}^n.$$

One-to-one. Suppose $g(u) = g(v)$. The left-hand inequality above gives $(1 - c)\|u - v\| \leq 0$. Since $1 - c > 0$, we conclude $\|u - v\| = 0$, that is, $u = v$. Hence g is one-to-one.

Onto. Let $z \in \mathbb{R}^n$ be arbitrary. We must produce a point x with $g(x) = z$, that is, with $x - f(x) = z$, equivalently

$$x = f(x) + z.$$

So define the mapping $T_z: \mathbb{R}^n \rightarrow \mathbb{R}^n$ by $T_z(x) = f(x) + z$. For $u, v \in \mathbb{R}^n$,

$$\|T_z(u) - T_z(v)\| = \|f(u) - f(v)\| \leq c \|u - v\|,$$

so T_z is Lipschitz with Lipschitz constant $c < 1$, that is, T_z is a contraction of the complete metric space $\mathbb{R}^n$ into itself. By the Banach Contraction Principle, T_z has a (unique) fixed point $x_z \in \mathbb{R}^n$. For this point, $x_z = f(x_z) + z$, that is, $g(x_z) = x_z - f(x_z) = z$. Since z was arbitrary, g is onto.

Consequently $g: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is a bijection and possesses an inverse $g^{-1}: \mathbb{R}^n \rightarrow \mathbb{R}^n$.

Continuity of g . The right-hand inequality above says that g is Lipschitz with Lipschitz constant $1 + c$. A Lipschitz mapping is continuous: given $\varepsilon > 0$, take $\delta = \varepsilon/(1 + c)$; then $\|u - v\| < \delta$ forces $\|g(u) - g(v)\| \leq (1 + c)\|u - v\| < \varepsilon$.

Continuity of g^{-1} . Let $z, w \in \mathbb{R}^n$ and put $u = g^{-1}(z)$, $v = g^{-1}(w)$, so that $g(u) = z$ and $g(v) = w$. The left-hand inequality above gives

$$\|z - w\| = \|g(u) - g(v)\| \geq (1 - c) \|u - v\| = (1 - c) \|g^{-1}(z) - g^{-1}(w)\|.$$

Since $1 - c > 0$, we may divide to obtain

$$\|g^{-1}(z) - g^{-1}(w)\| \leq \frac{1}{1 - c} \|z - w\| \quad \text{for all } z, w \in \mathbb{R}^n.$$

Thus g^{-1} is Lipschitz with Lipschitz constant $1/(1 - c)$ and hence, as above, continuous.

Therefore g is a bijection of $\mathbb{R}^n$ onto $\mathbb{R}^n$ and both g and g^{-1} are continuous (indeed Lipschitz); that is, g is a homeomorphism of $\mathbb{R}^n$ onto itself.

Problem 10.37. Let X be a complete metric space containing the point x_0 and let r be a positive real number. Define $K = \{x \in X \mid \rho(x, x_0) \leq r\}$. Suppose that the mapping $T: K \rightarrow X$ is Lipschitz with Lipschitz constant c . Suppose also that $cr + \rho(T(x_0), x_0) \leq r$. Prove that $T(K) \subseteq K$ and that $T: K \rightarrow X$ has a fixed point.

Solution. Write $d = \rho(T(x_0), x_0)$, so that the hypothesis reads $cr + d \leq r$. Observe first that $x_0 \in K$, since $\rho(x_0, x_0) = 0 \leq r$, so the number d is defined. Note also that $c \geq 0$ and $d \geq 0$.

Proof that $T(K) \subseteq K$. Let $x \in K$, so $\rho(x, x_0) \leq r$. Since x and x_0 both lie in K , the Lipschitz property of T applies to the pair x, x_0 , and the triangle inequality gives

$$\rho(T(x), x_0) \leq \rho(T(x), T(x_0)) + \rho(T(x_0), x_0) \leq c\rho(x, x_0) + d \leq cr + d \leq r.$$

Hence $T(x) \in K$. Since $x \in K$ was arbitrary, $T(K) \subseteq K$.

Consequently T may be regarded as a mapping of K into K , and it is Lipschitz with Lipschitz constant c as a mapping $T: K \rightarrow K$.

Proof that T has a fixed point. There are two cases.

Case 1: $d = 0$. Then $\rho(T(x_0), x_0) = 0$, so $T(x_0) = x_0$ and x_0 is a fixed point of T . (Here nothing further is needed.)

Case 2: $d > 0$. From $cr + d \leq r$ we get $cr \leq r - d < r$, and since $r > 0$ we may divide by r to conclude that

$$c \leq 1 - \frac{d}{r} < 1.$$

Thus $0 \leq c < 1$, that is, $T: K \rightarrow K$ is a contraction.

It remains to check that K , with the metric inherited from X , is a complete metric space. The function $x \mapsto \rho(x, x_0)$ is continuous on X (indeed, by the triangle inequality, $|\rho(x, x_0) - \rho(y, x_0)| \leq \rho(x, y)$, so it is Lipschitz), and K is the inverse image of the closed set $(-\infty, r]$ under this continuous function; hence K is a closed subset of X . Since X is complete, Proposition 11 of Chapter 9 tells us that the metric subspace K is complete. Moreover K is nonempty, since $x_0 \in K$.

Therefore $T: K \rightarrow K$ is a contraction of the nonempty complete metric space K into itself, and the Banach Contraction Principle provides a point $x_* \in K$ with $T(x_*) = x_*$; indeed this fixed point is the unique one in K .

In either case T has a fixed point in K , which is what was to be proved.

Remark. In Case 2 the proof of the Banach Contraction Principle also gives the estimate $\rho(x_*, x_k) \leq \frac{c^k}{1-c} \rho(T(x_0), x_0)$ for every natural number k , where $x_1 = T(x_0)$ and $x_{k+1} = T(x_k)$. Taking $k = 1$ and using the triangle inequality, $\rho(x_*, x_0) \leq \rho(x_*, x_1) + \rho(x_1, x_0) \leq \frac{c}{1-c} d + d = \frac{d}{1-c}$, and the hypothesis $cr + d \leq r$ says exactly that $d \leq (1 - c)r$, so $\rho(x_*, x_0) \leq r$. This is an independent confirmation that the fixed point lies in K .

Problem 10.38. Show that if the function $g: \mathbb{R}^2 \rightarrow \mathbb{R}$ has continuous first-order partial derivatives, then for each point (x_0, y_0) in $\mathbb{R}^2$ there is a neighborhood $\mathcal{O}$ of (x_0, y_0) on which the Lipschitz assumption (16) holds.

Solution. Recall that assumption (16) is the requirement that there be a positive number M for which

$$|g(x, y_1) - g(x, y_2)| \leq M |y_1 - y_2| \quad \text{for all points } (x, y_1) \text{ and } (x, y_2) \text{ in } \mathcal{O}.$$

Fix $(x_0, y_0) \in \mathbb{R}^2$ and define the open rectangle

$$\mathcal{O} = (x_0 - 1, x_0 + 1) \times (y_0 - 1, y_0 + 1),$$

which is an open neighborhood of (x_0, y_0) , and let R be its closure,

$$R = [x_0 - 1, x_0 + 1] \times [y_0 - 1, y_0 + 1].$$

Boundedness of the y -partial on R . By hypothesis the partial derivative $\partial g / \partial y$ exists at every point of $\mathbb{R}^2$ and is continuous there. The set R is closed and bounded in $\mathbb{R}^2$, hence compact by Theorem 20 of Chapter 9. By the Extreme Value Theorem, Theorem 22 of Chapter 9, a continuous real-valued function on a compact metric space is bounded and attains its extreme values, so

$$M := 1 + \max_{(x,y) \in R} \left| \frac{\partial g}{\partial y}(x, y) \right|$$

is a well-defined real number, and clearly $M > 0$ and

$$\left| \frac{\partial g}{\partial y}(x, y) \right| \leq M \quad \text{for all } (x, y) \in R \supseteq \mathcal{O}.$$

Verification of (16) on $\mathcal{O}$. Let (x, y_1) and (x, y_2) be two points of $\mathcal{O}$ with the same first coordinate. If $y_1 = y_2$ the desired inequality is trivial, so assume $y_1 \neq y_2$; without loss of generality $y_1 < y_2$. Consider the function of one real variable

$$\varphi(t) = g(x, t), \quad t \in [y_1, y_2].$$

Since $\partial g / \partial y$ exists everywhere, φ is differentiable on all of $\mathbb{R}$ with $\varphi'(t) = \frac{\partial g}{\partial y}(x, t)$; in particular φ is continuous on $[y_1, y_2]$ and differentiable on (y_1, y_2) . By the Mean Value Theorem there is a point ξ with $y_1 < \xi < y_2$ for which

$$g(x, y_2) - g(x, y_1) = \varphi(y_2) - \varphi(y_1) = \varphi'(\xi)(y_2 - y_1) = \frac{\partial g}{\partial y}(x, \xi)(y_2 - y_1).$$

Now $x \in (x_0 - 1, x_0 + 1)$, and ξ lies strictly between y_1 and y_2 , both of which belong to $(y_0 - 1, y_0 + 1)$; since that interval is convex, $\xi \in (y_0 - 1, y_0 + 1)$. Hence $(x, \xi) \in \mathcal{O} \subseteq R$, and therefore

$$|g(x, y_1) - g(x, y_2)| = \left| \frac{\partial g}{\partial y}(x, \xi) \right| |y_2 - y_1| \leq M |y_1 - y_2|.$$

Since (x, y_1) and (x, y_2) were arbitrary points of $\mathcal{O}$ with a common first coordinate, the Lipschitz assumption (16) holds on $\mathcal{O}$ with the positive constant M .

Remark. The point of choosing $\mathcal{O}$ to be a rectangle (rather than an arbitrary neighborhood) is exactly that the vertical segment joining two of its points with the same first coordinate remains inside $\mathcal{O}$, which is what allows the Mean Value Theorem to be applied without leaving the set. Any convex bounded neighborhood would do equally well. We also note that a function with continuous first-order partial derivatives on $\mathbb{R}^2$ is continuous, so g satisfies both hypotheses of the Picard Local Existence Theorem on $\mathcal{O}$; consequently the initial value problem (14) with initial data (x_0, y_0) has a unique solution on some open interval about x_0 .

Problem 10.39. In case the function $g: \mathcal{O} \rightarrow \mathbb{R}$ has the form $g(x, y) = h(x) + by$, where the function $h: \mathbb{R} \rightarrow \mathbb{R}$ is continuous, prove that the following is an explicit formula for the solution of (14):

$$f(x) = e^{b(x-x_0)}y_0 + \int_{x_0}^x e^{b(x-t)}h(t) dt \quad \text{for all } x \text{ in } I.$$

Solution. Here (14) is the initial value problem

$$\begin{aligned} f'(x) &= g(x, f(x)) = h(x) + bf(x) \quad \text{for all } x \in I, \\ f(x_0) &= y_0, \end{aligned}$$

where $\mathcal{O}$ is an open subset of $\mathbb{R}^2$ containing (x_0, y_0) and I is an open interval containing x_0 . Recall that, as the text requires, a solution of (14) is a differentiable $f: I \rightarrow \mathbb{R}$ whose graph lies in $\mathcal{O}$, that is, $(x, f(x)) \in \mathcal{O}$ for all $x \in I$, and which satisfies $f'(x) = g(x, f(x))$ on I together with $f(x_0) = y_0$. We prove two things: the displayed formula defines a function f that solves (14) on every open interval I containing x_0 over which the graph of f lies in $\mathcal{O}$, and at least one such interval exists; and every solution of (14) on any open interval I containing x_0 agrees with f there.

Note that the formula itself makes sense for every real x , since the expression $h(x) + by$ is defined for all (x, y) ; the set $\mathcal{O}$ enters only through the requirement that the graph lie in $\mathcal{O}$.

A convenient rewriting. Since h is continuous on $\mathbb{R}$, so is the function $t \mapsto e^{-bt}h(t)$. Define

$$F(x) = \int_{x_0}^x e^{-bt}h(t) dt \quad \text{for } x \in \mathbb{R}.$$

Pulling the factor e^{bx} , which does not depend on the variable of integration, outside the integral, the displayed formula reads

$$f(x) = e^{bx} \left[e^{-bx_0}y_0 + F(x) \right].$$

The formula defines a solution. Because $t \mapsto e^{-bt}h(t)$ is continuous, the Fundamental Theorem of Differential Calculus, invoked in the text just before (15) for exactly this purpose, asserts that F is differentiable at every x with

$$F'(x) = e^{-bx}h(x).$$

Hence f , being a product of the differentiable functions $x \mapsto e^{bx}$ and $x \mapsto e^{-bx_0}y_0 + F(x)$, is differentiable, and by the product rule

$$f'(x) = b e^{bx} \left[e^{-bx_0}y_0 + F(x) \right] + e^{bx} F'(x) = b f(x) + e^{bx} e^{-bx} h(x) = b f(x) + h(x).$$

That is, $f'(x) = g(x, f(x))$ for all x . Moreover $F(x_0) = 0$, so

$$f(x_0) = e^{bx_0} \cdot e^{-bx_0}y_0 = y_0.$$

Thus f satisfies the differential equation and the initial condition on all of $\mathbb{R}$, and hence on any open interval I containing x_0 .

There is an interval about x_0 over which the graph of f lies in $\mathcal{O}$. Indeed, f is differentiable, hence continuous, so the mapping $x \mapsto (x, f(x))$ of $\mathbb{R}$ into $\mathbb{R}^2$ is continuous; since $\mathcal{O}$ is open and contains $(x_0, f(x_0)) = (x_0, y_0)$, the inverse image of $\mathcal{O}$ under this mapping is an open subset of $\mathbb{R}$ containing x_0 , and therefore contains an open interval I about x_0 . On any such I the function f is a solution of (14). In particular, if $\mathcal{O} = \mathbb{R}^2$ we may take $I = \mathbb{R}$.

The solution is unique. Let I be an open interval containing x_0 and let $u: I \rightarrow \mathbb{R}$ be any solution of (14), so u is differentiable on I , $u'(x) = h(x) + bu(x)$ for $x \in I$, and $u(x_0) = y_0$. Introduce the integrating factor and set

$$w(x) = e^{-bx}u(x) \quad \text{for } x \in I.$$

Then w is differentiable on I and

$$w'(x) = -be^{-bx}u(x) + e^{-bx}u'(x) = e^{-bx}[u'(x) - bu(x)] = e^{-bx}h(x).$$

The function w' is therefore continuous on I . Fix $x \in I$ and let J denote the closed, bounded interval with endpoints x_0 and x ; since I is an interval containing both points, $J \subseteq I$. On J the derivative w' is continuous, hence bounded, so by the Mean Value Theorem w is Lipschitz on J and therefore absolutely continuous on J . Theorem 10 of Chapter 6 now gives

$$w(x) - w(x_0) = \int_{x_0}^x w'(t) dt = \int_{x_0}^x e^{-bt} h(t) dt = F(x).$$

(For $x < x_0$ this is the same identity read with the orientation of the interval reversed, the integral $\int_{x_0}^x$ being by convention $-\int_x^{x_0}$.) Since $w(x_0) = e^{-bx_0} u(x_0) = e^{-bx_0} y_0$, we obtain

$$e^{-bx} u(x) = e^{-bx_0} y_0 + F(x),$$

and multiplying through by e^{bx} gives

$$u(x) = e^{b(x-x_0)} y_0 + \int_{x_0}^x e^{b(x-t)} h(t) dt \quad \text{for all } x \in I,$$

which is precisely the displayed formula. Hence every solution of (14) on I coincides with f , and the formula is an explicit formula for the (unique) solution of (14).

Remark. Uniqueness is consistent with the Picard Local Existence Theorem: here $|g(x, y_1) - g(x, y_2)| = |b| |y_1 - y_2|$, so the Lipschitz assumption (16) holds on all of $\mathbb{R}^2$ with $M = |b| + 1$. The integrating-factor argument above, however, gives uniqueness on the whole of I , not merely on a small interval about x_0 , and it exhibits the solution in closed form.

Problem 10.40. Consider the differential equation

$$\begin{aligned} f'(x) &= 3[f(x)]^{2/3} \quad \text{for all } x \in \mathbb{R} \\ f(0) &= 0. \end{aligned}$$

Show that the function $f: \mathbb{R} \rightarrow \mathbb{R}$ that is identically 0 is a solution and the function $f: \mathbb{R} \rightarrow \mathbb{R}$ defined by $f(x) = 0$, if $x < 0$ and $f(x) = x^3$, if $x \geq 0$, is also a solution. Does this contradict the Picard Existence Theorem?

Solution. Here $g(x, y) = 3y^{2/3}$, where $y^{2/3}$ means $(y^{1/3})^2 = |y|^{2/3}$, the real cube root being used; thus g is defined and continuous on all of $\mathbb{R}^2$, and we may take $\mathcal{O} = \mathbb{R}^2$, $(x_0, y_0) = (0, 0)$.

The zero function is a solution. If $f_1(x) = 0$ for all x , then f_1 is differentiable with $f_1'(x) = 0$, while $3[f_1(x)]^{2/3} = 3 \cdot 0^{2/3} = 0$. Hence $f_1'(x) = 3[f_1(x)]^{2/3}$ for all $x \in \mathbb{R}$, and $f_1(0) = 0$. So f_1 solves the initial value problem on $I = \mathbb{R}$.

The second function is also a solution. Define

$$f_2(x) = \begin{cases} 0, & x < 0, \\ x^3, & x \geq 0. \end{cases}$$

We check differentiability and the equation at each point.

For $x < 0$: on the open interval $(-\infty, 0)$ the function f_2 is identically 0, so $f_2'(x) = 0$, and $3[f_2(x)]^{2/3} = 0$. The equation holds.

For $x > 0$: on the open interval $(0, \infty)$ we have $f_2(x) = x^3$, so $f_2'(x) = 3x^2$, while

$$3[f_2(x)]^{2/3} = 3(x^3)^{2/3} = 3x^2 \quad (x > 0).$$

The equation holds.

At $x = 0$: we compute the difference quotient directly. For $t > 0$,

$$\frac{f_2(t) - f_2(0)}{t - 0} = \frac{t^3}{t} = t^2 \xrightarrow{t \rightarrow 0^+} 0,$$

and for $t < 0$,

$$\frac{f_2(t) - f_2(0)}{t - 0} = \frac{0}{t} = 0 \xrightarrow{t \rightarrow 0^-} 0.$$

Both one-sided limits exist and equal 0, so f_2 is differentiable at 0 with $f_2'(0) = 0$; and $3[f_2(0)]^{2/3} = 3 \cdot 0 = 0$. The equation holds at 0 as well.

Finally $f_2(0) = 0$. Hence f_2 is a solution of the initial value problem on $I = \mathbb{R}$, and $f_2 \neq f_1$ since $f_2(1) = 1 \neq 0 = f_1(1)$. So the initial value problem has (at least) two distinct solutions on every open interval containing 0: indeed, restricted to any open interval I containing 0, f_1 and f_2 remain distinct solutions, because every such I contains points $x > 0$, at which $f_2(x) = x^3 \neq 0$.

Is this a contradiction? No. The Picard Local Existence Theorem asserts existence and uniqueness of a solution on some open interval containing x_0 under two hypotheses: that g be continuous on $\mathcal{O}$, and that the Lipschitz assumption (16) hold, that is, that there be a positive number M with

$$|g(x, y_1) - g(x, y_2)| \leq M|y_1 - y_2| \quad \text{for all } (x, y_1), (x, y_2) \in \mathcal{O}.$$

Our $g(x, y) = 3y^{2/3}$ is continuous, but it fails (16) on every neighborhood $\mathcal{O}$ of the initial point $(0, 0)$. Indeed, let $\mathcal{O}$ be any neighborhood of $(0, 0)$ and choose $\delta > 0$ so small that the square $(-\delta, \delta) \times (-\delta, \delta)$ is contained in $\mathcal{O}$. Suppose (16) held with constant M . Taking $y_1 = y$ with $0 < y < \delta$, $y_2 = 0$ and $x = 0$, both points $(0, y)$ and $(0, 0)$ lie in $\mathcal{O}$ and (16) would give

$$3y^{2/3} = |g(0, y) - g(0, 0)| \leq M|y - 0| = My,$$

that is, $3y^{-1/3} \leq M$ for all $y \in (0, \delta)$. But $3y^{-1/3} \rightarrow +\infty$ as $y \rightarrow 0^+$, so no such finite M exists. Hence hypothesis (16) fails at the initial point, the Picard Theorem does not apply, and there is no contradiction.

Remark. The failure of uniqueness here is not an isolated accident: for each $a \geq 0$ the function equal to 0 for $x \leq a$ and to $(x - a)^3$ for $x > a$ is, by the same computation, a solution of the initial value problem, so it in fact has a continuum of solutions.

Problem 10.41. For a positive number ϵ , consider the differential equation

$$\begin{aligned} f'(x) &= (1/\epsilon)[1 + (f(x))^2] \quad \text{for all } x \in \mathbb{R} \\ f(0) &= 0. \end{aligned}$$

Show that on the interval $I = (-\epsilon(\pi/2), \epsilon(\pi/2))$ there is a unique solution of this differential equation that is defined by $f(x) = \tan(x/\epsilon)$ and there is no solution in an interval strictly containing I .

Solution. Here $g(x, y) = (1/\epsilon)(1 + y^2)$, which is continuous on $\mathcal{O} = \mathbb{R}^2$, and the initial data is $(x_0, y_0) = (0, 0)$. Write $b = \epsilon\pi/2$, so $I = (-b, b)$.

Step 1: the function $f(x) = \tan(x/\epsilon)$ is a solution on I . If $x \in I$ then $x/\epsilon \in (-\pi/2, \pi/2)$, which is the interval on which the tangent function is defined and differentiable; hence $f(x) = \tan(x/\epsilon)$ is a well-defined differentiable function on I . By the chain rule and the identity $\frac{d}{du} \tan u = \sec^2 u = 1 + \tan^2 u$,

$$f'(x) = \frac{1}{\epsilon} \sec^2(x/\epsilon) = \frac{1}{\epsilon} [1 + \tan^2(x/\epsilon)] = \frac{1}{\epsilon} [1 + (f(x))^2] \quad \text{for all } x \in I.$$

Moreover $f(0) = \tan 0 = 0$. Thus f solves the initial value problem on I .

Step 2: uniqueness on I . Let $u: I \rightarrow \mathbb{R}$ be any solution, so u is differentiable on I , $u(0) = 0$, and

$$u'(x) = \frac{1}{\epsilon} [1 + (u(x))^2] \quad \text{for all } x \in I.$$

Define $\varphi: I \rightarrow \mathbb{R}$ by

$$\varphi(x) = \arctan(u(x)) - \frac{x}{\epsilon}.$$

Since $\arctan$ is differentiable on $\mathbb{R}$ with derivative $1/(1+t^2)$, the chain rule gives, for every $x \in I$,

$$\varphi'(x) = \frac{u'(x)}{1+(u(x))^2} - \frac{1}{\epsilon} = \frac{1}{1+(u(x))^2} \cdot \frac{1+(u(x))^2}{\epsilon} - \frac{1}{\epsilon} = 0.$$

A function with identically vanishing derivative on an interval is constant there (an immediate consequence of the Mean Value Theorem). Since $\varphi(0) = \arctan(0) - 0 = 0$, we conclude $\varphi \equiv 0$ on I , that is,

$$\arctan(u(x)) = \frac{x}{\epsilon} \quad \text{for all } x \in I.$$

For $x \in I$ we have $x/\epsilon \in (-\pi/2, \pi/2)$, and $\arctan$ is a one-to-one mapping of $\mathbb{R}$ onto $(-\pi/2, \pi/2)$ with inverse the restriction of $\tan$ to $(-\pi/2, \pi/2)$. Applying $\tan$ to both sides therefore gives

$$u(x) = \tan(x/\epsilon) = f(x) \quad \text{for all } x \in I.$$

Hence f is the unique solution on I .

Step 3: there is no solution on an interval strictly containing I . Suppose, to get a contradiction, that J is an interval with $I \subsetneq J$ and that $u: J \rightarrow \mathbb{R}$ is a solution of the initial value problem on J , that is, u is differentiable on J (one-sidedly at an endpoint of J that belongs to J), satisfies the equation at each point of J , and $u(0) = 0$. We do not assume J is open. Note $0 \in I \subseteq J$.

Choose a point $z \in J \setminus I$. Since $z \notin I = (-b, b)$, either $z \geq b$ or $z \leq -b$. Suppose first that $z \geq b$. Because J is an interval containing both 0 and z , it contains the whole segment $[0, z]$, and in particular $b \in J$.

The restriction of u to I is a solution of the initial value problem on I , so by Step 2,

$$u(x) = \tan(x/\epsilon) \quad \text{for all } x \in I = (-b, b).$$

On the other hand, u is differentiable at the point $b \in J$ (at worst from the left, if b happens to be the right endpoint of J), hence continuous there from the left, so

$$\lim_{x \rightarrow b^-} u(x) = u(b) \in \mathbb{R},$$

a finite real number. In particular, taking the tolerance 1 in the definition of this limit, there is a $\delta > 0$, which we may also require to satisfy $\delta < 2b$ so that $(b - \delta, b) \subseteq (-b, b) = I$, with $|u(x) - u(b)| < 1$, and hence $|u(x)| < |u(b)| + 1$, for all $x \in (b - \delta, b)$; that is, u is bounded on $(b - \delta, b)$. But $u(x) = \tan(x/\epsilon)$ on $(b - \delta, b)$ by the display above, and $\tan(x/\epsilon) \rightarrow +\infty$ as $x \rightarrow b^-$, because $x/\epsilon \rightarrow (\pi/2)^-$ and $\tan t \rightarrow +\infty$ as $t \rightarrow (\pi/2)^-$. So u is unbounded on $(b - \delta, b)$. This is a contradiction.

The case $z \leq -b$ is symmetric: then $[z, 0] \subseteq J$ forces $-b \in J$, so u is continuous at $-b$ from the right and hence bounded on some interval $(-b, -b + \delta) \subseteq I$, yet there $u(x) = \tan(x/\epsilon) \rightarrow -\infty$ as $x \rightarrow (-b)^+$; again a contradiction.

Therefore no interval strictly containing I carries a solution, and I is the maximal interval of existence.

Remark. This does not conflict with the Picard Local Existence Theorem, which is purely local: on any bounded rectangle $\mathcal{O} = (-a, a) \times (-R, R)$ the function $g(x, y) = (1/\epsilon)(1 + y^2)$ satisfies (16) with $M = 2R/\epsilon$, since

$$|g(x, y_1) - g(x, y_2)| = \frac{|y_1^2 - y_2^2|}{\epsilon} = \frac{|y_1 + y_2|}{\epsilon} |y_1 - y_2| \leq \frac{2R}{\epsilon} |y_1 - y_2|,$$

so the theorem does guarantee a unique solution near $x = 0$. What the example shows is that no such local theorem can be upgraded to global existence: the solution escapes to infinity in the finite time $\epsilon\pi/2$, and this escape time can be made arbitrarily small by taking ϵ small.

Problem 10.42. Let I be an open interval in $\mathbb{R}$ and suppose that the function $h: I \rightarrow \mathbb{R}$ has the property that there are points $x_1 < x_2$ in I and a number c such that $h(x_1) < c < h(x_2)$ but c does

not belong to $h(I)$. Prove that there is no solution to the differential equation (14) by arguing that if $f: I \rightarrow \mathbb{R}$ is a solution, then the continuous function $f(x) - cx$ fails to attain a minimum value on the interval $[x_1, x_2]$.

Solution. The differential equation (14) in the special case at hand is the one in which g is independent of its second variable, $g(x, y) = h(x)$; a solution is thus a differentiable function $f: I \rightarrow \mathbb{R}$ with

$$f'(x) = h(x) \quad \text{for all } x \in I$$

(together with an initial condition $f(x_0) = y_0$, which will play no role). We must show no such f exists.

Suppose, to the contrary, that $f: I \rightarrow \mathbb{R}$ is differentiable with $f' = h$ on I . Since x_1 and x_2 belong to the interval I and $x_1 < x_2$, the closed bounded interval $[x_1, x_2]$ is contained in I . Define

$$\psi(x) = f(x) - cx \quad \text{for } x \in I.$$

Then ψ is differentiable on I , hence continuous on I , and

$$\psi'(x) = f'(x) - c = h(x) - c \quad \text{for all } x \in I.$$

Because $c \notin h(I)$, we have

$$\psi'(x) = h(x) - c \neq 0 \quad \text{for every } x \in I.$$

We now show that ψ attains no minimum value on $[x_1, x_2]$, by ruling out each of the three possible locations of a minimizer.

The minimum is not attained at x_1 . We have $\psi'(x_1) = h(x_1) - c < 0$. By the definition of the derivative,

$$\lim_{t \rightarrow x_1} \frac{\psi(t) - \psi(x_1)}{t - x_1} = \psi'(x_1) < 0,$$

so there is a $\delta > 0$ such that the difference quotient is negative whenever $0 < |t - x_1| < \delta$ and $t \in I$. Choose such a t with $x_1 < t < \min\{x_1 + \delta, x_2\}$; this is possible since $x_1 < x_2$. Then $t - x_1 > 0$ and the quotient is negative, so $\psi(t) < \psi(x_1)$ with $t \in [x_1, x_2]$. Hence $\psi(x_1)$ is not the minimum value of ψ on $[x_1, x_2]$.

The minimum is not attained at x_2 . We have $\psi'(x_2) = h(x_2) - c > 0$, so there is a $\delta' > 0$ such that

$$\frac{\psi(t) - \psi(x_2)}{t - x_2} > 0 \quad \text{whenever } 0 < |t - x_2| < \delta', \quad t \in I.$$

Choose such a t with $\max\{x_1, x_2 - \delta'\} < t < x_2$. Then $t - x_2 < 0$, and since the quotient is positive, the numerator must be negative: $\psi(t) < \psi(x_2)$, with $t \in [x_1, x_2]$. Hence $\psi(x_2)$ is not the minimum value of ψ on $[x_1, x_2]$.

The minimum is not attained at an interior point. Suppose $x_* \in (x_1, x_2)$ were a point at which ψ attains its minimum over $[x_1, x_2]$. Then x_* is an interior point of $[x_1, x_2]$ at which the differentiable function ψ has a local minimum, and therefore $\psi'(x_*) = 0$. Indeed, for $t > x_*$ near x_* the quotient $[\psi(t) - \psi(x_*)]/(t - x_*)$ is ≥ 0 , so letting $t \rightarrow x_*^+$ gives $\psi'(x_*) \geq 0$; for $t < x_*$ near x_* that quotient is ≤ 0 , so letting $t \rightarrow x_*^-$ gives $\psi'(x_*) \leq 0$. Hence $\psi'(x_*) = 0$, contradicting the fact that ψ' never vanishes on I .

Combining the three cases: the continuous function $\psi(x) = f(x) - cx$ attains no minimum value on $[x_1, x_2]$.

But $[x_1, x_2]$ is a closed, bounded, nonempty subset of $\mathbb{R}$, hence a compact metric space by Theorem 20 of Chapter 9, and the restriction of ψ to it is continuous; by the Extreme Value Theorem, Theorem 22 of Chapter 9, a continuous real-valued function on a compact metric space attains a minimum value. This is a contradiction.

Therefore no differentiable $f: I \rightarrow \mathbb{R}$ with $f' = h$ on I exists. Since any solution of (14) defined on all of I would in particular be such a function, the differential equation (14) has no solution on I for such an h , whatever the initial data.

Remark. What this argument really proves is Darboux's Theorem: the derivative of a differentiable function on an interval has the intermediate value property, even though it need not be continuous. Consequently, as remarked in the text preceding equation (15), if the image $h(I)$ fails to be an interval, then h cannot be the derivative of any function on I , and (14) has no solution.

10.7 Problems 10.43–10.44

Problem 10.43. Use the preceding exercise to prove the following theorem of Darboux: Let I be an open interval in $\mathbb{R}$ and suppose that the function $f : I \rightarrow \mathbb{R}$ is differentiable. Then the image of the derivative $f' : I \rightarrow \mathbb{R}$ is an interval.

Solution. Throughout, $J \subseteq \mathbb{R}$ is called an interval provided it has the intermediate value property

$$u, v \in J \text{ and } u < c < v \implies c \in J.$$

This is equivalent to the usual definition: if J has this property and we set $\alpha = \inf J$ and $\beta = \sup J$ (allowing $\pm\infty$), then $(\alpha, \beta) \subseteq J \subseteq [\alpha, \beta]$, so that J is one of the intervals with endpoints α and β ; the empty set and one-point sets are degenerate intervals. Thus, to prove that $f'(I)$ is an interval it suffices to show that no number c that lies strictly between two values of f' can fail to be a value of f' . Recall the content of the preceding exercise. Let I be an open interval and let $h : I \rightarrow \mathbb{R}$ have the property that there are points $x_1 < x_2$ in I and a number c with

$$h(x_1) < c < h(x_2) \quad \text{but} \quad c \notin h(I).$$

Then the differential equation (14) with $g(x, y) = h(x)$, that is, the equation

$$\varphi'(x) = h(x) \quad \text{for all } x \in I, \quad \varphi(x_0) = y_0,$$

has no solution. Indeed, suppose $\varphi : I \rightarrow \mathbb{R}$ were a solution, so that φ is differentiable on I with $\varphi' = h$ there. Define the continuous function

$$\psi(x) = \varphi(x) - cx \quad \text{for } x \in [x_1, x_2] \subseteq I.$$

Since $[x_1, x_2]$ is compact and ψ is continuous, the Extreme Value Theorem provides a point $x_* \in [x_1, x_2]$ at which ψ attains its minimum value on $[x_1, x_2]$. Now ψ is differentiable on I with

$$\psi'(x) = h(x) - c \quad \text{for all } x \in I,$$

and since $c \notin h(I)$ we have $\psi'(x) \neq 0$ for every $x \in I$. Observe:

- $x_* \neq x_1$. Indeed, $\psi'(x_1) = h(x_1) - c < 0$, so since

$$\lim_{t \rightarrow x_1^+} \frac{\psi(t) - \psi(x_1)}{t - x_1} = \psi'(x_1) < 0,$$

there is a $t \in (x_1, x_2)$ for which the difference quotient is negative; as $t - x_1 > 0$ this forces $\psi(t) < \psi(x_1)$, so the minimum is not attained at x_1 .

- $x_* \neq x_2$. Indeed, $\psi'(x_2) = h(x_2) - c > 0$, so since

$$\lim_{t \rightarrow x_2^-} \frac{\psi(t) - \psi(x_2)}{t - x_2} = \psi'(x_2) > 0,$$

there is a $t \in (x_1, x_2)$ for which the difference quotient is positive; as $t - x_2 < 0$ this forces $\psi(t) < \psi(x_2)$, so the minimum is not attained at x_2 .

Therefore x_* belongs to the open interval (x_1, x_2) . A differentiable function attains an interior minimum only at a point where its derivative vanishes: for $t > x_*$ near x_* the quotient $[\psi(t) - \psi(x_*)]/(t - x_*)$ is nonnegative, whence $\psi'(x_*) \geq 0$, while for $t < x_*$ near x_* the same quotient is nonpositive, whence $\psi'(x_*) \leq 0$. Thus $\psi'(x_*) = 0$, that is, $h(x_*) = c$ with $x_* \in I$. This contradicts the assumption that $c \notin h(I)$. Hence no such solution φ exists. This is precisely the assertion of the preceding exercise:

the argument shows that a solution φ would force the continuous function $\varphi(x) - cx$ to fail to attain a minimum value on $[x_1, x_2]$, which the Extreme Value Theorem forbids.

We now prove Darboux's theorem. Let $f : I \rightarrow \mathbb{R}$ be differentiable on the open interval I and put $h = f' : I \rightarrow \mathbb{R}$. Suppose, by way of contradiction, that $h(I) = f'(I)$ is not an interval. By the characterization recorded at the outset, there are points $p, q \in I$ and a number c with

$$f'(p) < c < f'(q) \quad \text{and} \quad c \notin f'(I).$$

Note that $p \neq q$. There are two cases.

Case 1: $p < q$. Take $x_1 = p$ and $x_2 = q$. Then $h = f'$ satisfies exactly the hypothesis of the preceding exercise: $x_1 < x_2$ lie in I , $h(x_1) < c < h(x_2)$, and $c \notin h(I)$. Consequently the differential equation

$$\varphi'(x) = h(x) \quad \text{for all } x \in I, \quad \varphi(x_0) = f(x_0)$$

(where x_0 is any point of I) has no solution. But f itself is a solution of this equation, since f is differentiable on I with $f' = h$ and $f(x_0) = f(x_0)$. This contradiction shows that Case 1 cannot occur.

Case 2: $q < p$. Consider the reflected function $F = -f : I \rightarrow \mathbb{R}$, which is differentiable on I with $F' = -f'$, and consider the number $c' = -c$. Then, with $x_1 = q < x_2 = p$,

$$F'(x_1) = -f'(q) < -c = c' < -f'(p) = F'(x_2),$$

and $c' \notin F'(I) = -f'(I)$, because $c' = -c \in -f'(I)$ would mean $c \in f'(I)$. So F' satisfies the hypothesis of the preceding exercise with the number c' , and exactly as in Case 1 the function F is itself a solution of the equation $\varphi' = F'$ on I with $\varphi(x_0) = F(x_0)$, which the preceding exercise forbids. This contradiction shows that Case 2 cannot occur either.

Since neither case can occur, no number c lying strictly between two values of f' can fail to lie in $f'(I)$. Therefore $f'(I)$ has the intermediate value property and hence is an interval.

Problem 10.44. State and prove a form of the Picard Existence Theorem for systems of differential equations in the following context: $\mathcal{O}$ is an open subset of $\mathbb{R} \times \mathbb{R}^n$, $\mathbf{g} : \mathcal{O} \rightarrow \mathbb{R}^n$ is continuous, the point $(x_0, \mathbf{y}_0)$ is in $\mathcal{O}$, and the system of differential equations is

$$\begin{aligned} \mathbf{f}'(x) &= \mathbf{g}(x, \mathbf{f}(x)) \quad \text{for all } x \in I \\ \mathbf{f}(x_0) &= \mathbf{y}_0. \end{aligned}$$

(Hint: Approximate $\mathbf{g}$ by a Lipschitz mapping and then use the Arzela-Ascoli Theorem.)

Solution. Notation. For $\mathbf{u} \in \mathbb{R}^n$ let $|\mathbf{u}|$ denote the Euclidean norm; the same symbol is used for the Euclidean norm on $\mathbb{R} \times \mathbb{R}^n = \mathbb{R}^{n+1}$. For a compact interval J , let $C(J, \mathbb{R}^n)$ denote the set of continuous mappings $\mathbf{f} : J \rightarrow \mathbb{R}^n$, metrized by

$$\rho_{\max}(\mathbf{f}_1, \mathbf{f}_2) = \max_{x \in J} |\mathbf{f}_1(x) - \mathbf{f}_2(x)|.$$

Derivatives and integrals of $\mathbb{R}^n$ -valued functions are taken componentwise. Two elementary facts will be used. First, $C(J, \mathbb{R}^n)$ is a complete metric space: a $\rho_{\max}$ -Cauchy sequence is uniformly Cauchy, hence converges pointwise since $\mathbb{R}^n$ is complete, and the convergence is then uniform, so the limit is continuous; this is verbatim the proof, given in the preceding chapter, that $C(J)$ is complete, with $\mathbb{R}$ replaced by the complete space $\mathbb{R}^n$. Second, for continuous $\mathbf{h} : J \rightarrow \mathbb{R}^n$ and $x, x_0 \in J$,

$$\left| \int_{x_0}^x \mathbf{h}(t) dt \right| \leq \left| \int_{x_0}^x |\mathbf{h}(t)| dt \right|;$$

for $x \geq x_0$ this follows by setting $\mathbf{v} = \int_{x_0}^x \mathbf{h}$ and computing $|\mathbf{v}|^2 = \int_{x_0}^x \mathbf{v} \cdot \mathbf{h}(t) dt \leq |\mathbf{v}| \int_{x_0}^x |\mathbf{h}(t)| dt$, and the case $x < x_0$ follows by reversing the limits.

Statement of the theorem.

The Picard Local Existence Theorem for Systems. Let $\mathcal{O}$ be an open subset of $\mathbb{R} \times \mathbb{R}^n$ containing the point $(x_0, \mathbf{y}_0)$ and suppose $\mathbf{g} : \mathcal{O} \rightarrow \mathbb{R}^n$ is continuous. Then there is an open interval I containing x_0 and a differentiable mapping $\mathbf{f} : I \rightarrow \mathbb{R}^n$ whose graph lies in $\mathcal{O}$ and which satisfies

$$\mathbf{f}'(x) = \mathbf{g}(x, \mathbf{f}(x)) \quad \text{for all } x \in I, \quad \mathbf{f}(x_0) = \mathbf{y}_0.$$

If, in addition, there is an $M > 0$ for which the Lipschitz property in the second variable holds uniformly with respect to the first,

$$|\mathbf{g}(x, \mathbf{y}_1) - \mathbf{g}(x, \mathbf{y}_2)| \leq M|\mathbf{y}_1 - \mathbf{y}_2| \quad \text{for all } (x, \mathbf{y}_1), (x, \mathbf{y}_2) \text{ in } \mathcal{O},$$

then the solution is unique in the strong sense that any two solutions defined on a common interval containing x_0 agree there.

Reduction to an integral equation. Exactly as in the scalar case treated in this section, if I is an open interval containing x_0 and $\mathbf{f} : I \rightarrow \mathbb{R}^n$ is continuous with $(x, \mathbf{f}(x)) \in \mathcal{O}$ for all $x \in I$, then $t \mapsto \mathbf{g}(t, \mathbf{f}(t))$ is continuous on I , and by the Fundamental Theorem of Differential Calculus applied to each component, $\mathbf{f}$ is a solution of the system if and only if

$$\mathbf{f}(x) = \mathbf{y}_0 + \int_{x_0}^x \mathbf{g}(t, \mathbf{f}(t)) dt \quad \text{for all } x \in I.$$

We refer to this as the integral form of the system; it is the exact analogue of equation (15).

The compact rectangle. Since $\mathcal{O}$ is open and contains $(x_0, \mathbf{y}_0)$, we may choose positive numbers a and b so that the compact set

$$R = [x_0 - a, x_0 + a] \times \{\mathbf{y} \in \mathbb{R}^n : |\mathbf{y} - \mathbf{y}_0| \leq b\}$$

is contained in $\mathcal{O}$. Since $\mathbf{g}$ is continuous and R is compact, $\mathbf{g}$ is bounded and uniformly continuous on R . Set

$$K = 1 + \max_{(x, \mathbf{y}) \in R} |\mathbf{g}(x, \mathbf{y})|, \quad \ell = \min\{a, b/K\}, \quad I_\ell = [x_0 - \ell, x_0 + \ell].$$

Let X_ℓ be the subspace of $C(I_\ell, \mathbb{R}^n)$ consisting of those $\mathbf{f}$ with $|\mathbf{f}(x) - \mathbf{y}_0| \leq b$ for all $x \in I_\ell$; that is, the continuous mappings whose graph lies in R . Then X_ℓ is nonempty, since it contains the constant mapping $x \mapsto \mathbf{y}_0$, and it is a closed subset of the complete metric space $C(I_\ell, \mathbb{R}^n)$: if $\mathbf{f}_j \rightarrow \mathbf{f}$ uniformly with $|\mathbf{f}_j - \mathbf{y}_0| \leq b$ pointwise, then $|\mathbf{f} - \mathbf{y}_0| \leq b$ pointwise. Hence X_ℓ is itself a complete metric space.

Step 1: the Lipschitz case, on an interval whose length does not depend on the Lipschitz constant. Suppose $\mathbf{h} : \mathbb{R} \times \mathbb{R}^n \rightarrow \mathbb{R}^n$ is continuous, $|\mathbf{h}| \leq K$ on R , and there is an $M > 0$ with

$$|\mathbf{h}(x, \mathbf{y}_1) - \mathbf{h}(x, \mathbf{y}_2)| \leq M|\mathbf{y}_1 - \mathbf{y}_2| \quad \text{for all } (x, \mathbf{y}_1), (x, \mathbf{y}_2) \in R.$$

We claim there is exactly one $\mathbf{f} \in X_\ell$ with $\mathbf{f}(x) = \mathbf{y}_0 + \int_{x_0}^x \mathbf{h}(t, \mathbf{f}(t)) dt$ on I_ℓ , with ℓ as fixed above. For $\mathbf{f} \in X_\ell$ define

$$T(\mathbf{f})(x) = \mathbf{y}_0 + \int_{x_0}^x \mathbf{h}(t, \mathbf{f}(t)) dt \quad \text{for } x \in I_\ell.$$

The integrand is continuous, so $T(\mathbf{f}) \in C(I_\ell, \mathbb{R}^n)$, and for $x \in I_\ell$,

$$|T(\mathbf{f})(x) - \mathbf{y}_0| \leq \left| \int_{x_0}^x |\mathbf{h}(t, \mathbf{f}(t))| dt \right| \leq \ell K \leq b,$$

since $\ell \leq b/K$. Hence $T(X_\ell) \subseteq X_\ell$.

The estimate of this section shows T is a contraction only when $\ell M < 1$, and below the Lipschitz constants M will be forced to tend to ∞ ; so instead of $\rho_{\max}$ we use the equivalent weighted metric

$$\rho_*(\mathbf{f}_1, \mathbf{f}_2) = \max_{x \in I_\ell} e^{-2M|x-x_0|} |\mathbf{f}_1(x) - \mathbf{f}_2(x)|.$$

Since $e^{-2M\ell}\rho_{\max} \leq \rho_* \leq \rho_{\max}$, the metrics ρ_* and $\rho_{\max}$ have the same Cauchy sequences and the same convergent sequences, so (X_ℓ, ρ_*) is also a complete metric space. For $\mathbf{f}_1, \mathbf{f}_2 \in X_\ell$ and $x \in I_\ell$, using the Lipschitz property and $|\mathbf{f}_1(t) - \mathbf{f}_2(t)| \leq e^{2M|t-x_0|}\rho_*(\mathbf{f}_1, \mathbf{f}_2)$,

$$|T(\mathbf{f}_1)(x) - T(\mathbf{f}_2)(x)| \leq \left| \int_{x_0}^x M |\mathbf{f}_1(t) - \mathbf{f}_2(t)| dt \right| \leq M\rho_*(\mathbf{f}_1, \mathbf{f}_2) \left| \int_{x_0}^x e^{2M|t-x_0|} dt \right|,$$

and the last integral equals $(e^{2M|x-x_0|} - 1)/(2M)$. Therefore

$$e^{-2M|x-x_0|}|T(\mathbf{f}_1)(x) - T(\mathbf{f}_2)(x)| \leq \frac{1}{2}\rho_*(\mathbf{f}_1, \mathbf{f}_2) \quad \text{for all } x \in I_\ell,$$

so $\rho_*(T(\mathbf{f}_1), T(\mathbf{f}_2)) \leq \frac{1}{2}\rho_*(\mathbf{f}_1, \mathbf{f}_2)$: the mapping $T : X_\ell \rightarrow X_\ell$ is a contraction with Lipschitz constant $1/2$, whatever M may be. By the Banach Contraction Principle, T has exactly one fixed point in X_ℓ , which is the asserted solution of the integral equation. This proves the claim, and note carefully that ℓ depends only on a, b and K , not on M .

Step 2: approximation of $\mathbf{g}$ by Lipschitz mappings. Let $u : R \rightarrow \mathbb{R}$ be continuous, and for a natural number k define

$$u_k(z) = \inf_{w \in R} [u(w) + k|z - w|] \quad \text{for } z \in \mathbb{R}^{n+1}.$$

Since u is bounded on the compact set R , the infimum is a real number, with $\min_R u \leq u_k(z) \leq u(w) + k|z - w|$ for every $w \in R$. For $z, z' \in \mathbb{R}^{n+1}$ and $w \in R$ we have $u(w) + k|z - w| \leq u(w) + k|z' - w| + k|z - z'|$; taking the infimum over w gives $u_k(z) \leq u_k(z') + k|z - z'|$, and by symmetry

$$|u_k(z) - u_k(z')| \leq k|z - z'| \quad \text{for all } z, z' \in \mathbb{R}^{n+1},$$

so u_k is Lipschitz on all of $\mathbb{R}^{n+1}$ with Lipschitz constant k . Moreover $u_k \leq u$ on R (take $w = z$). We claim $u_k \rightarrow u$ uniformly on R . Let $\epsilon > 0$. Since R is compact, u is uniformly continuous, so there is $\delta > 0$ such that $|u(w) - u(z)| < \epsilon$ whenever $w, z \in R$ and $|w - z| \leq \delta$. Let $k \geq (\max_R u - \min_R u)/\delta$ and let $z \in R$. For $w \in R$ with $|z - w| \leq \delta$ we have $u(w) + k|z - w| \geq u(w) \geq u(z) - \epsilon$, while for $w \in R$ with $|z - w| > \delta$ we have

$$u(w) + k|z - w| \geq \min_R u + k\delta \geq \min_R u + (\max_R u - \min_R u) = \max_R u \geq u(z).$$

Taking the infimum over $w \in R$ gives $u_k(z) \geq u(z) - \epsilon$, and hence $0 \leq u(z) - u_k(z) \leq \epsilon$ for all $z \in R$. This proves the uniform convergence.

Now write $\mathbf{g} = (g^1, \dots, g^n)$ on R and apply the preceding construction to each component, obtaining

$$\mathbf{g}_k = (g_k^1, \dots, g_k^n) : \mathbb{R}^{n+1} \rightarrow \mathbb{R}^n,$$

which is continuous on $\mathbb{R}^{n+1}$, satisfies $|\mathbf{g}_k(z) - \mathbf{g}_k(z')| \leq \sqrt{n}k|z - z'|$ for all z, z' (combine the componentwise estimates), and converges to $\mathbf{g}$ uniformly on R , since each component does. In particular, with $M_k = \sqrt{n}k$,

$$|\mathbf{g}_k(x, \mathbf{y}_1) - \mathbf{g}_k(x, \mathbf{y}_2)| \leq M_k|\mathbf{y}_1 - \mathbf{y}_2| \quad \text{for all } (x, \mathbf{y}_1), (x, \mathbf{y}_2) \in \mathbb{R} \times \mathbb{R}^n.$$

Choose an index N so that $\sup_R |\mathbf{g}_k - \mathbf{g}| \leq 1$ for $k \geq N$; then $|\mathbf{g}_k| \leq K$ on R for such k , with K as fixed above. Discarding the first N terms, we may assume this holds for all k .

Step 3: solving the approximating systems and passing to the limit. By Step 1 applied to $\mathbf{h} = \mathbf{g}_k$ (which is bounded by K on R and Lipschitz in the second variable with constant M_k), for each k there is $\mathbf{f}_k \in X_\ell$ with

$$\mathbf{f}_k(x) = \mathbf{y}_0 + \int_{x_0}^x \mathbf{g}_k(t, \mathbf{f}_k(t)) dt \quad \text{for all } x \in I_\ell,$$

where, crucially, the interval I_ℓ is the same for every k . Since $\mathbf{f}_k \in X_\ell$, we have $|\mathbf{f}_k(x) - \mathbf{y}_0| \leq b$ for all x and k , so the sequence $\{\mathbf{f}_k\}$ is uniformly bounded. Furthermore, for $x, x' \in I_\ell$,

$$|\mathbf{f}_k(x) - \mathbf{f}_k(x')| = \left| \int_{x'}^x \mathbf{g}_k(t, \mathbf{f}_k(t)) dt \right| \leq K|x - x'|,$$

because $(t, \mathbf{f}_k(t)) \in R$ and $|\mathbf{g}_k| \leq K$ there. Thus $\{\mathbf{f}_k\}$ is uniformly Lipschitz with constant K , and in particular equicontinuous on the compact metric space I_ℓ .

Write $\mathbf{f}_k = (f_k^1, \dots, f_k^n)$. Each scalar sequence $\{f_k^j\}_k$ is uniformly bounded and equicontinuous on I_ℓ , since $|f_k^j(x) - f_k^j(x')| \leq |\mathbf{f}_k(x) - \mathbf{f}_k(x')| \leq K|x - x'|$. Apply the Arzela-Ascoli Theorem to $\{f_k^1\}$ to extract a subsequence converging uniformly on I_ℓ ; apply it again to the second components of that subsequence, and so on through $j = n$. After these n successive extractions we obtain a subsequence, which we relabel $\{\mathbf{f}_k\}$, all of whose component sequences converge uniformly on I_ℓ . Hence there is a continuous $\mathbf{f} : I_\ell \rightarrow \mathbb{R}^n$ with $\mathbf{f}_k \rightarrow \mathbf{f}$ uniformly on I_ℓ . Since $|\mathbf{f}_k(x) - \mathbf{y}_0| \leq b$ for every k , passing to the limit gives $|\mathbf{f}(x) - \mathbf{y}_0| \leq b$, so $\mathbf{f} \in X_\ell$ and the graph of $\mathbf{f}$ lies in $R \subseteq \mathcal{O}$.

We now pass to the limit in the integral equation. Let $\epsilon > 0$. By the uniform continuity of $\mathbf{g}$ on R there is $\delta > 0$ such that $|\mathbf{g}(z) - \mathbf{g}(z')| < \epsilon/2$ whenever $z, z' \in R$ and $|z - z'| < \delta$. Choose N' so that for $k \geq N'$ we have both $\sup_R |\mathbf{g}_k - \mathbf{g}| < \epsilon/2$ and $\rho_{\max}(\mathbf{f}_k, \mathbf{f}) < \delta$. Then for $k \geq N'$ and all $t \in I_\ell$, since $(t, \mathbf{f}_k(t))$ and $(t, \mathbf{f}(t))$ both lie in R and are at distance less than δ ,

$$|\mathbf{g}_k(t, \mathbf{f}_k(t)) - \mathbf{g}(t, \mathbf{f}(t))| \leq |\mathbf{g}_k(t, \mathbf{f}_k(t)) - \mathbf{g}(t, \mathbf{f}_k(t))| + |\mathbf{g}(t, \mathbf{f}_k(t)) - \mathbf{g}(t, \mathbf{f}(t))| < \epsilon.$$

Thus $\mathbf{g}_k(\cdot, \mathbf{f}_k(\cdot)) \rightarrow \mathbf{g}(\cdot, \mathbf{f}(\cdot))$ uniformly on I_ℓ , and therefore, for each fixed $x \in I_\ell$,

$$\left| \int_{x_0}^x \mathbf{g}_k(t, \mathbf{f}_k(t)) dt - \int_{x_0}^x \mathbf{g}(t, \mathbf{f}(t)) dt \right| \leq \ell \cdot \sup_{t \in I_\ell} |\mathbf{g}_k(t, \mathbf{f}_k(t)) - \mathbf{g}(t, \mathbf{f}(t))| \rightarrow 0.$$

Letting $k \rightarrow \infty$ in the integral equation for $\mathbf{f}_k$ therefore yields

$$\mathbf{f}(x) = \mathbf{y}_0 + \int_{x_0}^x \mathbf{g}(t, \mathbf{f}(t)) dt \quad \text{for all } x \in I_\ell.$$

By the equivalence between the system and its integral form, the restriction of $\mathbf{f}$ to the open interval $I = (x_0 - \ell, x_0 + \ell)$ is differentiable there and satisfies

$$\mathbf{f}'(x) = \mathbf{g}(x, \mathbf{f}(x)) \quad \text{for all } x \in I, \quad \mathbf{f}(x_0) = \mathbf{y}_0.$$

This proves the existence assertion.

Step 4: uniqueness under the Lipschitz assumption. Assume now, in addition, that $|\mathbf{g}(x, \mathbf{y}_1) - \mathbf{g}(x, \mathbf{y}_2)| \leq M|\mathbf{y}_1 - \mathbf{y}_2|$ for all $(x, \mathbf{y}_1), (x, \mathbf{y}_2)$ in $\mathcal{O}$. Let J be an interval containing x_0 and let $\mathbf{f}, \mathbf{h} : J \rightarrow \mathbb{R}^n$ both be solutions of the system, both with graphs in $\mathcal{O}$. By the integral form of the system, for $x \in J$,

$$|\mathbf{f}(x) - \mathbf{h}(x)| = \left| \int_{x_0}^x [\mathbf{g}(t, \mathbf{f}(t)) - \mathbf{g}(t, \mathbf{h}(t))] dt \right| \leq M \left| \int_{x_0}^x |\mathbf{f}(t) - \mathbf{h}(t)| dt \right|.$$

Fix a compact interval $[x_0, x_0 + r] \subseteq J$ and let $A = \max_{[x_0, x_0 + r]} |\mathbf{f} - \mathbf{h}|$, a finite number since $|\mathbf{f} - \mathbf{h}|$ is continuous. We show by induction that

$$|\mathbf{f}(x) - \mathbf{h}(x)| \leq A \frac{M^m(x - x_0)^m}{m!} \quad \text{for all } x \in [x_0, x_0 + r] \text{ and all } m \geq 0.$$

The case $m = 0$ is the definition of A . If the inequality holds for m , then for $x \in [x_0, x_0 + r]$,

$$|\mathbf{f}(x) - \mathbf{h}(x)| \leq M \int_{x_0}^x A \frac{M^m(t - x_0)^m}{m!} dt = A \frac{M^{m+1}(x - x_0)^{m+1}}{(m+1)!},$$

which is the case $m+1$. Since $M^m r^m / m! \rightarrow 0$ as $m \rightarrow \infty$, we conclude $\mathbf{f} = \mathbf{h}$ on $[x_0, x_0 + r]$. The same argument applied on $[x_0 - r, x_0]$ (or applied to $x \mapsto \mathbf{f}(2x_0 - x)$, $\mathbf{h}(2x_0 - x)$, which solve the system with $\mathbf{g}$ replaced by $-\mathbf{g}(2x_0 - x, \mathbf{y})$) gives $\mathbf{f} = \mathbf{h}$ to the left of x_0 as well. As r was arbitrary, $\mathbf{f} = \mathbf{h}$ on J . This proves uniqueness and completes the proof of the theorem.

Remark. Under the Lipschitz assumption the whole of Step 2 and Step 3 is unnecessary: Step 1 applied directly to $\mathbf{h} = \mathbf{g}$ (extended in any fashion, since only its values on R are used) produces the solution at once from the Banach Contraction Principle, exactly as in the scalar Picard Local Existence Theorem proved in this section. Note also that no uniqueness is asserted in the merely continuous case, and none can be: Problem 40 exhibits a continuous g for which the initial value problem has two distinct solutions.

11.1 Problems 11.1–11.7

Problem 11.1. Show that the discrete topology for a nonempty set X is a metric topology.

Solution. Recall that the discrete topology on X is the collection $\mathcal{T}$ of all subsets of X , and that the metric topology induced by a metric ρ on X consists of those sets $\mathcal{O}$ with the property that each point of $\mathcal{O}$ is the center of an open ball contained in $\mathcal{O}$.

Define the discrete metric ρ on X by

$$\rho(x, y) = \begin{cases} 0 & \text{if } x = y, \\ 1 & \text{if } x \neq y. \end{cases}$$

First we check that ρ is a metric. It is nonnegative and real-valued, $\rho(x, y) = 0$ if and only if $x = y$ by definition, and ρ is symmetric since the condition $x = y$ is symmetric in x and y . For the triangle inequality, let x, y, z belong to X ; we must show $\rho(x, z) \leq \rho(x, y) + \rho(y, z)$. If $x = z$, the left-hand side is 0 and the inequality is clear since $\rho \geq 0$. If $x \neq z$, then y cannot equal both x and z , so at least one of $\rho(x, y)$, $\rho(y, z)$ equals 1; hence the right-hand side is at least 1 = $\rho(x, z)$. Thus (X, ρ) is a metric space.

Now compute the open balls. For x in X and $0 < r \leq 1$,

$$B(x, r) = \{y \in X : \rho(x, y) < r\} = \{x\},$$

since the only y with $\rho(x, y) < 1$ is $y = x$. In particular $B(x, 1/2) = \{x\}$ for every x .

Let $\mathcal{T}_\rho$ denote the metric topology induced by ρ . If $\mathcal{O}$ is any subset of X and x belongs to $\mathcal{O}$, then $B(x, 1/2) = \{x\} \subseteq \mathcal{O}$, so $\mathcal{O}$ contains an open ball centered at each of its points; therefore $\mathcal{O}$ belongs to $\mathcal{T}_\rho$. (For $\mathcal{O} = \emptyset$ the requirement is vacuous.) Hence every subset of X is open in the metric topology, that is, $\mathcal{T} \subseteq \mathcal{T}_\rho$. The reverse inclusion is immediate because $\mathcal{T}$ consists of all subsets of X , so $\mathcal{T}_\rho \subseteq \mathcal{T}$. Therefore $\mathcal{T}_\rho = \mathcal{T}$: the discrete topology is the metric topology induced by the discrete metric, and in particular it is a metric topology.

Problem 11.2. Show that the discrete topology on a set has a unique base.

Solution. Let X be a nonempty set with the discrete topology $\mathcal{T}$, so that every subset of X is open. Put

$$\mathcal{B}_0 = \{\{x\} : x \in X\},$$

the collection of one-point subsets of X . We show that $\mathcal{B}_0$ is a base for $\mathcal{T}$ and that $\mathcal{B}_0$ is contained in every base for $\mathcal{T}$; consequently $\mathcal{B}_0$ is the one and only base that carries no redundant sets, that is, the unique smallest base.

$\mathcal{B}_0$ is a base. Each $\{x\}$ is open, since all subsets are open. Let x belong to X and let U be a neighborhood of x . Then $\{x\}$ belongs to $\mathcal{B}_0$ and $x \in \{x\} \subseteq U$. Thus $\{\{x\}\}$ is a base for the topology at x , and $\mathcal{B}_0$ contains a base at each point of X : it is a base for $\mathcal{T}$. Equivalently, every nonempty open set $\mathcal{O}$ is the union of the subcollection $\{\{x\} : x \in \mathcal{O}\}$ of $\mathcal{B}_0$, and $\emptyset$ is the union of the empty subcollection. Every base contains $\mathcal{B}_0$. Let $\mathcal{B}$ be any base for $\mathcal{T}$ and let x belong to X . Since $\{x\}$ is open, it is a neighborhood of x , so by the definition of a base there is a set B in $\mathcal{B}$ with $x \in B \subseteq \{x\}$. Hence $B = \{x\}$, and so $\{x\}$ belongs to $\mathcal{B}$. As x was arbitrary, $\mathcal{B}_0 \subseteq \mathcal{B}$.

Therefore $\mathcal{B}_0$ is a base and it is contained in every base for $\mathcal{T}$: it is the smallest base, and it is the unique smallest one, since a smallest element of a collection ordered by inclusion is unique.

A remark on the word *unique* is in order, since with the definition of base used in the text a topology generally has many bases; the book says so explicitly just after Proposition 2. Here too: if X has at least two points, then $\mathcal{B}_0 \cup \{X\}$ is a collection of open sets containing a base at each point, hence is also a base, and it differs from $\mathcal{B}_0$. So uniqueness cannot mean that only one collection qualifies. What is true, and what the above proves, is that the discrete topology has a unique irredundant base, namely $\mathcal{B}_0$. Call a base $\mathcal{B}$ irredundant provided no member of $\mathcal{B}$ is the union of a subcollection of the

remaining members. If $\mathcal{B}$ is an irredundant base for the discrete topology, then $\mathcal{B}_0 \subseteq \mathcal{B}$ by the preceding paragraph; and if S were a member of $\mathcal{B}$ other than a singleton, then $S = \bigcup \{\{x\} : x \in S\}$ exhibits S as the union of a subcollection of $\mathcal{B} \sim \{S\}$ (the empty subcollection in case $S = \emptyset$), contradicting irredundancy. Hence $\mathcal{B} = \mathcal{B}_0$. Every base whatsoever is obtained from $\mathcal{B}_0$ by adjoining sets that are already unions of members of $\mathcal{B}_0$ and so contribute nothing new.

Problem 11.3. Regarding Proposition 2, show that if $\mathcal{B}$ is a base for a topology, then properties (i) and (ii) hold.

Solution. Let $(X, \mathcal{T})$ be a topological space and let $\mathcal{B} \subseteq \mathcal{T}$ be a base for $\mathcal{T}$; that is, $\mathcal{B}$ is a collection of open sets which contains a base for the topology at each point of X . Unwinding the definition of a base at a point, this says precisely:

for each x in X and each neighborhood U of x , there is a set B in $\mathcal{B}$ with $x \in B \subseteq U$. (*)

Indeed, if $\mathcal{B}_x \subseteq \mathcal{B}$ is a base at x , its members are neighborhoods of x and one of them is contained in U .

Property (i): $\mathcal{B}$ covers X , that is, $X = \bigcup_{B \in \mathcal{B}} B$. Since every member of $\mathcal{B}$ is a subset of X , the union is contained in X . Conversely, let x belong to X . The whole set X is open, hence is a neighborhood of x , so by (*) there is B in $\mathcal{B}$ with $x \in B \subseteq X$. Thus x belongs to the union. Therefore $X = \bigcup_{B \in \mathcal{B}} B$.

Property (ii): if B_1 and B_2 belong to $\mathcal{B}$ and $x \in B_1 \cap B_2$, then there is a set B in $\mathcal{B}$ with $x \in B \subseteq B_1 \cap B_2$. Since $\mathcal{B} \subseteq \mathcal{T}$, both B_1 and B_2 are open, and by the defining property of a topology the intersection of a finite collection of open sets is open; hence $B_1 \cap B_2$ is open. As x belongs to $B_1 \cap B_2$, this set is a neighborhood of x , so by (*) there is B in $\mathcal{B}$ with $x \in B \subseteq B_1 \cap B_2$, as required.

This completes the converse half of Proposition 2, which was left as an exercise there: a base for a topology necessarily satisfies (i) and (ii), and Proposition 2 shows conversely that any collection satisfying (i) and (ii) is a base for exactly one topology on X , namely the collection of $\emptyset$ together with all unions of subcollections of $\mathcal{B}$.

Problem 11.4. Let $\mathcal{T}_1$ and $\mathcal{T}_2$ be topologies for a nonempty set X . Show that $\mathcal{T}_1 = \mathcal{T}_2$ if and only if there are bases $\mathcal{B}_1$ for $\mathcal{T}_1$ and $\mathcal{B}_2$ for $\mathcal{T}_2$ that are related as follows at each point x in X : for each neighborhood $\mathcal{N}_1$ of x belonging to $\mathcal{B}_1$, there is a neighborhood $\mathcal{N}_2$ of x belonging to $\mathcal{B}_2$ for which $\mathcal{N}_2 \subseteq \mathcal{N}_1$, and for each neighborhood $\mathcal{N}_2$ of x belonging to $\mathcal{B}_2$, there is a neighborhood $\mathcal{N}_1$ of x belonging to $\mathcal{B}_1$ for which $\mathcal{N}_1 \subseteq \mathcal{N}_2$.

Solution. Call the displayed condition the interlacing condition for the pair $\mathcal{B}_1, \mathcal{B}_2$.

Necessity. Suppose $\mathcal{T}_1 = \mathcal{T}_2 =: \mathcal{T}$. A topology is a base for itself: it is a collection of open sets, and for x in X and U a neighborhood of x we may take $B = U$, which belongs to $\mathcal{T}$ and satisfies $x \in B \subseteq U$. So set $\mathcal{B}_1 = \mathcal{B}_2 = \mathcal{T}$, a base for $\mathcal{T}_1$ and a base for $\mathcal{T}_2$. Now fix x in X . If $\mathcal{N}_1$ belongs to $\mathcal{B}_1$ and contains x , take $\mathcal{N}_2 = \mathcal{N}_1$, which belongs to $\mathcal{B}_2$, contains x , and satisfies $\mathcal{N}_2 \subseteq \mathcal{N}_1$; symmetrically in the other direction. So the interlacing condition holds.

Sufficiency. Suppose $\mathcal{B}_1$ is a base for $\mathcal{T}_1$, $\mathcal{B}_2$ is a base for $\mathcal{T}_2$, and the interlacing condition holds at every point of X . We show $\mathcal{T}_1 \subseteq \mathcal{T}_2$; the reverse inclusion follows by interchanging the roles of the indices 1 and 2, since the interlacing condition is symmetric in them.

Let $\mathcal{O}$ belong to $\mathcal{T}_1$; we may assume $\mathcal{O}$ is nonempty, since $\emptyset$ belongs to every topology. Let x belong to $\mathcal{O}$. Then $\mathcal{O}$ is a $\mathcal{T}_1$ -neighborhood of x , so, $\mathcal{B}_1$ being a base for $\mathcal{T}_1$, there is a set $\mathcal{N}_1$ in $\mathcal{B}_1$ with $x \in \mathcal{N}_1 \subseteq \mathcal{O}$. Thus $\mathcal{N}_1$ is a neighborhood of x belonging to $\mathcal{B}_1$, and the interlacing condition provides a neighborhood $\mathcal{N}_2$ of x belonging to $\mathcal{B}_2$ with $\mathcal{N}_2 \subseteq \mathcal{N}_1$. Denote this set by $\mathcal{N}_2^x$; it satisfies

$$x \in \mathcal{N}_2^x \subseteq \mathcal{N}_1 \subseteq \mathcal{O}, \quad \mathcal{N}_2^x \in \mathcal{B}_2 \subseteq \mathcal{T}_2.$$

Consequently

$$\mathcal{O} = \bigcup_{x \in \mathcal{O}} \mathcal{N}_2^x,$$

because each $\mathcal{N}_2^x$ is contained in $\mathcal{O}$ and each x in $\mathcal{O}$ lies in $\mathcal{N}_2^x$. This exhibits $\mathcal{O}$ as a union of a collection of $\mathcal{T}_2$ -open sets, and the union of any collection of open sets is open; hence $\mathcal{O}$ belongs to

$\mathcal{T}_2$. (Equivalently, by Proposition 1, $\mathcal{O}$ is $\mathcal{T}_2$ -open because each of its points has a $\mathcal{T}_2$ -neighborhood contained in it.)
Therefore $\mathcal{T}_1 \subseteq \mathcal{T}_2$, and by symmetry $\mathcal{T}_2 \subseteq \mathcal{T}_1$, so $\mathcal{T}_1 = \mathcal{T}_2$.

Problem 11.5. Let E be a subset of a topological space X .

- (i) A point $x \in X$ is called an interior point of E provided there is a neighborhood of x that is contained in E : the collection of interior points of E is called the interior of E and denoted by $\text{int } E$. Show that $\text{int } E$ is always open and E is open if and only if $E = \text{int } E$.
- (ii) A point $x \in X$ is called an exterior point of E provided there is a neighborhood of x that is contained in $X \sim E$: the collection of exterior points of E is called the exterior of E and denoted by $\text{ext } E$. Show that $\text{ext } E$ is always open and E is open if and only if $\overline{E} \sim E \subseteq \text{ext } E$.
- (iii) A point $x \in X$ is called a boundary point of E provided every neighborhood of x contains points in E and points in $X \sim E$: the collection of boundary points of E is called the boundary of E and denoted by $\text{bd } E$. Show that (i) $\text{bd } E$ is always closed, (ii) E is open if and only if $E \cap \text{bd } E = \emptyset$, and (iii) E is closed if and only if $\text{bd } E \subseteq E$.

Solution. Throughout, a neighborhood of a point means an open set containing that point.

Part (i). First, $\text{int } E \subseteq E$: if x is an interior point of E , some neighborhood U of x satisfies $x \in U \subseteq E$, so $x \in E$.

$\text{int } E$ is open. Let x belong to $\text{int } E$ and choose a neighborhood U of x with $U \subseteq E$. If y belongs to U , then U is itself a neighborhood of y contained in E , so y is an interior point of E . Hence $U \subseteq \text{int } E$, and U is a neighborhood of x contained in $\text{int } E$. Since x was an arbitrary point of $\text{int } E$, Proposition 1 tells us $\text{int } E$ is open.

If E is open, then for each x in E the set E itself is a neighborhood of x contained in E , so $E \subseteq \text{int } E$; with the reverse inclusion above, $E = \text{int } E$. Conversely, if $E = \text{int } E$, then E is open because $\text{int } E$ is open.

Part (ii). By definition $\text{ext } E = \text{int}(X \sim E)$: a point has a neighborhood contained in $X \sim E$ exactly when it is an interior point of $X \sim E$. Hence, by part (i) applied to the set $X \sim E$, the set $\text{ext } E$ is open.

Next observe

$$\text{ext } E \cap \overline{E} = \emptyset.$$

Indeed, if x belongs to $\text{ext } E$, there is a neighborhood U of x with $U \subseteq X \sim E$, that is, $U \cap E = \emptyset$; so x has a neighborhood containing no point of E and therefore x is not a point of closure of E .

Now consider the asserted criterion $\overline{E} \sim E \subseteq \text{ext } E$. Since $\overline{E} \sim E \subseteq \overline{E}$ and $\overline{E}$ is disjoint from $\text{ext } E$, the inclusion $\overline{E} \sim E \subseteq \text{ext } E$ holds if and only if $\overline{E} \sim E = \emptyset$, that is, if and only if $\overline{E} \subseteq E$. Since always $E \subseteq \overline{E}$, this says exactly $\overline{E} = E$, i.e. that E is closed. So what the stated inclusion characterizes is closedness, not openness: the word *open* in the printed statement should read *closed*.

That the statement as printed is false is shown by an example. In $X = \mathbb{R}$ with the Euclidean topology take $E = (0, 1)$. Then E is open, while $\overline{E} = [0, 1]$, so $\overline{E} \sim E = \{0, 1\}$, and 0 does not belong to $\text{ext } E$ because every neighborhood of 0 contains points of $(0, 1)$. Hence the inclusion $\overline{E} \sim E \subseteq \text{ext } E$ fails for this open set. Conversely the inclusion can hold for a set that is not open: take $E = [0, 1]$ in $\mathbb{R}$, for which $\overline{E} \sim E = \emptyset$.

Thus the correct assertion, which we have proved, is: $\text{ext } E$ is always open, and $\overline{E} \sim E \subseteq \text{ext } E$ if and only if E is closed.

Part (iii). We first record that X is the disjoint union

$$X = \text{int } E \cup \text{bd } E \cup \text{ext } E,$$

the three sets being pairwise disjoint. Indeed, a point x of X fails to be a boundary point exactly when some neighborhood of x contains no point of E (so $x \in \text{ext } E$) or some neighborhood of x contains no point of $X \sim E$, i.e. is contained in E (so $x \in \text{int } E$). Hence $\text{bd } E = X \sim (\text{int } E \cup \text{ext } E)$ and the three sets cover X . They are pairwise disjoint: $\text{bd } E$ is disjoint from the other two by what was just said; and if x belonged to $\text{int } E \cap \text{ext } E$ there would be neighborhoods $U \subseteq E$ and $V \subseteq X \sim E$ of x , whence $x \in U \cap V \subseteq E \cap (X \sim E) = \emptyset$, a contradiction.

(iii)(i) $\text{bd } E$ is closed. By the displayed identity, $X \sim \text{bd } E = \text{int } E \cup \text{ext } E$, which is the union of two open sets by parts (i) and (ii), hence open. By Proposition 4, a subset of X is closed if and only if its complement is open; therefore $\text{bd } E$ is closed.

(iii)(ii) E is open if and only if $E \cap \text{bd } E = \emptyset$. Suppose E is open. If x belongs to E , then E is a neighborhood of x contained in E , so $x \in \text{int } E$, and since $\text{int } E$ and $\text{bd } E$ are disjoint, $x \notin \text{bd } E$. Hence $E \cap \text{bd } E = \emptyset$. Conversely, suppose $E \cap \text{bd } E = \emptyset$ and let x belong to E . Then $x \notin \text{bd } E$ by hypothesis, and $x \notin \text{ext } E$ since $\text{ext } E \subseteq X \sim E$. By the trichotomy above, $x \in \text{int } E$. Thus $E \subseteq \text{int } E$, so $E = \text{int } E$ and E is open by part (i).

(iii)(iii) E is closed if and only if $\text{bd } E \subseteq E$. We claim $\overline{E} = \text{int } E \cup \text{bd } E$. Indeed, x belongs to $\overline{E}$ if and only if every neighborhood of x contains a point of E , that is, if and only if $x \notin \text{ext } E$; and by the trichotomy the complement of $\text{ext } E$ is $\text{int } E \cup \text{bd } E$. Since $\text{int } E \subseteq E \subseteq \overline{E}$, it follows that

$$\overline{E} = \text{int } E \cup \text{bd } E = E \cup \text{bd } E.$$

Hence E is closed, i.e. $\overline{E} = E$, if and only if $E \cup \text{bd } E = E$, which holds if and only if $\text{bd } E \subseteq E$.

Problem 11.6. Let A and B be subsets of a topological space X . Show that if $A \subseteq B$, then $\overline{A} \subseteq \overline{B}$. Also, show that $\overline{(A \cup B)} = \overline{A} \cup \overline{B}$ and $\overline{(A \cap B)} \subseteq \overline{A} \cap \overline{B}$.

Solution. Monotonicity. Suppose $A \subseteq B$ and let x belong to $\overline{A}$. Let U be any neighborhood of x . Since x is a point of closure of A , there is a point of A in U ; that point belongs to B as well, since $A \subseteq B$. So every neighborhood of x contains a point of B , that is, x belongs to $\overline{B}$. Hence $\overline{A} \subseteq \overline{B}$.

The union. Since $A \subseteq A \cup B$ and $B \subseteq A \cup B$, monotonicity gives $\overline{A} \subseteq \overline{A \cup B}$ and $\overline{B} \subseteq \overline{A \cup B}$, so

$$\overline{A} \cup \overline{B} \subseteq \overline{A \cup B}.$$

For the reverse inclusion, argue by contraposition. Let x be a point of X that does not belong to $\overline{A \cup B}$. Since $x \notin \overline{A}$ there is a neighborhood U of x with $U \cap A = \emptyset$, and since $x \notin \overline{B}$ there is a neighborhood V of x with $V \cap B = \emptyset$. Then $U \cap V$ is open, being the intersection of a finite collection of open sets, and it contains x ; thus $U \cap V$ is a neighborhood of x , and

$$(U \cap V) \cap (A \cup B) \subseteq (U \cap A) \cup (V \cap B) = \emptyset.$$

So some neighborhood of x misses $A \cup B$, whence $x \notin \overline{A \cup B}$. This proves $\overline{A \cup B} \subseteq \overline{A} \cup \overline{B}$, and therefore $\overline{(A \cup B)} = \overline{A} \cup \overline{B}$.

(Alternatively: by Proposition 3 the sets $\overline{A}$ and $\overline{B}$ are closed, so by Proposition 5 their union $\overline{A} \cup \overline{B}$ is closed, being the union of a finite collection of closed sets; it contains $A \cup B$, so by the minimality assertion of Proposition 3 it contains $\overline{A \cup B}$.)

The intersection. Since $A \cap B \subseteq A$ and $A \cap B \subseteq B$, monotonicity gives $\overline{A \cap B} \subseteq \overline{A}$ and $\overline{A \cap B} \subseteq \overline{B}$, hence

$$\overline{(A \cap B)} \subseteq \overline{A} \cap \overline{B}.$$

This inclusion can be strict, so no equality holds in general. For instance, in $\mathbb{R}$ with the Euclidean topology take $A = (0, 1)$ and $B = (1, 2)$. Then $A \cap B = \emptyset$, so $\overline{A \cap B} = \emptyset$, while $\overline{A} \cap \overline{B} = [0, 1] \cap [1, 2] = \{1\}$.

Problem 11.7. Let $\mathcal{O}$ be an open subset of a topological space X . For a subset E of X , show that $\mathcal{O}$ is disjoint from E if and only if it is disjoint from $\overline{E}$.

Solution. Suppose first that $\mathcal{O} \cap \overline{E} = \emptyset$. Since $E \subseteq \overline{E}$ (every point of E is a point of closure of E , because each of its neighborhoods contains the point itself), we get $\mathcal{O} \cap E \subseteq \mathcal{O} \cap \overline{E} = \emptyset$. So $\mathcal{O}$ is disjoint from E . Observe that openness of $\mathcal{O}$ was not needed here.

Conversely, suppose $\mathcal{O} \cap E = \emptyset$, and let x be a point of $\mathcal{O}$. Because $\mathcal{O}$ is open and contains x , the set $\mathcal{O}$ is a neighborhood of x ; and it contains no point of E , since $\mathcal{O} \cap E = \emptyset$. Thus x possesses a

neighborhood containing no point of E , so x is not a point of closure of E , that is, $x \notin \overline{E}$. As x was an arbitrary point of $\mathcal{O}$, we conclude $\mathcal{O} \cap \overline{E} = \emptyset$.

Therefore $\mathcal{O} \cap E = \emptyset$ if and only if $\mathcal{O} \cap \overline{E} = \emptyset$.

Equivalently, this says $\mathcal{O} \subseteq X \sim E$ implies $\mathcal{O} \subseteq X \sim \overline{E}$, i.e. $X \sim \overline{E}$ is the largest open subset of $X \sim E$; this is consistent with Proposition 3, which asserts that $\overline{E}$ is the smallest closed set containing E , and with Proposition 4, which identifies open sets as complements of closed sets.

11.2 Problems 11.8–11.14

Problem 11.8. For a collection $\mathcal{S}$ of subsets of a nonempty set X , show that there is a topology $\mathcal{T}$ on X that contains the collection $\mathcal{S}$ and has the property that any other topology that contains $\mathcal{S}$ also contains $\mathcal{T}$: it is the topology with the fewest sets that contains $\mathcal{S}$.

Solution. Let Σ denote the family of all topologies on X that contain $\mathcal{S}$. This family is nonempty: the discrete topology $\mathcal{P}(X)$, consisting of all subsets of X , is a topology on X and it certainly contains $\mathcal{S}$. Define

$$\mathcal{T} = \bigcap_{\mathcal{T}' \in \Sigma} \mathcal{T}',$$

the collection of those subsets of X that belong to every topology containing $\mathcal{S}$.

We claim $\mathcal{T}$ is a topology on X .

First, $\emptyset$ and X belong to every topology on X , hence to every member of Σ , hence to $\mathcal{T}$.

Second, let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be any collection of members of $\mathcal{T}$ and fix $\mathcal{T}' \in \Sigma$. Each $\mathcal{O}_\lambda$ belongs to $\mathcal{T}'$ by the definition of $\mathcal{T}$, and $\mathcal{T}'$ is a topology, so $\bigcup_{\lambda \in \Lambda} \mathcal{O}_\lambda$ belongs to $\mathcal{T}'$. Since $\mathcal{T}' \in \Sigma$ was arbitrary, $\bigcup_{\lambda \in \Lambda} \mathcal{O}_\lambda$ belongs to $\mathcal{T}$.

Third, let $\mathcal{O}_1, \dots, \mathcal{O}_n$ belong to $\mathcal{T}$ and fix $\mathcal{T}' \in \Sigma$. Each $\mathcal{O}_k$ belongs to $\mathcal{T}'$, and a topology is closed under finite intersections, so $\bigcap_{k=1}^n \mathcal{O}_k$ belongs to $\mathcal{T}'$. As $\mathcal{T}'$ was arbitrary, $\bigcap_{k=1}^n \mathcal{O}_k$ belongs to $\mathcal{T}$.

Therefore $\mathcal{T}$ is a topology on X .

Moreover $\mathcal{S} \subseteq \mathcal{T}$: if $S \in \mathcal{S}$, then S belongs to every $\mathcal{T}' \in \Sigma$ by the very definition of Σ , and hence $S \in \mathcal{T}$.

Finally, $\mathcal{T}$ has the asserted minimality. If $\mathcal{T}''$ is any topology on X with $\mathcal{S} \subseteq \mathcal{T}''$, then $\mathcal{T}'' \in \Sigma$, and an intersection of a family of sets is contained in each member of the family; thus $\mathcal{T} \subseteq \mathcal{T}''$. So $\mathcal{T}$ is contained in every topology containing $\mathcal{S}$, that is, it is the topology with the fewest sets that contains $\mathcal{S}$. Uniqueness is immediate: if $\mathcal{T}_1$ and $\mathcal{T}_2$ both contain $\mathcal{S}$ and both have this minimality property, then $\mathcal{T}_1 \subseteq \mathcal{T}_2$ and $\mathcal{T}_2 \subseteq \mathcal{T}_1$, so $\mathcal{T}_1 = \mathcal{T}_2$.

It is worth recording the concrete description of $\mathcal{T}$, since it is what one uses in practice. Let $\mathcal{S}_0 = \mathcal{S} \cup \{X\}$; this collection covers X . Let

$$\mathcal{B} = \{S_1 \cap S_2 \cap \dots \cap S_n : n \in \mathbb{N}, S_k \in \mathcal{S}_0\}$$

be the collection of intersections of finite subcollections of $\mathcal{S}_0$. Then $\mathcal{B}$ covers X (it contains X), and $\mathcal{B}$ is closed under finite intersection, so property (ii) of Proposition 2 holds trivially: if $B_1, B_2 \in \mathcal{B}$ and $x \in B_1 \cap B_2$, take $B = B_1 \cap B_2 \in \mathcal{B}$. By Proposition 2, $\mathcal{B}$ is a base for a topology $\mathcal{T}_{\mathcal{B}}$ on X , consisting of $\emptyset$ together with all unions of subcollections of $\mathcal{B}$. Clearly $\mathcal{S} \subseteq \mathcal{B} \subseteq \mathcal{T}_{\mathcal{B}}$. On the other hand, any topology $\mathcal{T}''$ containing $\mathcal{S}$ contains X , hence contains $\mathcal{S}_0$, hence contains $\mathcal{B}$ (closure under finite intersections), hence contains all unions of subcollections of $\mathcal{B}$ together with $\emptyset$, that is, $\mathcal{T}_{\mathcal{B}} \subseteq \mathcal{T}''$. Thus $\mathcal{T}_{\mathcal{B}}$ has exactly the minimality property proved above, and by the uniqueness just noted, $\mathcal{T} = \mathcal{T}_{\mathcal{B}}$. In other words, the smallest topology containing $\mathcal{S}$ is precisely the topology for which $\mathcal{S} \cup \{X\}$ is a subbase.

Problem 11.9. (The Sorgenfrey Line) Show that the collection of intervals of the form $[a, b)$, where $a < b$, is a base for a topology for the set of real numbers $\mathbb{R}$. The set of real numbers $\mathbb{R}$ with this topology is called the **Sorgenfrey Line**.

Solution. Let

$$\mathcal{B} = \{[a, b) : a, b \in \mathbb{R}, a < b\}.$$

By Proposition 2, it suffices to verify the two properties (i) and (ii) there.

(i) $\mathcal{B}$ covers $\mathbb{R}$. Let $x \in \mathbb{R}$. Then $x < x + 1$, so $[x, x + 1)$ belongs to $\mathcal{B}$, and $x \in [x, x + 1)$. Hence $\mathbb{R} = \bigcup_{B \in \mathcal{B}} B$.

(ii) Suppose $B_1 = [a, b)$ and $B_2 = [c, d)$ belong to $\mathcal{B}$ and $x \in B_1 \cap B_2$. Set

$$e = \max\{a, c\}, \quad f = \min\{b, d\}.$$

Since $x \in [a, b)$ we have $a \leq x < b$, and since $x \in [c, d)$ we have $c \leq x < d$. Consequently $e = \max\{a, c\} \leq x$ and $x < \min\{b, d\} = f$. In particular $e \leq x < f$, so $e < f$ and therefore $[e, f)$ belongs to $\mathcal{B}$ and contains x . Finally

$$[e, f) \subseteq [a, b) \quad \text{and} \quad [e, f) \subseteq [c, d),$$

because $a \leq e$ and $f \leq b$ give $[e, f) \subseteq [a, b)$, and $c \leq e$, $f \leq d$ give $[e, f) \subseteq [c, d)$. Thus $x \in [e, f) \subseteq B_1 \cap B_2$ with $[e, f) \in \mathcal{B}$, which is exactly property (ii).

By Proposition 2, $\mathcal{B}$ is a base for a (unique) topology on $\mathbb{R}$, namely the topology whose members are $\emptyset$ together with all unions of subcollections of $\mathcal{B}$. This is the Sorgenfrey Line.

Two remarks that identify the topology more concretely. Since

$$(a, b) = \bigcup_{n \geq N} [a + \frac{1}{n}, b)$$

for N large enough that $a + 1/N < b$, every Euclidean open interval is open in this topology; as the Euclidean open intervals form a base for the Euclidean topology on $\mathbb{R}$, the Sorgenfrey topology contains the Euclidean topology. The containment is strict, since $[0, 1)$ is not Euclidean open: no Euclidean neighborhood of the point 0 is contained in $[0, 1)$, because every such neighborhood contains points less than 0.

Problem 11.10. (The Moore Plane) Consider the upper half plane, $\mathbb{R}^{2,+} = \{(x, y) \in \mathbb{R}^2 \mid y \geq 0\}$. For points (x, y) with $y > 0$, take as a basic open neighborhood a usual Euclidean open ball centered at (x, y) and contained in the upper half plane. As a basic open neighborhood of a point $(x, 0)$ take the set consisting of the point itself and all the points in an open Euclidean ball in the upper half plane that is tangent to the real line at $(x, 0)$. Show that this collection of sets is a base. The set $\mathbb{R}^{2,+}$ with this topology is called the **Moore Plane**.

Solution. Write $B(p, r)$ for the usual Euclidean open ball in $\mathbb{R}^2$ of center p and radius $r > 0$. The described collection is $\mathcal{B} = \mathcal{B}_1 \cup \mathcal{B}_2$, where

$$\mathcal{B}_1 = \{B((x, y), r) : y > 0, 0 < r \leq y\},$$

$$\mathcal{B}_2 = \{T(x, r) := \{(x, 0)\} \cup B((x, r), r) : x \in \mathbb{R}, r > 0\}.$$

Here $\mathcal{B}_1$ is exactly the family of Euclidean balls centered at a point of positive height and contained in $\mathbb{R}^{2,+}$: indeed the points of $B((x, y), r)$ have second coordinate lying in $(y-r, y+r)$, so $B((x, y), r) \subseteq \mathbb{R}^{2,+}$ if and only if $r \leq y$. And $B((x, r), r)$ is the open ball lying in the open upper half plane and tangent to the real line at $(x, 0)$.

Two elementary observations will be used repeatedly.

(a) **Every set in $\mathcal{B}_1$ consists of points of positive height.** If $0 < r \leq y$ and $(u, v) \in B((x, y), r)$ then $|v - y| < r \leq y$, so $v > 0$.

(b) **Tangent balls at a fixed point of tangency are nested:** if $0 < r \leq s$ then $B((x, r), r) \subseteq B((x, s), s)$. Indeed, expanding the defining inequality,

$$(u, v) \in B((x, r), r) \iff (u - x)^2 + (v - r)^2 < r^2 \iff (u - x)^2 + v^2 < 2rv,$$

and the last inequality forces $v > 0$. Hence $(u - x)^2 + v^2 < 2rv \leq 2sv$, which is equivalent to

$(u - x)^2 + (v - s)^2 < s^2$, that is, $(u, v) \in B((x, s), s)$. Consequently $T(x, r) \subseteq T(x, s)$ whenever $0 < r \leq s$.

We verify the two conditions of Proposition 2 for $\mathcal{B}$ regarded as a collection of subsets of $X = \mathbb{R}^{2,+}$. Note first that each member of $\mathcal{B}$ is indeed a subset of $\mathbb{R}^{2,+}$, by the description of $\mathcal{B}_1$ above and by (b).

(i) $\mathcal{B}$ covers X . If $p = (x, y)$ with $y > 0$, then $p \in B((x, y), y) \in \mathcal{B}_1$. If $p = (x, 0)$, then $p \in T(x, 1) \in \mathcal{B}_2$.
(ii) The intersection condition. Let $B_1, B_2 \in \mathcal{B}$ and let $p \in B_1 \cap B_2$. We produce $B \in \mathcal{B}$ with $p \in B \subseteq B_1 \cap B_2$. There are two cases.

Case 1: $p = (x, y)$ with $y > 0$. For $i = 1, 2$ define a Euclidean open subset U_i of $\mathbb{R}^2$ containing p with $U_i \subseteq B_i$, as follows. If $B_i \in \mathcal{B}_1$, put $U_i = B_i$, which is a Euclidean open ball. If $B_i = T(x_i, r_i) \in \mathcal{B}_2$, then $p \neq (x_i, 0)$ because p has positive height, so $p \in B((x_i, r_i), r_i)$; put $U_i = B((x_i, r_i), r_i)$, again a Euclidean open ball, and $U_i \subseteq B_i$. In both cases U_i is Euclidean open and $p \in U_i \subseteq B_i$.

Since $U_1 \cap U_2$ is a Euclidean open set containing p , there is $\varepsilon > 0$ with $B(p, \varepsilon) \subseteq U_1 \cap U_2$. Put $r = \min\{\varepsilon, y\} > 0$. Then $B(p, r) \in \mathcal{B}_1$, since p has height $y > 0$ and $r \leq y$; moreover

$$p \in B(p, r) \subseteq B(p, \varepsilon) \subseteq U_1 \cap U_2 \subseteq B_1 \cap B_2.$$

So $B = B(p, r)$ works.

Case 2: $p = (x, 0)$. By observation (a), no member of $\mathcal{B}_1$ contains a point of height 0; hence neither B_1 nor B_2 lies in $\mathcal{B}_1$, and we may write $B_i = T(x_i, r_i)$ for $i = 1, 2$. Again by (b) the ball part $B((x_i, r_i), r_i)$ contains only points of positive height, so the only point of $T(x_i, r_i)$ of height 0 is $(x_i, 0)$. Since $p = (x, 0) \in T(x_i, r_i)$, we conclude $x_i = x$ for $i = 1, 2$. Thus $B_1 = T(x, r_1)$ and $B_2 = T(x, r_2)$. Put $r = \min\{r_1, r_2\} > 0$. By the nesting property (b), $T(x, r) \subseteq T(x, r_1)$ and $T(x, r) \subseteq T(x, r_2)$, so

$$p = (x, 0) \in T(x, r) \subseteq B_1 \cap B_2,$$

and $T(x, r) \in \mathcal{B}_2 \subseteq \mathcal{B}$. So $B = T(x, r)$ works.

Both conditions of Proposition 2 hold, so $\mathcal{B}$ is a base for a unique topology on $\mathbb{R}^{2,+}$, whose open sets are $\emptyset$ together with the unions of subcollections of $\mathcal{B}$. This is the Moore Plane.

Problem 11.11. (Kuratowski 14-subset problem)

- (i) Let E be a subset of a topological space X . Show that at most 14 different sets can be obtained from E by repeated use of complementation and closure.
- (ii) Give an example in $\mathbb{R}^2$ where there are 14 different sets coming from a suitable E .

Solution. Throughout, X is a topological space and, for $A \subseteq X$, we write

$$c(A) = X \sim A, \quad k(A) = \overline{A}, \quad i(A) = X \sim \overline{X \sim A} = ckc(A).$$

Operators are composed as functions, so in a word such as ckc the rightmost letter acts first. We freely use the following facts.

- $cc = \text{id}$, since $X \sim (X \sim A) = A$.
- $kk = k$, since $\overline{A}$ is closed and a closed set equals its own closure (Proposition 3).
- k is monotone: if $A \subseteq B$ then $\overline{A} \subseteq \overline{B}$ (Problem 6).
- $i(A)$ is the largest open subset of A : it is open because $\overline{X \sim A}$ is closed (Proposition 3) and complements of closed sets are open (Proposition 4); it is contained in A because $X \sim A \subseteq \overline{X \sim A}$; and if $\mathcal{O}$ is open with $\mathcal{O} \subseteq A$, then $X \sim \mathcal{O}$ is closed (Proposition 4) and contains $X \sim A$, so $\overline{X \sim A} \subseteq X \sim \mathcal{O}$ by Proposition 3, i.e. $\mathcal{O} \subseteq i(A)$. (This is the interior of Problem 5(i).)

(i) At most 14 sets.

Step 1: reduction to alternating words. Every set obtainable from E is $w(E)$ for some word w in the two letters c and k . Using $cc = \text{id}$ and $kk = k$ we may delete any pair of adjacent equal letters (replacing kk by k , deleting cc), which strictly shortens the word; iterating, every word equals an **alternating** word, one in which no two consecutive letters are equal. For each length $n \geq 1$ there are exactly two alternating words, one beginning with c and one beginning with k ; together with the empty word id this gives $1 + 2n$ words of length at most n .

Step 2: the Kuratowski identity $ckcckck = ckc$. We first prove:

Lemma. If U is open, then $\overline{i(\overline{U})} = \overline{U}$.

Proof. Since $i(\overline{U}) \subseteq \overline{U}$, monotonicity of closure and $kk = k$ give $\overline{i(\overline{U})} \subseteq \overline{\overline{U}} = \overline{U}$. Conversely, U is an open subset of $\overline{U}$, so by the maximality of the interior, $U \subseteq i(\overline{U})$; taking closures, $\overline{U} \subseteq \overline{i(\overline{U})}$. The two inclusions give the equality. $\square$

Now let $A \subseteq X$ be arbitrary and put $U = ck(A) = X \sim \overline{A}$, which is open by Proposition 4. Then $kck(A) = \overline{U}$, and since $kckc = k \circ (ckc) = k \circ i$,

$$kckckck(A) = (kckc)(kck(A)) = ki(\overline{U}) = \overline{i(\overline{U})} = \overline{U} = kck(A),$$

the fourth equality by the Lemma. Hence $kckckck = kck$ as operators.

Step 3: no alternating word of length ≥ 8 is needed. Multiplying the identity of Step 2 on the left and/or right by c and using $cc = \text{id}$:

$$kckckckc = kckc, \quad ckckckck = ckck.$$

Let w be an alternating word of length $n \geq 8$ and write $w = uv$, where u consists of the first (leftmost) eight letters. Since w alternates, u is either $kckckckc$ or $ckckckck$, so u equals a word u' of length 4 ($kckc$ or $ckck$, respectively). Then $w = u'v$ is a word of length $n - 4 < n$. By Step 1 it equals an alternating word of length at most $n - 4$. Induction on n shows every word equals an alternating word of length at most 7.

Step 4: the count. By Steps 1 and 3, every set obtainable from E is $w(E)$ for one of the alternating words of length at most 7, of which there are $1 + 2 \cdot 7 = 15$, namely

$$\text{id}, c, k, ck, kc, ckc, kck, ckck, kckc, ckckc, kckck, ckckck, kckckc, ckckckc, kckckck.$$

By Step 2 the last of these coincides with kck . Hence at most 14 distinct sets arise.

(ii) A subset of $\mathbb{R}^2$ realizing 14.

We first exhibit a subset of $\mathbb{R}$ realizing 14 and then transport it to $\mathbb{R}^2$.

Let

$$A = (0, 1) \cup (1, 2) \cup \{3\} \cup ([4, 5] \cap \mathbb{Q}) \subseteq \mathbb{R},$$

with the usual topology. Note that the words $\text{id}, k, ckc = i, ckck = ik, kckck = kik, kckc = ki, ckckckc = iki$ are seven of the fourteen words of Step 4, and prefixing each with c (and using $cc = \text{id}$) produces exactly the remaining seven. So the fourteen sets are the seven sets

$$A, \quad kA, \quad ikA, \quad kikA, \quad iA, \quad kiA, \quad ikiA$$

together with their complements. Computing directly:

$$\begin{aligned} A &= (0, 1) \cup (1, 2) \cup \{3\} \cup ([4, 5] \cap \mathbb{Q}), \\ kA &= [0, 2] \cup \{3\} \cup [4, 5], \\ ikA &= (0, 2) \cup (4, 5), \\ kikA &= [0, 2] \cup [4, 5], \\ iA &= (0, 1) \cup (1, 2), \\ kiA &= [0, 2], \\ ikiA &= (0, 2). \end{aligned}$$

(For kA : every point of $[0, 2]$ is a limit of points of $(0, 1) \cup (1, 2)$, and every point of $[4, 5]$ is a limit of rationals in $[4, 5]$. For iA : the sets $\{3\}$ and $[4, 5] \cap \mathbb{Q}$ have empty interior, since every interval about such a point meets the complement of A , and $1 \notin A$.)

These seven sets are pairwise distinct. Only A and kA contain the point 3, and these two differ because $1 \in kA$ while $1 \notin A$. Among the remaining five, exactly ikA and $kikA$ meet the interval $(4, 5)$, the other three being subsets of $[0, 2]$; and $ikA \neq kikA$ because $0 \in kikA \sim ikA$. Finally, among iA , kiA and $ikiA$: the point 1 belongs to kiA and to $ikiA$ but not to iA , so iA differs from the other two, and $0 \in kiA \sim ikiA$, so $kiA \neq ikiA$.

Furthermore no one of the seven equals the complement of another: each of the seven is a subset of $[0, 5]$, hence bounded, whereas the complement of a subset of $[0, 5]$ contains $(5, \infty)$ and is therefore unbounded. Consequently the fourteen sets are pairwise distinct, and A realizes the bound in $\mathbb{R}$.

Now set

$$E = A \times \mathbb{R} \subseteq \mathbb{R}^2,$$

with $\mathbb{R}^2$ carrying its usual topology. Write $\Phi(S) = S \times \mathbb{R}$ for $S \subseteq \mathbb{R}$. Then:

- Φ is injective: $S \times \mathbb{R} = S' \times \mathbb{R}$ forces $S = S'$.
- Φ commutes with complementation: $\mathbb{R}^2 \sim (S \times \mathbb{R}) = (\mathbb{R} \sim S) \times \mathbb{R}$.
- Φ commutes with closure: $\overline{S \times \mathbb{R}} = \overline{S} \times \mathbb{R}$. Indeed, the Euclidean balls $B((x, y), r)$, $r > 0$, form a base at (x, y) for the topology of $\mathbb{R}^2$, and for each $r > 0$,

$$B((x, y), r) \cap (S \times \mathbb{R}) \neq \emptyset \iff \text{there is } u \in S \text{ with } |u - x| < r.$$

For if (u, v) belongs to the left-hand intersection then $u \in S$ and $|u - x| < r$; conversely if $u \in S$ and $|u - x| < r$ then the point (u, y) lies in both $B((x, y), r)$ and $S \times \mathbb{R}$. Hence (x, y) is a point of closure of $S \times \mathbb{R}$ if and only if every $r > 0$ admits such a u , that is, if and only if x is a point of closure of S in $\mathbb{R}$. Thus $\overline{S \times \mathbb{R}} = \overline{S} \times \mathbb{R}$.

By induction on the length of a word w in c and k , these three properties give $w(E) = w(A) \times \mathbb{R} = \Phi(w(A))$ for every such w . Since the fourteen sets $w(A)$ are distinct and Φ is injective, the fourteen sets $w(E)$ are distinct. Thus $E = A \times \mathbb{R}$ is a subset of $\mathbb{R}^2$ from which exactly 14 different sets are obtained by repeated complementation and closure.

Problem 11.12. Show that if F is a closed subset of a normal space X , then the subspace F is normal. Is it necessary to assume that F is closed?

Solution. Recall that the subspace F of X carries the topology whose open sets are the sets $\mathcal{O} \cap F$ with $\mathcal{O}$ open in X , and that a space is normal provided it is Tychonoff and each two disjoint closed subsets can be separated by disjoint neighborhoods.

Step 1: F is Tychonoff. By Proposition 6, X is Tychonoff if and only if each singleton set is closed. Let $x \in F$. Since X is normal, hence Tychonoff, $\{x\}$ is closed in X , so $X \sim \{x\}$ is open in X (Proposition 4) and therefore $(X \sim \{x\}) \cap F = F \sim \{x\}$ is open in the subspace F . Thus $\{x\}$ is closed in F . By Proposition 6 applied to the space F , the subspace F is Tychonoff.

Step 2: closed subsets of the subspace F are closed in X . Let A be closed in the subspace F . Then $F \sim A$ is open in F , so $F \sim A = \mathcal{O} \cap F$ for some open $\mathcal{O} \subseteq X$. Hence

$$A = F \sim (\mathcal{O} \cap F) = F \cap (X \sim \mathcal{O}).$$

Both F and $X \sim \mathcal{O}$ are closed in X (the latter by Proposition 4, since $\mathcal{O}$ is open), and by Proposition 5 the intersection of closed sets is closed. Therefore A is closed in X . It is here, and only here, that the hypothesis that F is closed in X is used.

Step 3: separation. Let A and B be disjoint closed subsets of the subspace F . By Step 2 they are disjoint closed subsets of X . Since X is normal, there are disjoint open subsets $\mathcal{O}_1, \mathcal{O}_2$ of X with $A \subseteq \mathcal{O}_1$ and $B \subseteq \mathcal{O}_2$. Then $\mathcal{O}_1 \cap F$ and $\mathcal{O}_2 \cap F$ are open in the subspace F , they contain A and B respectively (as $A, B \subseteq F$), and

$$(\mathcal{O}_1 \cap F) \cap (\mathcal{O}_2 \cap F) \subseteq \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset.$$

So A and B are separated by disjoint neighborhoods in F . Together with Step 1, the subspace F is normal.

Is closedness necessary? Yes: normality is not hereditary, so the hypothesis cannot simply be deleted. Note first that no cheap counterexample is possible. If Y is any subspace of a normal space X , then Y is Tychonoff (the argument of Step 1 used nothing about F) and in fact regular: if C is closed in Y and $y \in Y \sim C$, write $C = C' \cap Y$ with C' closed in X ; then $y \notin C'$, and since a normal space is regular, there are disjoint open $\mathcal{O}_1 \ni y$ and $\mathcal{O}_2 \supseteq C'$ in X , whence $\mathcal{O}_1 \cap Y$ and $\mathcal{O}_2 \cap Y$ are disjoint neighborhoods of y and C in Y . So a counterexample must be a regular space that fails to be normal, and such spaces are necessarily somewhat elaborate.

The standard example is the **deleted Tychonoff plank**; producing it requires machinery from later in the book, which we cite explicitly. Let ω_1 denote the first uncountable ordinal and ω the first infinite ordinal, and give the ordinal intervals $[0, \omega_1]$ and $[0, \omega]$ their order topologies, that is, the topologies for which the rays $[0, \delta)$ and $(\gamma, \lambda]$ form a subbase, λ denoting the largest element of the interval in question. Each of these two spaces is Hausdorff: two distinct ordinals $\gamma < \delta$ of $[0, \lambda]$ are separated by the disjoint open sets $[0, \gamma + 1)$ and $(\gamma, \lambda]$. Each is also compact: if $\mathcal{U}$ is an open cover of a closed ordinal interval $[0, \lambda]$ and the set of $\mu \leq \lambda$ for which $[0, \mu]$ admits a finite subcover failed to contain λ , its complement in $[0, \lambda]$ would have a least element μ_0 ; a member U of $\mathcal{U}$ containing μ_0 contains a basic neighborhood of μ_0 , and every basic neighborhood of μ_0 , being a finite intersection of the subbasic rays, contains either $[0, \mu_0]$ or a set $(\gamma, \mu_0]$ with $\gamma < \mu_0$. In the first case U alone covers $[0, \mu_0]$; in the second, $\gamma < \mu_0$, so by the minimality of μ_0 the set $[0, \gamma]$ has a finite subcover, and adjoining U to it covers $[0, \gamma] \cup (\gamma, \mu_0] = [0, \mu_0]$. Either way we contradict the choice of μ_0 . Hence, by the Tychonoff Product Theorem of Section 12.2, the product

$$X = [0, \omega_1] \times [0, \omega]$$

with the product topology is compact, and it is Hausdorff, since two distinct points of a product differ in a coordinate and may be separated there. By Theorem 18 of Chapter 11, a compact Hausdorff space is normal, so X is normal. Let

$$T = X \sim \{(\omega_1, \omega)\},$$

an open, hence non-closed, subspace of X . Put

$$A = \{\omega_1\} \times [0, \omega), \quad B = [0, \omega_1] \times \{\omega\}.$$

These are disjoint, and each is closed in T , since $A = (\{\omega_1\} \times [0, \omega]) \cap T$ and $B = ([0, \omega_1] \times \{\omega\}) \cap T$ are intersections with T of closed subsets of X .

We claim A and B cannot be separated by disjoint neighborhoods in T ; hence T is not normal. Suppose U and V are open in T with $A \subseteq U$ and $B \subseteq V$. For each $n < \omega$ the point (ω_1, n) lies in U ; since $\{n\}$ is open in $[0, \omega]$ (each $n < \omega$ is an isolated point) and the intervals $(\alpha, \omega_1]$ form a base at ω_1 , there is an ordinal $\alpha_n < \omega_1$ with

$$(\alpha_n, \omega_1] \times \{n\} \subseteq U.$$

Let $\alpha = \sup_{n < \omega} \alpha_n$. A countable supremum of countable ordinals is again a countable ordinal, so $\alpha < \omega_1$. Choose any β with $\alpha < \beta < \omega_1$. Then $(\beta, n) \in U$ for every $n < \omega$.

On the other hand $(\beta, \omega) \in B \subseteq V$, and the sets $(\gamma, \beta] \times (m, \omega]$ with $\gamma < \beta$ and $m < \omega$ form a base at (β, ω) in the product topology; hence there are such γ and m with $(\gamma, \beta] \times (m, \omega] \subseteq V$. In particular $(\beta, m + 1) \in V$. But $(\beta, m + 1) \in U$ as well. So $U \cap V \neq \emptyset$, and no such disjoint pair exists.

Thus T is a non-normal subspace of the normal space X , and the hypothesis that F be closed cannot be dropped. (Of course closedness is not **necessary** for a particular subspace to be normal: every open subspace of $\mathbb{R}$, for instance, is metrizable and hence normal by Proposition 7. The point is that closedness cannot be omitted from the general theorem.)

Problem 11.13. Let X be a topological space. Show that X is Hausdorff if and only if the diagonal $D = \{(x_1, x_2) \in X \times X \mid x_1 = x_2\}$ is a closed subset of $X \times X$.

Solution. Give $X \times X$ the product topology, for which the collection

$$\mathcal{B} = \{\mathcal{O}_1 \times \mathcal{O}_2 : \mathcal{O}_1, \mathcal{O}_2 \text{ open in } X\}$$

is a base (the Example following Proposition 2). We use repeatedly the elementary equivalence

$$(\mathcal{O}_1 \times \mathcal{O}_2) \cap D = \emptyset \iff \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset,$$

which holds because $(\mathcal{O}_1 \times \mathcal{O}_2) \cap D = \{(z, z) : z \in \mathcal{O}_1 \cap \mathcal{O}_2\}$.

Suppose X is Hausdorff. By Proposition 4 it suffices to show $(X \times X) \sim D$ is open. Let (x_1, x_2) belong to $(X \times X) \sim D$, so that $x_1 \neq x_2$. By the Hausdorff separation property there are disjoint

neighborhoods $\mathcal{O}_1$ of x_1 and $\mathcal{O}_2$ of x_2 . Then $\mathcal{O}_1 \times \mathcal{O}_2$ is open in $X \times X$, contains (x_1, x_2) , and, since $\mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset$, the displayed equivalence gives $(\mathcal{O}_1 \times \mathcal{O}_2) \cap D = \emptyset$, that is,

$$(x_1, x_2) \in \mathcal{O}_1 \times \mathcal{O}_2 \subseteq (X \times X) \sim D.$$

Thus every point of $(X \times X) \sim D$ has an open neighborhood contained in $(X \times X) \sim D$, so $(X \times X) \sim D$ is the union of a collection of open sets and hence is open. By Proposition 4, D is closed.

Suppose D is closed. Let x_1 and x_2 be two distinct points of X . Then $(x_1, x_2) \notin D$, and by Proposition 4 the set $(X \times X) \sim D$ is open. Since $\mathcal{B}$ is a base for the product topology, there is a basic open set $\mathcal{O}_1 \times \mathcal{O}_2$ with

$$(x_1, x_2) \in \mathcal{O}_1 \times \mathcal{O}_2 \subseteq (X \times X) \sim D.$$

Thus $\mathcal{O}_1$ is a neighborhood of x_1 , $\mathcal{O}_2$ is a neighborhood of x_2 , and $(\mathcal{O}_1 \times \mathcal{O}_2) \cap D = \emptyset$; by the displayed equivalence, $\mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset$. Hence x_1 and x_2 are separated by disjoint neighborhoods. As $x_1 \neq x_2$ were arbitrary, X is Hausdorff.

Problem 11.14. Consider the set of real numbers with the topology consisting of the empty-set and sets of the form $(-\infty, c)$, $c \in \mathbb{R}$. Show that this space is Tychonoff but not Hausdorff.

Solution. Write $X = \mathbb{R}$ and

$$\mathcal{T} = \{\emptyset\} \cup \{(-\infty, c) : c \in \mathbb{R}\} \cup \{\mathbb{R}\}.$$

The whole set $\mathbb{R}$ must be adjoined, since $\mathbb{R} = \bigcup_{c \in \mathbb{R}} (-\infty, c)$ and a topology contains the unions of its members; with this understanding (one may think of $\mathbb{R}$ as the case $c = \infty$) the collection is indeed a topology:

- $\emptyset$ and $\mathbb{R}$ belong to $\mathcal{T}$.
- **Unions.** Let $\{(-\infty, c_\lambda)\}_{\lambda \in \Lambda}$ be a nonempty subfamily and put $s = \sup_\lambda c_\lambda \in (-\infty, \infty]$. If $s = \infty$, the union is $\mathbb{R}$; otherwise the union is $(-\infty, s)$, since $x < c_\lambda$ for some λ exactly when $x < s$. Adjoining $\emptyset$ or $\mathbb{R}$ to the family changes nothing. So $\mathcal{T}$ is closed under arbitrary unions.
- **Finite intersections.** $(-\infty, c_1) \cap (-\infty, c_2) = (-\infty, \min\{c_1, c_2\})$, and intersecting with $\emptyset$ or $\mathbb{R}$ again stays in $\mathcal{T}$.

The space is not Hausdorff. Any two nonempty members of $\mathcal{T}$ intersect: if $\mathcal{O}_1, \mathcal{O}_2$ are nonempty and open, each contains a half-line $(-\infty, c_i)$ with $c_i \in \mathbb{R}$ (taking c_i arbitrary if $\mathcal{O}_i = \mathbb{R}$), so $\mathcal{O}_1 \cap \mathcal{O}_2 \supseteq (-\infty, \min\{c_1, c_2\}) \neq \emptyset$. Hence no two points possess disjoint neighborhoods, and since X has more than one point, the Hausdorff separation property fails badly. (In particular, by Problem 13 the diagonal is not closed in $X \times X$.)

The Tychonoff separation property, as defined in this section, also fails; the exercise is misstated. Royden's Tychonoff separation property requires, for each two points u and v , a neighborhood of u not containing v **and** a neighborhood of v not containing u . Take $u < v$. Every neighborhood of v is either $\mathbb{R}$ or a set $(-\infty, c)$ with $c > v$, and in either case it contains u , since $u < v < c$. So there is no neighborhood of v that excludes u , and the Tychonoff separation property fails.

Equivalently, one may argue through Proposition 6, which says that X is Tychonoff if and only if every singleton is closed. Here no singleton is closed: for $x \in \mathbb{R}$ the set $\mathbb{R} \sim \{x\}$ is neither $\emptyset$, nor $\mathbb{R}$, nor a half-line $(-\infty, c)$ (it contains points $> x$ but not x), hence is not open, so $\{x\}$ is not closed by Proposition 4. In fact one computes the closures exactly:

$$\overline{\{x\}} = [x, \infty).$$

Indeed, if $y \geq x$ then every neighborhood of y is $\mathbb{R}$ or $(-\infty, c)$ with $c > y \geq x$, and so contains x ; thus y is a point of closure of $\{x\}$. If $y < x$, choose c with $y < c \leq x$; then $(-\infty, c)$ is a neighborhood of y missing x , so y is not a point of closure.

The conclusion is not an artifact of Royden's particular use of the word. Under the other common use, in which "Tychonoff" means completely regular, the space still fails: the only continuous real-valued functions on X are the constants. Indeed, suppose $f: X \rightarrow \mathbb{R}$ is continuous and $f(x_1) < f(x_2)$ for some x_1, x_2 ; choose t with $f(x_1) < t < f(x_2)$. The set $f^{-1}((t, \infty))$ is open, contains x_2 , and omits x_1 ,

so it is neither $\emptyset$ nor $\mathbb{R}$ and hence equals some $(-\infty, c)$ with $x_2 < c \leq x_1$, giving $x_2 < x_1$. The set $f^{-1}((-\infty, t))$ is open, contains x_1 , and omits x_2 , so by the same reasoning $x_1 < x_2$. This contradiction shows f is constant. Since the closed sets are $\emptyset$, $\mathbb{R}$ and the half-lines $[c, \infty)$, no constant function can separate the point y from the closed set $[c, \infty)$ when $y < c$.

What is true. The space does satisfy the weaker (Kolmogorov) separation condition: for each two distinct points $u < v$, there is an open set containing one of them and not the other, namely $(-\infty, v)$, which contains u and not v . This is presumably the intended content of the exercise: the space distinguishes points by open sets, yet it is not Hausdorff. Indeed, by the two paragraphs above, it is not even Tychonoff in the sense of this section. Note that this is consistent with the chain of inclusions

$$\mathcal{T}_{\text{metric}} \subseteq \mathcal{T}_{\text{normal}} \subseteq \mathcal{T}_{\text{regular}} \subseteq \mathcal{T}_{\text{Hausdorff}} \subseteq \mathcal{T}_{\text{Tychonoff}}$$

displayed in this section: a space that fails to be Tychonoff must fail to be Hausdorff, so the present space cannot serve as an example of a Tychonoff space that is not Hausdorff. For a genuine such example see Problem 15, the Zariski topology, in which singletons **are** closed while any two nonempty open sets meet.

11.3 Problems 11.15–11.21

Problem 11.15. (Zariski Topology) In $\mathbb{R}^n$ let $\mathcal{B}$ be the family of sets $\{x \in \mathbb{R}^n \mid p(x) \neq 0\}$, where p is a polynomial in n variables. Let $\mathcal{T}$ be the topology on X that has $\mathcal{B}$ as a subbase. Show that $\mathcal{T}$ is a topology for $\mathbb{R}^n$ that is Tychonoff but not Hausdorff.

Solution. Throughout, $n \geq 1$, and for a polynomial p in n real variables write

$$\mathcal{O}_p = \{x \in \mathbb{R}^n \mid p(x) \neq 0\},$$

so that $\mathcal{B} = \{\mathcal{O}_p \mid p \text{ a polynomial}\}$.

Step 1: $\mathcal{B}$ is in fact a base, and $\mathcal{T}$ is the collection of unions of members of $\mathcal{B}$.

By Proposition 2, a collection $\mathcal{B}$ of subsets of a set X is a base for a topology on X provided $\mathcal{B}$ covers X and, for B_1, B_2 in $\mathcal{B}$ and $x \in B_1 \cap B_2$, there is $B \in \mathcal{B}$ with $x \in B \subseteq B_1 \cap B_2$. Both hold here. For the covering property, take p to be the constant polynomial 1; then $\mathcal{O}_p = \mathbb{R}^n$. For the intersection property, observe that for polynomials p, q ,

$$\mathcal{O}_p \cap \mathcal{O}_q = \{x \mid p(x) \neq 0 \text{ and } q(x) \neq 0\} = \{x \mid p(x)q(x) \neq 0\} = \mathcal{O}_{pq},$$

since a product of two real numbers is nonzero if and only if both factors are nonzero, and pq is again a polynomial. Thus $\mathcal{B}$ is closed under finite intersections, and one may take $B = B_1 \cap B_2$.

Consequently, by the remark following the definition of subbase in Section 11.1, the collection $\mathcal{B}$, which covers $\mathbb{R}^n$, is a subbase for a unique topology $\mathcal{T}$, obtained by first forming intersections of finite subcollections of $\mathcal{B}$ — which by the displayed identity gives back $\mathcal{B}$ itself — and then taking $\emptyset$ together with all unions of subcollections. So

$$\mathcal{T} = \left\{ \bigcup_{\lambda \in \Lambda} \mathcal{O}_{p_\lambda} \mid \{p_\lambda\}_{\lambda \in \Lambda} \text{ a family of polynomials} \right\}.$$

That this is a topology is immediate. The empty set is the union of the empty family, and also $\emptyset = \mathcal{O}_0$; the whole space is $\mathbb{R}^n = \mathcal{O}_1$; a union of sets of the displayed form is again of that form; and the intersection of two of them is

$$\left(\bigcup_{\lambda} \mathcal{O}_{p_\lambda} \right) \cap \left(\bigcup_{\mu} \mathcal{O}_{q_\mu} \right) = \bigcup_{\lambda, \mu} (\mathcal{O}_{p_\lambda} \cap \mathcal{O}_{q_\mu}) = \bigcup_{\lambda, \mu} \mathcal{O}_{p_\lambda q_\mu} \in \mathcal{T}.$$

Hence $\mathcal{T}$ is a topology for $\mathbb{R}^n$. Equivalently, the closed sets of $\mathcal{T}$ are exactly the intersections of zero sets of polynomials.

Step 2: a polynomial that vanishes at every point of $\mathbb{R}^n$ is the zero polynomial.

Argue by induction on n . For $n = 1$ a nonzero polynomial of degree d has at most d real roots, while $\mathbb{R}$ is infinite. Assume the claim for $n - 1$ and write

$$p(x_1, \dots, x_n) = \sum_{k=0}^d c_k(x_1, \dots, x_{n-1}) x_n^k$$

with each c_k a polynomial in $n - 1$ variables. Fix $(x_1, \dots, x_{n-1}) \in \mathbb{R}^{n-1}$. Then $t \mapsto p(x_1, \dots, x_{n-1}, t)$ is a one-variable polynomial vanishing for all real t , so each $c_k(x_1, \dots, x_{n-1}) = 0$ by the case $n = 1$. Since $(x_1, \dots, x_{n-1})$ was arbitrary, each c_k vanishes identically on $\mathbb{R}^{n-1}$, hence each c_k is the zero polynomial by the inductive hypothesis, and therefore so is p . In particular, if p is not the zero polynomial then $\mathcal{O}_p \neq \emptyset$.

Step 3: if p and q are nonzero polynomials, then $\mathcal{O}_{pq} \neq \emptyset$.

By Step 2 choose $a, b \in \mathbb{R}^n$ with $p(a) \neq 0$ and $q(b) \neq 0$. If $p(b) \neq 0$ we are done, since then $(pq)(b) \neq 0$. So assume $p(b) = 0$; since $p(a) \neq 0$ this forces $a \neq b$, and we may restrict attention to the line through a and b , setting

$$s(t) = p(a + t(b - a)), \quad r(t) = q(a + t(b - a)).$$

These are polynomials in the single real variable t , and $s(0) = p(a) \neq 0$, $r(1) = q(b) \neq 0$, so neither is the zero polynomial. Hence sr is a nonzero one-variable polynomial (the degree of a product of nonzero one-variable real polynomials is the sum of the degrees, because the product of the leading coefficients is nonzero), so sr has only finitely many roots and there is t_0 with $s(t_0)r(t_0) \neq 0$. The point $x_0 = a + t_0(b - a)$ then satisfies $(pq)(x_0) \neq 0$.

Step 4: $(\mathbb{R}^n, \mathcal{T})$ is Tychonoff.

By Proposition 6 it suffices to show each singleton is closed. Let $x_0 = (a_1, \dots, a_n)$. For $1 \leq i \leq n$ let $p_i(x) = x_i - a_i$. A point x fails to equal x_0 exactly when $x_i \neq a_i$ for some i , so

$$\mathbb{R}^n \sim \{x_0\} = \bigcup_{i=1}^n \mathcal{O}_{p_i},$$

a union of members of $\mathcal{B}$ and hence open. Therefore $\{x_0\}$ is closed and, by Proposition 6, $\mathcal{T}$ has the Tychonoff separation property. (Concretely, given $u \neq v$, the set $\mathbb{R}^n \sim \{v\}$ is a neighborhood of u not containing v , and symmetrically.)

Step 5: $(\mathbb{R}^n, \mathcal{T})$ is not Hausdorff.

We show more: any two nonempty open sets meet. Let $\mathcal{U}$ and $\mathcal{V}$ be nonempty members of $\mathcal{T}$, say $u \in \mathcal{U}$ and $v \in \mathcal{V}$. Since $\mathcal{B}$ is a base there are polynomials p and q with

$$u \in \mathcal{O}_p \subseteq \mathcal{U}, \quad v \in \mathcal{O}_q \subseteq \mathcal{V}.$$

Since $p(u) \neq 0$ and $q(v) \neq 0$, neither p nor q is the zero polynomial, so by Step 3

$$\emptyset \neq \mathcal{O}_{pq} = \mathcal{O}_p \cap \mathcal{O}_q \subseteq \mathcal{U} \cap \mathcal{V}.$$

Now take any two distinct points $u \neq v$ of $\mathbb{R}^n$, which is possible since $n \geq 1$. Every neighborhood of u and every neighborhood of v is a nonempty open set, so any two such neighborhoods meet. Hence u and v cannot be separated by disjoint neighborhoods, and $\mathcal{T}$ is not Hausdorff.

Thus the Zariski topology on $\mathbb{R}^n$ is Tychonoff but not Hausdorff. In particular it witnesses that the inclusion of the Hausdorff topologies in the Tychonoff topologies, in the string of inclusions displayed in Section 11.2, is strict.

Problem 11.16. Show the Sorgenfrey Line and the Moore Plane are Hausdorff (see Problems 9 and 10).

Solution. Recall the two spaces. The Sorgenfrey Line is $\mathbb{R}$ with the topology having as a base the collection of intervals $[a, b)$ with $a < b$ (Problem 9). The Moore Plane is the closed upper half plane

$\mathbb{R}^{2,+} = \{(x, y) \in \mathbb{R}^2 \mid y \geq 0\}$ with the topology having as a base the following sets (Problem 10): for a point (x, y) with $y > 0$, the ordinary Euclidean open balls $B((x, y), r)$ centered at (x, y) and contained in $\mathbb{R}^{2,+}$, which are exactly those with $0 < r \leq y$: for such r every point of the ball has second coordinate greater than $y - r \geq 0$, so the ball even lies in the open upper half plane, while if $r > y$ one may choose s with $y < s < r$ and then $(x, y - s)$ belongs to the ball but has negative second coordinate. And for a point $(x, 0)$ on the horizontal axis, the sets

$$N_r(x) = \{(x, 0)\} \cup B((x, r), r), \quad r > 0,$$

that is, the point itself together with the open Euclidean disc of radius r lying in the upper half plane and tangent to the real line at $(x, 0)$. Here $B(c, r)$ denotes the open Euclidean ball of $\mathbb{R}^2$ with center c and radius r , and $|\cdot|$ denotes the Euclidean norm.

The Sorgenfrey Line.

Let u and v be distinct real numbers; without loss of generality $u < v$. Consider the basic open sets

$$\mathcal{U} = [u, v), \quad \mathcal{V} = [v, v + 1).$$

Then $u \in \mathcal{U}$ and $v \in \mathcal{V}$, and $\mathcal{U} \cap \mathcal{V} = \emptyset$ since every point of $\mathcal{U}$ is strictly less than v while every point of $\mathcal{V}$ is at least v . Thus u and v are separated by disjoint neighborhoods, and the Sorgenfrey Line is Hausdorff.

The Moore Plane.

Let $p \neq q$ be points of $\mathbb{R}^{2,+}$ and put $d = |p - q| > 0$. We first record an estimate for the tangent discs: if $z \in N_r(x)$ then

$$|z - (x, 0)| \leq |z - (x, r)| + |(x, r) - (x, 0)| < r + r = 2r$$

when $z \in B((x, r), r)$, and $|z - (x, 0)| = 0$ when $z = (x, 0)$. Hence

$$N_r(x) \subseteq B((x, 0), 2r) \quad \text{for every } r > 0. \quad (*)$$

Also note that if $A \subseteq B(p, \rho)$ and $C \subseteq B(q, \sigma)$ with $\rho + \sigma \leq d$, then $A \cap C = \emptyset$: a common point z would give $d = |p - q| \leq |p - z| + |z - q| < \rho + \sigma \leq d$, a contradiction. We use this repeatedly with $\rho = \sigma = d/2$.

Case 1: both points lie off the axis, say $p = (a, s)$ and $q = (b, t)$ with $s > 0$ and $t > 0$. Put

$$\rho = \min\{d/2, s\}, \quad \sigma = \min\{d/2, t\}.$$

Then $B(p, \rho)$ and $B(q, \sigma)$ are basic open sets of the Moore Plane containing p and q respectively (their radii do not exceed the second coordinates of their centers, so they lie in the open upper half plane), and since $\rho + \sigma \leq d/2 + d/2 = d$ they are disjoint.

Case 2: $p = (a, 0)$ lies on the axis and $q = (b, t)$ with $t > 0$. Choose $r = d/4$ and $\sigma = \min\{d/2, t\}$. By $(*)$, $N_r(a) \subseteq B(p, 2r) = B(p, d/2)$, while $B(q, \sigma) \subseteq B(q, d/2)$. Since $d/2 + d/2 = d$, the observation above gives

$$N_r(a) \cap B(q, \sigma) = \emptyset.$$

These are basic open sets containing p and q respectively.

Case 3: both points lie on the axis, say $p = (a, 0)$ and $q = (b, 0)$ with $a \neq b$, so $d = |a - b|$. Put $r = d/2$ and consider the tangent discs $N_r(a)$ and $N_r(b)$. Their discs $B((a, r), r)$ and $B((b, r), r)$ have centers at Euclidean distance $|a - b| = d = r + r$, so they are disjoint: a common point z would give $2r = |(a, r) - (b, r)| \leq |(a, r) - z| + |z - (b, r)| < r + r$, a contradiction. Moreover $(a, 0) \notin B((b, r), r)$, because $|(a, 0) - (b, r)| = \sqrt{d^2 + r^2} > r$; symmetrically $(b, 0) \notin B((a, r), r)$; and $(a, 0) \neq (b, 0)$. Assembling,

$$N_r(a) \cap N_r(b) = \emptyset,$$

and these are basic open sets containing p and q respectively.

In every case p and q have disjoint neighborhoods, so the Moore Plane is Hausdorff.

Problem 11.17. A topological space is said to be a Lindelof space or to have the Lindelof property provided each open cover of X has a countable subcover. Show that if X is second countable, then it is Lindelof.

Solution. Let X be second countable, and let $\{\mathcal{B}_n\}_{n=1}^\infty$ be a countable base for the topology of X . Let $\mathcal{F}$ be an open cover of X ; we must extract a countable subcover.

Let

$$N = \{n \in \mathbb{N} \mid \text{there is some } \mathcal{U} \in \mathcal{F} \text{ with } \mathcal{B}_n \subseteq \mathcal{U}\}.$$

For each $n \in N$ use the countable axiom of choice to select one member $\mathcal{U}_n \in \mathcal{F}$ with $\mathcal{B}_n \subseteq \mathcal{U}_n$. The collection

$$\mathcal{F}' = \{\mathcal{U}_n \mid n \in N\}$$

is a subcollection of $\mathcal{F}$ indexed by a subset of $\mathbb{N}$, hence is countable. We claim it covers X .

Indeed, let $x \in X$. Since $\mathcal{F}$ is a cover of X there is $\mathcal{U} \in \mathcal{F}$ with $x \in \mathcal{U}$. Since $\mathcal{U}$ is open and $\{\mathcal{B}_n\}$ is a base for the topology, by the definition of a base there is an index n with

$$x \in \mathcal{B}_n \subseteq \mathcal{U}.$$

The existence of this $\mathcal{U}$ witnesses that $n \in N$, so $\mathcal{U}_n$ is defined and $\mathcal{B}_n \subseteq \mathcal{U}_n$. Therefore

$$x \in \mathcal{B}_n \subseteq \mathcal{U}_n \in \mathcal{F}'.$$

Since $x \in X$ was arbitrary, $\mathcal{F}'$ is a countable subcover of $\mathcal{F}$. Hence X is a Lindelof space.

(The same argument shows a little more: from any base $\mathcal{B}$ for the topology one gets a subcover indexed by a subset of $\mathcal{B}$, so a space with a base of cardinality κ has the property that every open cover admits a subcover of cardinality at most κ .)

Problem 11.18. Let X be an uncountable set of points, and let $\mathcal{T}$ consist of $\emptyset$ and all subsets of X that have finite complements. Show that $\mathcal{T}$ is a topology for X and that the space $(X, \mathcal{T})$ is not first countable.

Solution. This $\mathcal{T}$ is the so-called finite complement, or cofinite, topology.

Part 1: $\mathcal{T}$ is a topology.

By definition $\emptyset \in \mathcal{T}$. Also $X \in \mathcal{T}$, since $X \sim X = \emptyset$ is finite.

Closure under arbitrary unions. Let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be a family of members of $\mathcal{T}$ and put $\mathcal{O} = \bigcup_\lambda \mathcal{O}_\lambda$. If every $\mathcal{O}_\lambda$ is empty (in particular if $\Lambda = \emptyset$), then $\mathcal{O} = \emptyset \in \mathcal{T}$. Otherwise fix λ_0 with $\mathcal{O}_{\lambda_0} \neq \emptyset$, so that $X \sim \mathcal{O}_{\lambda_0}$ is finite. By De Morgan's identities,

$$X \sim \mathcal{O} = \bigcap_{\lambda \in \Lambda} (X \sim \mathcal{O}_\lambda) \subseteq X \sim \mathcal{O}_{\lambda_0},$$

and a subset of a finite set is finite. Hence $X \sim \mathcal{O}$ is finite and $\mathcal{O} \in \mathcal{T}$.

Closure under finite intersections. It suffices to treat two sets $\mathcal{O}_1, \mathcal{O}_2 \in \mathcal{T}$. If either is empty then $\mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset \in \mathcal{T}$. Otherwise both complements are finite and

$$X \sim (\mathcal{O}_1 \cap \mathcal{O}_2) = (X \sim \mathcal{O}_1) \cup (X \sim \mathcal{O}_2)$$

is a union of two finite sets, hence finite; so $\mathcal{O}_1 \cap \mathcal{O}_2 \in \mathcal{T}$.

Therefore $\mathcal{T}$ is a topology for X .

Part 2: $(X, \mathcal{T})$ is not first countable.

We show that no point of X has a countable base of neighborhoods; in particular X is not first countable.

Fix $x \in X$ and suppose, to get a contradiction, that $\{\mathcal{B}_n\}_{n=1}^\infty$ is a countable base at x : each $\mathcal{B}_n$ is an open set containing x , and every open set containing x contains some $\mathcal{B}_n$.

Since $x \in \mathcal{B}_n$, each $\mathcal{B}_n$ is nonempty, so by the definition of $\mathcal{T}$ the set $F_n = X \sim \mathcal{B}_n$ is finite. Put

$$F = \bigcup_{n=1}^{\infty} F_n.$$

A countable union of finite sets is countable (Chapter 1, Corollary 6), so F is countable, and hence so is $F \cup \{x\}$. Since X is uncountable, $X \sim (F \cup \{x\})$ is nonempty; choose a point y in it. Thus $y \neq x$ and $y \notin F_n$, that is $y \in \mathcal{B}_n$, for every n .

Now consider $\mathcal{O} = X \sim \{y\}$. Its complement $\{y\}$ is finite, so $\mathcal{O} \in \mathcal{T}$, and $x \in \mathcal{O}$ because $y \neq x$. Since $\{\mathcal{B}_n\}$ is a base at x , there must be an index n with

$$x \in \mathcal{B}_n \subseteq \mathcal{O} = X \sim \{y\},$$

which forces $y \notin \mathcal{B}_n$. This contradicts the fact that y belongs to every $\mathcal{B}_n$.

Hence there is no countable base at x , and $(X, \mathcal{T})$ is not first countable at any of its points. Since second countable spaces are first countable, $(X, \mathcal{T})$ is not second countable either. Observe also that $(X, \mathcal{T})$ is Tychonoff: each singleton $\{z\}$ is closed because its complement $X \sim \{z\}$ has the finite complement $\{z\}$ and so is open, and Proposition 6 applies. It is not Hausdorff, since any two nonempty open sets meet: their complements are finite while X is infinite, so the complement of their intersection is finite and the intersection cannot be empty.

Problem 11.19. Show that a second countable space is separable and every subspace of a second countable space is second countable.

Solution. Let X be a second countable topological space and let $\{\mathcal{B}_n\}_{n \in N}$, with $N \subseteq \mathbb{N}$, be a countable base for its topology. Discarding those $\mathcal{B}_n$ that are empty changes nothing (a base remains a base after deleting the empty set, since the empty set contains no point and so is never needed to exhibit a point inside an open set), so we may and do assume every $\mathcal{B}_n$ is nonempty.

Part 1: X is separable.

For each $n \in N$ use the countable axiom of choice to select a point $x_n \in \mathcal{B}_n$, and set

$$E = \{x_n \mid n \in N\}.$$

Then E is countable, being the image of the countable set N . We claim E is dense in X , that is, every nonempty open subset of X contains a point of E .

Let $\mathcal{O}$ be a nonempty open subset of X and pick $x \in \mathcal{O}$. Since $\{\mathcal{B}_n\}$ is a base, there is $n \in N$ with $x \in \mathcal{B}_n \subseteq \mathcal{O}$. Then $x_n \in \mathcal{B}_n \subseteq \mathcal{O}$, so $\mathcal{O}$ contains the point x_n of E . Hence E is dense and X is separable.

(Equivalently, in the language of the text: every point of X is a point of closure of E , so $\overline{E} = X$. Indeed if $x \in X$ and $\mathcal{U}$ is any neighborhood of x , the argument just given produces a point of E in $\mathcal{U}$.)

Part 2: every subspace of X is second countable.

Let $Y \subseteq X$ carry the subspace topology, whose open sets are exactly the sets $\mathcal{O} \cap Y$ with $\mathcal{O}$ open in X . Define

$$\mathcal{B}'_n = \mathcal{B}_n \cap Y \quad (n \in N).$$

Each $\mathcal{B}'_n$ is open in Y , and $\{\mathcal{B}'_n\}_{n \in N}$ is a countable collection. We claim it is a base for the subspace topology of Y .

Let $\mathcal{V}$ be open in Y and let $y \in \mathcal{V}$. Write $\mathcal{V} = \mathcal{O} \cap Y$ with $\mathcal{O}$ open in X . Then $y \in \mathcal{O}$, so since $\{\mathcal{B}_n\}$ is a base for X there is $n \in N$ with $y \in \mathcal{B}_n \subseteq \mathcal{O}$. Intersecting with Y and using $y \in Y$,

$$y \in \mathcal{B}_n \cap Y = \mathcal{B}'_n \subseteq \mathcal{O} \cap Y = \mathcal{V}.$$

Thus every open subset of Y is a union of members of $\{\mathcal{B}'_n\}$, so this countable collection is a base for the topology of Y , and Y is second countable.

Remark. Separability, unlike second countability, is not inherited by subspaces: Problem 20 exhibits the Moore Plane, which is separable, together with its subspace $\mathbb{R} \times \{0\}$, which is not. Combined with Part 2 this gives another proof that the Moore Plane is not second countable.

Problem 11.20. Show that the Moore Plane is separable (see Problem 10). Show that the subspace $\mathbb{R} \times \{0\}$ of the Moore Plane is not separable. Conclude that the Moore Plane is not metrizable and not second countable.

Solution. Recall from Problem 10 that the Moore Plane is $\mathbb{R}^{2,+} = \{(x, y) \in \mathbb{R}^2 \mid y \geq 0\}$ with the base consisting of: the Euclidean open balls $B((x, y), r)$ with $y > 0$ and $0 < r \leq y$ (these are precisely the Euclidean balls centered at (x, y) and contained in $\mathbb{R}^{2,+}$, and each of them in fact lies in the open upper half plane); and, for each $x \in \mathbb{R}$ and $r > 0$, the tangent-disc sets

$$N_r(x) = \{(x, 0)\} \cup B((x, r), r).$$

Here $B(c, \rho)$ is the ordinary Euclidean open disc.

Part 1: the Moore Plane is separable.

Let

$$E = \{(p, q) \mid p, q \in \mathbb{Q}, q > 0\},$$

the set of points with rational coordinates lying strictly above the axis. Being in one-to-one correspondence with a subset of $\mathbb{Q} \times \mathbb{Q}$, the set E is countable.

We check E is dense, that is, meets every nonempty open set; since every nonempty open set contains a basic open set, it suffices to check the two kinds of basic sets. Note first that if $\mathcal{D}$ is any nonempty open subset of $\mathbb{R}^2$ (in the Euclidean topology) contained in the open upper half plane, then $\mathcal{D}$ contains a point of E : $\mathcal{D}$ contains a Euclidean ball, and $\mathbb{Q} \times \mathbb{Q}$ is dense in the Euclidean plane, so $\mathcal{D}$ contains a point (p, q) with p, q rational, and $q > 0$ because $\mathcal{D}$ lies in the open upper half plane.

Now, a basic set $B((x, y), r)$ with $y > 0$ and $r \leq y$ is a nonempty Euclidean open set contained in the open upper half plane, so it meets E . A basic set $N_r(x)$ contains the Euclidean open disc $B((x, r), r)$, which is nonempty and lies in the open upper half plane (if $|z - (x, r)| < r$ and $z = (z_1, z_2)$ then $|z_2 - r| < r$, so $z_2 > 0$); hence $N_r(x)$ meets E as well.

So every nonempty open subset of the Moore Plane contains a point of E ; equivalently every point of $\mathbb{R}^{2,+}$ is a point of closure of E , so $\overline{E} = \mathbb{R}^{2,+}$. Thus the Moore Plane is separable.

Part 2: the subspace $L = \mathbb{R} \times \{0\}$ is not separable.

We claim the subspace topology that L inherits from the Moore Plane is the discrete topology. Fix $a \in \mathbb{R}$ and consider the basic open set $N_1(a) = \{(a, 0)\} \cup B((a, 1), 1)$. As noted above, every point of $B((a, 1), 1)$ has strictly positive second coordinate, so $B((a, 1), 1) \cap L = \emptyset$ and therefore

$$N_1(a) \cap L = \{(a, 0)\}.$$

Since $N_1(a)$ is open in the Moore Plane, $\{(a, 0)\}$ is open in the subspace L . As a was arbitrary, every singleton of L is open in L , so every subset of L is open in L ; the subspace topology on L is discrete. Now let $D \subseteq L$ be dense in L . For each $a \in \mathbb{R}$ the set $\{(a, 0)\}$ is a nonempty open subset of L , so it must contain a point of D ; that forces $(a, 0) \in D$. Hence $D = L$. So the only dense subset of L is L itself, and L is uncountable, being in one-to-one correspondence with $\mathbb{R}$. Therefore L has no countable dense subset: L is not separable.

Part 3: the Moore Plane is not second countable.

Suppose it were. By Problem 19, every subspace of a second countable space is second countable, so L would be second countable; and, again by Problem 19, a second countable space is separable, so L would be separable. This contradicts Part 2. Hence the Moore Plane is not second countable.

(One can see the failure directly: if $\{\mathcal{B}_n\}$ were a countable base, then for each $a \in \mathbb{R}$ there is an index $n(a)$ with $(a, 0) \in \mathcal{B}_{n(a)} \subseteq N_1(a)$; since $N_1(a) \cap L = \{(a, 0)\}$, the point $(a, 0)$ is the only point of L in $\mathcal{B}_{n(a)}$, so $a \mapsto n(a)$ is one-to-one on $\mathbb{R}$, which is impossible for an uncountable $\mathbb{R}$ and a countable index set.)

Part 4: the Moore Plane is not metrizable.

Suppose the topology of the Moore Plane were induced by a metric ρ . By Part 1 the space is separable, and in Chapter 9 it was proved that a metric space is second countable if and only if it is separable. Hence the Moore Plane would be second countable, contradicting Part 3. Therefore the Moore Plane is not metrizable.

(Alternatively, without invoking Part 3: if the topology were induced by a metric ρ , then the subspace L would carry the topology induced by the restriction of ρ , so L would be a metric space; by Part 1 and the Chapter 9 result the Moore Plane would be second countable, hence L would be second countable by Problem 19 and therefore separable, again contradicting Part 2.)

Problem 11.21. Show that the Sorgenfrey Line is first countable but not second countable and yet the rationals are dense (see Problem 9). Conclude that the Sorgenfrey Line is not metrizable.

Solution. By Problem 9 the Sorgenfrey Line is the set $\mathbb{R}$ with the topology $\mathcal{T}$ having as a base the collection

$$\mathcal{B} = \{[a, b) \mid a, b \in \mathbb{R}, a < b\}.$$

Thus a set is open exactly when it is a union of such half-open intervals; equivalently, $\mathcal{O}$ is open if and only if for each $x \in \mathcal{O}$ there is $\varepsilon > 0$ with $[x, x + \varepsilon) \subseteq \mathcal{O}$.

Part 1: the Sorgenfrey Line is first countable.

Fix $x \in \mathbb{R}$ and consider the countable collection of open sets

$$\mathcal{B}_x = \left\{ \left[x, x + \frac{1}{n} \right) \mid n \in \mathbb{N} \right\},$$

each of which contains x . We claim $\mathcal{B}_x$ is a base at x . Let $\mathcal{U}$ be any neighborhood of x . Since $\mathcal{B}$ is a base for $\mathcal{T}$, there are $a < b$ with $x \in [a, b) \subseteq \mathcal{U}$; in particular $a \leq x < b$, so $b - x > 0$. By the Archimedean property choose $n \in \mathbb{N}$ with $1/n \leq b - x$, that is $x + 1/n \leq b$. Then

$$x \in \left[x, x + \frac{1}{n} \right) \subseteq [a, b) \subseteq \mathcal{U},$$

the middle inclusion because $a \leq x$ and $x + 1/n \leq b$. So every neighborhood of x contains a member of $\mathcal{B}_x$ that contains x , and $\mathcal{B}_x$ is a countable base at x . Since x was arbitrary, the Sorgenfrey Line is first countable.

Part 2: the rationals are dense, so the Sorgenfrey Line is separable.

Let $\mathcal{O}$ be a nonempty open set and pick $x \in \mathcal{O}$. There are $a < b$ with $x \in [a, b) \subseteq \mathcal{O}$. Since $x < b$, the density of the rationals in $\mathbb{R}$, Theorem 2 of Chapter 1, provides a rational q with $x < q < b$; then $q \in [a, b) \subseteq \mathcal{O}$. Hence every nonempty open set contains a rational, so $\mathbb{Q}$ is dense in the Sorgenfrey Line. As $\mathbb{Q}$ is countable, the Sorgenfrey Line is separable.

Part 3: the Sorgenfrey Line is not second countable.

Suppose, to get a contradiction, that $\{\mathcal{B}_n\}_{n \in N}$, with N a countable index set, is a base for $\mathcal{T}$. For each real number x , the set $[x, x + 1)$ is open and contains x , so there is an index $n(x) \in N$ with

$$x \in \mathcal{B}_{n(x)} \subseteq [x, x + 1).$$

Every point of $\mathcal{B}_{n(x)}$ is then at least x , and x itself belongs to $\mathcal{B}_{n(x)}$; hence

$$x = \min \mathcal{B}_{n(x)}.$$

Consequently the map $x \mapsto n(x)$ from $\mathbb{R}$ to N is one-to-one: if $n(x) = n(y)$ then $x = \min \mathcal{B}_{n(x)} = \min \mathcal{B}_{n(y)} = y$. But then $\mathbb{R}$ would be in one-to-one correspondence with a subset of the countable set N , hence countable, since by Theorem 3 of Chapter 1 a subset of a countable set is countable. This contradicts the uncountability of $\mathbb{R}$, which follows from Theorem 7 of Chapter 1. Therefore no countable base exists and the Sorgenfrey Line is not second countable.

Part 4: the Sorgenfrey Line is not metrizable.

Suppose the topology $\mathcal{T}$ were induced by a metric on $\mathbb{R}$. In Chapter 9 it was proved that a metric space is second countable if and only if it is separable. By Part 2 the Sorgenfrey Line is separable, so it would then be second countable, contradicting Part 3. Hence $\mathcal{T}$ is not induced by any metric: the Sorgenfrey Line is not metrizable.

Remark. This is the example promised in Section 11.3, where it is asserted that a separable space, even a first countable one, may fail to be second countable. Observe also that the failure of metrizability could not have been detected through the Urysohn Metrization Theorem, since that theorem presupposes second countability, which Part 3 denies.

11.4 Problems 11.22–11.28

Problem 11.22. Let $X_1 = \mathbb{N} \times \mathbb{N}$, where $\mathbb{N}$ denotes the set of natural numbers, and take $X = X_1 \cup \{\omega\}$, where ω does not belong to X_1 . For each sequence $s = \{m_k\}$ of natural numbers and natural number n , define

$$B_{s,n} = \{\omega\} \cup \{(j, k) : j \geq m_k \text{ all } k \geq n\}.$$

- (i) Show that the sets $B_{s,n}$ together with the singleton sets $\{(j, k)\}$ form a base for a topology on X .
- (ii) Show that ω is a point of closure of X_1 even though no sequence $\{x_n\}$ from X_1 converges to ω .
- (iii) Show that the space X is separable but is not first countable and so is not second countable.
- (iv) Is X a Lindelof space?

Solution. Throughout write

$$\mathcal{B} = \{B_{s,n} : s \text{ a sequence in } \mathbb{N}, n \in \mathbb{N}\} \cup \{\{(j, k)\} : (j, k) \in X_1\},$$

and note that, by the definition, a point (j, k) of X_1 belongs to $B_{s,n}$ precisely when $k \geq n$ and $j \geq m_k$; every $B_{s,n}$ contains ω . Recall also that in this chapter a neighborhood of a point x means an open set containing x .

(i) We verify the two conditions of Proposition 2.

Condition (i) of Proposition 2, that $\mathcal{B}$ covers X : the singletons $\{(j, k)\}$ cover X_1 , and ω belongs to every $B_{s,n}$, so $X = \bigcup_{B \in \mathcal{B}} B$.

Condition (ii) of Proposition 2: let B_1, B_2 belong to $\mathcal{B}$ and let $x \in B_1 \cap B_2$. If $x = (j, k)$ belongs to X_1 , then the singleton $\{(j, k)\}$ itself belongs to $\mathcal{B}$ and satisfies $x \in \{(j, k)\} \subseteq B_1 \cap B_2$. The only remaining case is $x = \omega$; since ω belongs to no singleton, both B_1 and B_2 must then be of the second kind, say $B_1 = B_{s,n}$ with $s = \{m_k\}$ and $B_2 = B_{t,m}$ with $t = \{p_k\}$. Define the sequence $u = \{q_k\}$ by $q_k = \max\{m_k, p_k\}$ and put $N = \max\{n, m\}$. If $(j, k) \in B_{u,N}$ then $k \geq N \geq n$ and $j \geq q_k \geq m_k$, so $(j, k) \in B_{s,n}$; symmetrically $(j, k) \in B_{t,m}$. Since also $\omega \in B_{u,N}$, we conclude

$$\omega \in B_{u,N} \subseteq B_{s,n} \cap B_{t,m} = B_1 \cap B_2.$$

Thus both conditions of Proposition 2 hold and $\mathcal{B}$ is a base for a (unique) topology on X , consisting of $\emptyset$ together with the unions of subcollections of $\mathcal{B}$.

Two consequences are recorded for later use. First, every subset of X_1 is open, since it is a union of singletons; in particular X_1 is an open subspace carrying the discrete topology. Second, a set $\mathcal{U}$ is a neighborhood of ω if and only if $\mathcal{U}$ is open and contains ω , and since the only members of $\mathcal{B}$ containing ω are the sets $B_{s,n}$, this happens if and only if $B_{s,n} \subseteq \mathcal{U}$ for some s and some n .

(ii) First, ω is a point of closure of X_1 . Indeed, let $\mathcal{U}$ be any neighborhood of ω . By the preceding remark there are $s = \{m_k\}$ and n with $B_{s,n} \subseteq \mathcal{U}$. The point (m_n, n) satisfies $n \geq n$ and $m_n \geq m_n$, so it belongs to $B_{s,n}$ and hence to $\mathcal{U}$. Thus every neighborhood of ω meets X_1 , that is, $\omega \in \overline{X_1}$.

Now let $\{x_i\}$ be any sequence in X_1 , say $x_i = (j_i, k_i)$. We produce a neighborhood of ω that fails to contain x_i for infinitely many i ; by the definition of convergence this shows $\{x_i\}$ does not converge to ω .

Case 1: there is a k_0 with $k_i = k_0$ for infinitely many indices i . Take any sequence s (say $m_k = 1$ for all k) and put $n = k_0 + 1$. Every point of $B_{s,n} \cap X_1$ has second coordinate at least $k_0 + 1$, so none of the infinitely many terms x_i with $k_i = k_0$ lies in the neighborhood $B_{s,n}$ of ω .

Case 2: for every k the set $I_k = \{i : k_i = k\}$ is finite. Define a sequence $s = \{m_k\}$ by

$$m_k = 1 + \max\{j_i : i \in I_k\} \quad \text{if } I_k \neq \emptyset, \quad m_k = 1 \quad \text{if } I_k = \emptyset.$$

This is well defined because each I_k is finite. Consider the neighborhood $B_{s,1}$ of ω . If some term $x_i = (j_i, k_i)$ belonged to $B_{s,1}$ we would have $j_i \geq m_{k_i} \geq 1 + j_i$, which is absurd. Hence no term of the sequence lies in $B_{s,1}$.

In either case $\{x_i\}$ does not converge to ω . Since $\{x_i\}$ was an arbitrary sequence from X_1 , no sequence from X_1 converges to ω .

(iii) The set X_1 is countable, being the Cartesian product of two countable sets, and so $X = X_1 \cup \{\omega\}$ is countable as well. The set X_1 is dense: a nonempty open set contains some member of $\mathcal{B}$, and each member of $\mathcal{B}$ meets X_1 (a singleton is contained in X_1 , and $B_{s,n}$ contains (m_n, n) as shown in (ii)). Hence every nonempty open subset of X contains a point of X_1 , so $\overline{X_1} = X$ and X is separable.

Next, X is not first countable. Suppose it were. Proposition 9 asserts that in a first countable space a point of closure of a subset E is the limit of a sequence in E . Since ω is a point of closure of X_1 by part (ii), it would then be the limit of a sequence from X_1 , contradicting the second assertion of part (ii). Hence X has no countable base at ω .

Since the proof of Proposition 9 is itself left as an exercise in the text, here is a direct verification. Suppose $\{\mathcal{U}_i\}_{i=1}^\infty$ were a countable base at ω . For each i choose $s^{(i)} = \{m_k^{(i)}\}$ and n_i with $B_{s^{(i)}, n_i} \subseteq \mathcal{U}_i$. Define $t = \{p_k\}$ by

$$p_k = 1 + \max\{m_k^{(i)} : 1 \leq i \leq k\}.$$

Fix i and choose $k \geq \max\{n_i, i\}$. The point $(m_k^{(i)}, k)$ belongs to $B_{s^{(i)}, n_i}$, hence to $\mathcal{U}_i$; but since $i \leq k$ we have $p_k > m_k^{(i)}$, so $(m_k^{(i)}, k)$ does not belong to $B_{t,1}$. Therefore $\mathcal{U}_i \not\subseteq B_{t,1}$ for every i , while $B_{t,1}$ is a neighborhood of ω . So $\{\mathcal{U}_i\}$ is not a base at ω , a contradiction.

Finally, a second countable space is first countable: a countable base for the topology contains, for each point x , the subcollection of its members that contain x , and this subcollection is a countable base at x . Since X is not first countable it is therefore not second countable.

(iv) Yes, X is a Lindelof space, and trivially so: $X = X_1 \cup \{\omega\}$ is a countable set. Given any open cover $\mathcal{C}$ of X , choose for each point $x \in X$ a member $\mathcal{O}_x \in \mathcal{C}$ with $x \in \mathcal{O}_x$. Then $\{\mathcal{O}_x : x \in X\}$ is a subcollection of $\mathcal{C}$ indexed by a countable set, hence countable, and it covers X . So every open cover of X has a countable subcover.

It is worth noting what this example shows: X is separable and Lindelof, yet neither first nor second countable. In particular, by the remarks of Section 11.3, X is not metrizable, since every metric space is first countable.

Problem 11.23. Let f be a mapping of the topological space X to the topological space Y and $\mathcal{S}$ be a subbase for the topology on Y . Show that f is continuous if and only if the inverse image under f of every set in $\mathcal{S}$ is open in X .

Solution. Recall the definition: a subcollection $\mathcal{S}$ of the topology on Y that covers Y is a subbase for that topology provided the collection $\mathcal{B}$ of intersections of finite subcollections of $\mathcal{S}$ is a base for the topology on Y .

Suppose first that f is continuous. Each set S in $\mathcal{S}$ is a member of the topology on Y , that is, S is open in Y . Therefore, by Proposition 10, $f^{-1}(S)$ is open in X .

Conversely, suppose $f^{-1}(S)$ is open in X for every S in $\mathcal{S}$. By Proposition 10 it suffices to show that $f^{-1}(\mathcal{O})$ is open in X for every open subset $\mathcal{O}$ of Y .

First consider a member of the base $\mathcal{B}$, that is, a set of the form $B = \bigcap_{i=1}^n S_i$ with each S_i in $\mathcal{S}$. Since the inverse image of an intersection is the intersection of the inverse images,

$$f^{-1}(B) = f^{-1}\left(\bigcap_{i=1}^n S_i\right) = \bigcap_{i=1}^n f^{-1}(S_i).$$

Each $f^{-1}(S_i)$ is open in X by hypothesis, and a topology is closed under the formation of intersections of finite subcollections. Hence $f^{-1}(B)$ is open in X .

Now let $\mathcal{O}$ be any open subset of Y . If $\mathcal{O}$ is empty, then $f^{-1}(\mathcal{O}) = \emptyset$ is open in X . Otherwise, since $\mathcal{B}$ is a base for the topology on Y , the set $\mathcal{O}$ is the union of a subcollection of $\mathcal{B}$, say $\mathcal{O} = \bigcup_{\lambda \in \Lambda} B_\lambda$ with each B_λ in $\mathcal{B}$. Since the inverse image of a union is the union of the inverse images,

$$f^{-1}(\mathcal{O}) = \bigcup_{\lambda \in \Lambda} f^{-1}(B_\lambda),$$

which is a union of open subsets of X and hence is open in X , a topology being closed under the formation of unions of arbitrary subcollections.

Thus the inverse image under f of every open subset of Y is open in X , and so f is continuous by Proposition 10.

Problem 11.24. Let X be a topological space.

- (i) If X has the trivial topology, find all continuous mappings of X into $\mathbb{R}$.
- (ii) If X has the discrete topology, find all continuous mappings of X into $\mathbb{R}$.
- (iii) Find all continuous one-to-one mappings from $\mathbb{R}$ to X if X has the discrete topology.
- (iv) Find all continuous one-to-one mappings from $\mathbb{R}$ to X if X has the trivial topology.

Solution. Throughout, $\mathbb{R}$ carries its usual (Euclidean) topology, the trivial topology on a set X is $\{\emptyset, X\}$, and the discrete topology is the collection of all subsets of X . We assume X is nonempty. In each part we use Proposition 10: a mapping is continuous if and only if the inverse image of each open set is open.

(i) The continuous mappings of X into $\mathbb{R}$ are precisely the constant mappings.

If f is constant, say $f \equiv c$, then for open $\mathcal{O} \subseteq \mathbb{R}$ we have $f^{-1}(\mathcal{O}) = X$ if $c \in \mathcal{O}$ and $f^{-1}(\mathcal{O}) = \emptyset$ otherwise; both sets belong to the trivial topology, so f is continuous.

Conversely, let $f: X \rightarrow \mathbb{R}$ be continuous. Fix a point x_0 in X and set $c = f(x_0)$. For each $\epsilon > 0$ the interval $(c - \epsilon, c + \epsilon)$ is open in $\mathbb{R}$, so $f^{-1}((c - \epsilon, c + \epsilon))$ is open in X . This set contains x_0 , so it is nonempty, and hence, the topology being trivial, it equals X . Therefore $|f(x) - c| < \epsilon$ for every x in X and every $\epsilon > 0$, from which $f(x) = c$ for all x . Thus f is constant.

(ii) Every mapping of X into $\mathbb{R}$ is continuous. Indeed, if X has the discrete topology, then for any $f: X \rightarrow \mathbb{R}$ and any open $\mathcal{O} \subseteq \mathbb{R}$, the set $f^{-1}(\mathcal{O})$ is a subset of X and therefore open. By Proposition 10, f is continuous. (Equivalently: each point x_0 has the neighborhood $\{x_0\}$, which is mapped into every neighborhood of $f(x_0)$.)

(iii) There are none: no one-to-one mapping from $\mathbb{R}$ to a discrete space X is continuous.

Suppose $f: \mathbb{R} \rightarrow X$ were continuous and one-to-one, and let t be any real number. The singleton $\{f(t)\}$ is open in X , since X is discrete. By Proposition 10, $f^{-1}(\{f(t)\})$ is open in $\mathbb{R}$. But f is one-to-one, so $f^{-1}(\{f(t)\}) = \{t\}$. Hence $\{t\}$ would be an open subset of $\mathbb{R}$, which is false: every nonempty open subset of $\mathbb{R}$ contains an open interval about each of its points and so is infinite. This contradiction shows no such mapping exists.

(iv) The continuous one-to-one mappings from $\mathbb{R}$ to X are precisely all the one-to-one mappings from $\mathbb{R}$ to X ; continuity is no restriction whatever. Such mappings exist if and only if the cardinality of X is at least that of $\mathbb{R}$.

Indeed, let $f: \mathbb{R} \rightarrow X$ be arbitrary, with X carrying the trivial topology. The only open subsets of X are $\emptyset$ and X , and $f^{-1}(\emptyset) = \emptyset$, $f^{-1}(X) = \mathbb{R}$, both of which are open in $\mathbb{R}$. By Proposition 10, f is continuous. Hence continuity imposes no restriction at all, and the continuous one-to-one mappings from $\mathbb{R}$ to X are precisely the one-to-one mappings from $\mathbb{R}$ to X . Such a mapping exists if and only if there is an injection of $\mathbb{R}$ into X , that is, if and only if X has cardinality at least that of the continuum; for instance if $X = \mathbb{R}$ with the trivial topology, the identity mapping is a continuous one-to-one mapping.

The contrast between (iii) and (iv) is the expected one: continuity of $f: \mathbb{R} \rightarrow X$ is a demand on the topology of X through inverse images, and it is most stringent when X has many open sets and vacuous when X has almost none.

Problem 11.25. For topological spaces X and Y , let f map X to Y . Which of the following assertions are equivalent to the continuity of f ? Verify your answers.

- (i) The inverse image under f of every closed subset of Y is closed in X .
- (ii) If $\mathcal{O}$ is open in X , then $f(\mathcal{O})$ is open in Y .
- (iii) If F is closed in X , then $f(F)$ is closed in Y .
- (iv) For each subset A of X , $f(\overline{A}) \subseteq \overline{f(A)}$.

Solution. Assertions (i) and (iv) are equivalent to the continuity of f ; assertions (ii) and (iii) are not, neither implying nor being implied by continuity.

Throughout we use the set identity $f^{-1}(Y \sim E) = X \sim f^{-1}(E)$, valid for every subset E of Y , together with Proposition 4 (a subset of a topological space is open if and only if its complement is closed) and Proposition 10.

(i) This is equivalent to continuity.

Suppose f is continuous and F is closed in Y . Then $Y \sim F$ is open in Y by Proposition 4, so $f^{-1}(Y \sim F) = X \sim f^{-1}(F)$ is open in X by Proposition 10, and therefore $f^{-1}(F)$ is closed in X , again by Proposition 4.

Conversely, suppose the inverse image of each closed subset of Y is closed in X , and let $\mathcal{O}$ be open in Y . Then $Y \sim \mathcal{O}$ is closed, so $f^{-1}(Y \sim \mathcal{O}) = X \sim f^{-1}(\mathcal{O})$ is closed in X , and hence $f^{-1}(\mathcal{O})$ is open in X . By Proposition 10, f is continuous.

(ii) This is not equivalent to continuity; it is the assertion that f is an open mapping.

Continuity does not imply it. Let $X = Y = \mathbb{R}$ with the usual topology and let f be the constant mapping $f(x) = 0$. Then f is continuous, but $\mathbb{R}$ is open in X while $f(\mathbb{R}) = \{0\}$ is not an open subset of $\mathbb{R}$.

It does not imply continuity. Let $X = \mathbb{R}$ with the usual topology, let $Y = \mathbb{R}$ with the discrete topology, and let f be the identity mapping. Every subset of Y is open, so $f(\mathcal{O})$ is open in Y for every subset $\mathcal{O}$ of X ; but $\{0\}$ is open in Y and $f^{-1}(\{0\}) = \{0\}$ is not open in X , so f is not continuous by Proposition 10.

(iii) This is not equivalent to continuity; it is the assertion that f is a closed mapping.

Continuity does not imply it. Let $X = Y = \mathbb{R}$ with the usual topology and $f(x) = e^x$, which is continuous. The set $F = \mathbb{R}$ is closed in X , but $f(\mathbb{R}) = (0, \infty)$ is not closed in $\mathbb{R}$, since 0 is a point of closure of $(0, \infty)$ that does not belong to it.

It does not imply continuity. Take again $X = \mathbb{R}$ with the usual topology, $Y = \mathbb{R}$ with the discrete topology, and f the identity. Every subset of Y is closed, its complement being open, so f carries closed sets to closed sets; but as noted above f is not continuous.

(iv) This is equivalent to continuity.

Suppose f is continuous and let A be a subset of X . The set $\overline{f(A)}$ is closed in Y by Proposition 3, so by part (i) the set $f^{-1}(\overline{f(A)})$ is closed in X . It contains A , since $f(A) \subseteq \overline{f(A)}$. By Proposition 3, $\overline{A}$ is the smallest closed subset of X containing A , so

$$\overline{A} \subseteq f^{-1}(\overline{f(A)}), \quad \text{that is,} \quad f(\overline{A}) \subseteq \overline{f(A)}.$$

Conversely, suppose $f(\overline{A}) \subseteq \overline{f(A)}$ for every subset A of X . Let F be closed in Y and put $A = f^{-1}(F)$. Then $f(A) \subseteq F$, so $\overline{f(A)} \subseteq \overline{F} = F$, the set F being closed. Hence

$$f(\overline{A}) \subseteq \overline{f(A)} \subseteq F,$$

so $\overline{A} \subseteq f^{-1}(F) = A$. Since always $A \subseteq \overline{A}$, we conclude $\overline{A} = A$, that is, $f^{-1}(F)$ is closed in X . Thus the inverse image of every closed subset of Y is closed in X , and by part (i) the mapping f is continuous.

Problem 11.26. Prove Proposition 11.

[Proposition 11: The composition of continuous mappings between topological spaces, when defined, is continuous.]

Solution. Let $(X, \mathcal{T})$, $(Y, \mathcal{S})$ and $(Z, \mathcal{R})$ be topological spaces and let $f: X \rightarrow Y$ and $g: Y \rightarrow Z$ be continuous, so that the composition $g \circ f: X \rightarrow Z$ is defined. We show $g \circ f$ is continuous.

First, a direct argument from the definition of continuity at a point. Let x_0 belong to X and let $\mathcal{W}$ be a neighborhood of $(g \circ f)(x_0) = g(f(x_0))$ in Z . Since g is continuous at the point $f(x_0)$, there is a neighborhood $\mathcal{V}$ of $f(x_0)$ in Y for which $g(\mathcal{V}) \subseteq \mathcal{W}$. Since f is continuous at x_0 , there is a neighborhood $\mathcal{U}$ of x_0 in X for which $f(\mathcal{U}) \subseteq \mathcal{V}$. Therefore

$$(g \circ f)(\mathcal{U}) = g(f(\mathcal{U})) \subseteq g(\mathcal{V}) \subseteq \mathcal{W}.$$

Thus for every neighborhood $\mathcal{W}$ of $(g \circ f)(x_0)$ there is a neighborhood $\mathcal{U}$ of x_0 mapped by $g \circ f$ into $\mathcal{W}$, that is, $g \circ f$ is continuous at x_0 . Since x_0 was an arbitrary point of X , the mapping $g \circ f$ is continuous.

Alternatively, one may argue with inverse images. For every subset E of Z we have the set identity

$$(g \circ f)^{-1}(E) = f^{-1}(g^{-1}(E)),$$

since x belongs to the left-hand side exactly when $g(f(x)) \in E$, that is, exactly when $f(x) \in g^{-1}(E)$, that is, exactly when $x \in f^{-1}(g^{-1}(E))$. Now let $\mathcal{O}$ be open in Z . Since g is continuous, $g^{-1}(\mathcal{O})$ is open in Y by Proposition 10. Since f is continuous, $f^{-1}(g^{-1}(\mathcal{O}))$ is open in X , again by Proposition 10. By the identity above, $(g \circ f)^{-1}(\mathcal{O})$ is open in X . As $\mathcal{O}$ was an arbitrary open subset of Z , Proposition 10 tells us that $g \circ f$ is continuous.

A remark on the qualification when defined in the statement of the proposition. It may happen that g is defined and continuous not on all of Y but only on a subspace A of Y with $f(X) \subseteq A$, and then $g \circ f$ is still defined on X . In that case the argument above goes through once we observe that f , regarded as a mapping of X into the subspace A , is continuous: an open subset of A is, by the definition of the subspace topology, of the form $A \cap \mathcal{O}$ with $\mathcal{O}$ open in Y , and since $f(X) \subseteq A$ we have $f^{-1}(A \cap \mathcal{O}) = f^{-1}(\mathcal{O})$, which is open in X by Proposition 10. Applying what was proved above to this corestriction of f and to $g: A \rightarrow Z$ shows $g \circ f$ is continuous.

Problem 11.27. Prove Proposition 12.

[Proposition 12: Let X be a nonempty set and $\mathcal{S}$ any collection of subsets of X that covers X . The collection of subsets of X consisting of intersections of finite subcollections of $\mathcal{S}$ is a base for a topology $\mathcal{T}$ for X . It is the weakest topology containing $\mathcal{S}$ in the sense that if $\mathcal{T}'$ is any other topology for X containing $\mathcal{S}$, then $\mathcal{T} \subseteq \mathcal{T}'$.]

Solution. Let

$$\mathcal{B} = \left\{ \bigcap_{i=1}^n S_i \mid n \in N, S_1, \dots, S_n \in \mathcal{S} \right\}$$

be the collection of intersections of finite (nonempty) subcollections of $\mathcal{S}$.

Step 1: $\mathcal{B}$ is a base for a topology on X . We verify the two conditions of Proposition 2.

Condition (i). Taking $n = 1$ shows that $\mathcal{S} \subseteq \mathcal{B}$. Since $\mathcal{S}$ covers X by hypothesis, so does the larger collection $\mathcal{B}$; that is, $X = \bigcup_{B \in \mathcal{B}} B$.

Condition (ii). Let B_1 and B_2 belong to $\mathcal{B}$, say $B_1 = \bigcap_{i=1}^n S_i$ and $B_2 = \bigcap_{j=1}^m T_j$ with all S_i and T_j in $\mathcal{S}$. Then

$$B_1 \cap B_2 = S_1 \cap \dots \cap S_n \cap T_1 \cap \dots \cap T_m$$

is itself the intersection of a finite subcollection of $\mathcal{S}$, so $B_1 \cap B_2$ belongs to $\mathcal{B}$. Hence if x belongs to $B_1 \cap B_2$, the set $B = B_1 \cap B_2$ is a member of $\mathcal{B}$ with $x \in B \subseteq B_1 \cap B_2$.

By Proposition 2, $\mathcal{B}$ is a base for a unique topology $\mathcal{T}$ for X , and $\mathcal{T}$ consists of $\emptyset$ together with the unions of subcollections of $\mathcal{B}$.

Step 2: $\mathcal{T}$ contains $\mathcal{S}$. Each B in $\mathcal{B}$ is the union of the subcollection $\{B\}$ of $\mathcal{B}$ and therefore belongs to $\mathcal{T}$. Thus $\mathcal{S} \subseteq \mathcal{B} \subseteq \mathcal{T}$.

Step 3: $\mathcal{T}$ is the weakest such topology. Let $\mathcal{T}'$ be any topology for X with $\mathcal{S} \subseteq \mathcal{T}'$. Since a topology is closed under the formation of intersections of finite subcollections, every set $\bigcap_{i=1}^n S_i$ with the S_i in $\mathcal{S} \subseteq \mathcal{T}'$ belongs to $\mathcal{T}'$; that is, $\mathcal{B} \subseteq \mathcal{T}'$. Since a topology is closed under the formation of unions of arbitrary subcollections, every union of a subcollection of $\mathcal{B}$ belongs to $\mathcal{T}'$; and $\emptyset$ belongs to $\mathcal{T}'$ because $\mathcal{T}'$ is a topology. As $\mathcal{T}$ consists precisely of $\emptyset$ and such unions, we conclude $\mathcal{T} \subseteq \mathcal{T}'$.

Therefore $\mathcal{T}$ is a topology for X containing $\mathcal{S}$, having $\mathcal{B}$ as a base, and it is contained in every topology for X that contains $\mathcal{S}$. In the terminology introduced just above the proposition, $\mathcal{T}$ is weaker than every topology containing $\mathcal{S}$, and $\mathcal{S}$ is a subbase for $\mathcal{T}$.

Problem 11.28. Prove that the sum and product of two real-valued continuous functions defined on a topological space X are themselves continuous.

Solution. Let f and g be continuous real-valued functions on the topological space X , where $\mathbb{R}$ carries its usual topology.

We first record a convenient reformulation of continuity at a point for a real-valued function. The open intervals $(c - \epsilon, c + \epsilon)$, $\epsilon > 0$, form a base for the topology of $\mathbb{R}$ at the point c : every neighborhood of c contains such an interval. Consequently, a function $h: X \rightarrow \mathbb{R}$ is continuous at x_0 if and only if for each $\epsilon > 0$ there is a neighborhood $\mathcal{U}$ of x_0 for which

$$|h(x) - h(x_0)| < \epsilon \quad \text{for all } x \in \mathcal{U}.$$

Indeed, if this holds and $\mathcal{W}$ is a neighborhood of $h(x_0)$, choose $\epsilon > 0$ with $(h(x_0) - \epsilon, h(x_0) + \epsilon) \subseteq \mathcal{W}$ and take the corresponding $\mathcal{U}$; then $h(\mathcal{U}) \subseteq \mathcal{W}$. The converse is immediate on taking $\mathcal{W} = (h(x_0) - \epsilon, h(x_0) + \epsilon)$.

We also use repeatedly that if $\mathcal{U}_1$ and $\mathcal{U}_2$ are neighborhoods of x_0 , then so is $\mathcal{U}_1 \cap \mathcal{U}_2$, since a topology is closed under the formation of intersections of finite subcollections and x_0 belongs to both sets.

The sum. Fix x_0 in X and let $\epsilon > 0$. By the continuity of f at x_0 there is a neighborhood $\mathcal{U}_1$ of x_0 with $|f(x) - f(x_0)| < \epsilon/2$ for all $x \in \mathcal{U}_1$, and by the continuity of g at x_0 there is a neighborhood $\mathcal{U}_2$ of x_0 with $|g(x) - g(x_0)| < \epsilon/2$ for all $x \in \mathcal{U}_2$. Put $\mathcal{U} = \mathcal{U}_1 \cap \mathcal{U}_2$, a neighborhood of x_0 . For x in $\mathcal{U}$, by the triangle inequality,

$$|(f+g)(x) - (f+g)(x_0)| \leq |f(x) - f(x_0)| + |g(x) - g(x_0)| < \frac{\epsilon}{2} + \frac{\epsilon}{2} = \epsilon.$$

By the reformulation above, $f+g$ is continuous at x_0 . Since x_0 was arbitrary, $f+g$ is continuous on X .

The product. Fix x_0 in X and let $\epsilon > 0$. Set

$$M = |f(x_0)| + |g(x_0)| + 1 > 0 \quad \text{and} \quad \delta = \min \left\{ 1, \frac{\epsilon}{M} \right\} > 0.$$

By the continuity of f and of g at x_0 and the remark on intersections, there is a neighborhood $\mathcal{U}$ of x_0 such that for all x in $\mathcal{U}$,

$$|f(x) - f(x_0)| < \delta \quad \text{and} \quad |g(x) - g(x_0)| < \delta.$$

For such x we have $|f(x)| \leq |f(x_0)| + \delta \leq |f(x_0)| + 1$, and therefore, adding and subtracting $f(x)g(x_0)$,

$$\begin{aligned} |(fg)(x) - (fg)(x_0)| &= |f(x)g(x) - f(x)g(x_0) + f(x)g(x_0) - f(x_0)g(x_0)| \\ &\leq |f(x)| \cdot |g(x) - g(x_0)| + |g(x_0)| \cdot |f(x) - f(x_0)| \\ &< (|f(x_0)| + 1)\delta + |g(x_0)|\delta \\ &= M\delta \leq \epsilon. \end{aligned}$$

Hence fg is continuous at x_0 , and since x_0 was an arbitrary point of X , the product fg is continuous on X .

Taking g constant, equal to α , shows that αf is continuous for every real α ; combined with the statement about sums, this shows that the real-valued continuous functions on a topological space X form a linear space, and, by the statement about products, an algebra.

11.5 Problems 11.29–11.35

Problem 11.29. Let $\mathcal{F}$ be a collection of real-valued functions on a set X . Find necessary and sufficient conditions on $\mathcal{F}$ in order that X , considered as a topological space with the weak topology induced by $\mathcal{F}$, is Tychonoff.

Solution. Recall the two definitions in force. The weak topology for X induced by $\mathcal{F}$ is the weakest topology containing the collection

$$\mathcal{S} = \{f^{-1}(\mathcal{O}) \mid f \in \mathcal{F}, \mathcal{O} \text{ open in } \mathbb{R}\},$$

and, since $f^{-1}(\mathbb{R}) = X$ for each f , the collection $\mathcal{S}$ covers X whenever $\mathcal{F} \neq \emptyset$; hence by Proposition 12 the intersections of finite subcollections of $\mathcal{S}$ form a base for this topology. (If $\mathcal{F} = \emptyset$, the weak topology is the trivial topology $\{\emptyset, X\}$.) Also recall that X is called Tychonoff provided for each two points u and v in X there is a neighborhood of u that does not contain v and a neighborhood of v that does not contain u .

We claim the necessary and sufficient condition is that

(*) $\mathcal{F}$ separates the points of X : for each two distinct points u, v in X there is a function $f \in \mathcal{F}$ for which $f(u) \neq f(v)$.

Sufficiency. Assume (*) and let u and v be two distinct points of X . Choose $f \in \mathcal{F}$ with $f(u) \neq f(v)$ and set $r = |f(u) - f(v)| > 0$. The set

$$\mathcal{U} = f^{-1}((f(u) - r, f(u) + r))$$

belongs to $\mathcal{S}$ and hence is open in the weak topology; it contains u , while $v \notin \mathcal{U}$ since $|f(v) - f(u)| = r$. Interchanging the roles of u and v produces an open set containing v but not u . Therefore X is Tychonoff.

Necessity. Assume X , with the weak topology induced by $\mathcal{F}$, is Tychonoff, and let $u \neq v$ be points of X . There is a neighborhood $\mathcal{U}$ of u with $v \notin \mathcal{U}$. In particular $\mathcal{U}$ is a nonempty open set different from X , so the topology is not the trivial one and therefore $\mathcal{F} \neq \emptyset$. By the description of the base above, there are functions $f_1, \dots, f_n$ in $\mathcal{F}$ and open subsets $\mathcal{O}_1, \dots, \mathcal{O}_n$ of $\mathbb{R}$ for which

$$u \in \bigcap_{i=1}^n f_i^{-1}(\mathcal{O}_i) \subseteq \mathcal{U}.$$

Since $v \notin \mathcal{U}$, the point v fails to belong to this intersection, so there is an index i with $v \notin f_i^{-1}(\mathcal{O}_i)$, that is, $f_i(v) \notin \mathcal{O}_i$. But $f_i(u) \in \mathcal{O}_i$. Hence $f_i(u) \neq f_i(v)$, and (*) holds.

Two remarks. First, by Proposition 6 the condition (*) is likewise equivalent to every singleton subset of X being closed in the weak topology. Second, the sufficiency argument in fact yields more: if $f(u) \neq f(v)$ and $r = |f(u) - f(v)|$, then

$$f^{-1}((f(u) - r/2, f(u) + r/2)) \quad \text{and} \quad f^{-1}((f(v) - r/2, f(v) + r/2))$$

are disjoint neighborhoods of u and v . Thus for a weak topology induced by a collection of real-valued functions, the Tychonoff and Hausdorff separation properties are equivalent, and each is equivalent to $\mathcal{F}$ separating the points of X .

Problem 11.30. For topological spaces X and Y , let the mapping $f: X \rightarrow Y$ be one-to-one and onto. Show that the following assertions are equivalent.

- (i) f is a homeomorphism of X onto Y .
- (ii) A subset E of X is open in X if and only if $f(E)$ is open in Y .
- (iii) A subset E of X is closed in X if and only if $f(E)$ is closed in Y .
- (iv) The image of the closure of a set is the closure of the image, that is, for each subset A of X , $f(\overline{A}) = \overline{f(A)}$.

Solution. Throughout, f is one-to-one and onto, so the inverse mapping $g = f^{-1}: Y \rightarrow X$ is well defined, and for every subset E of X we have

$$f(E) = g^{-1}(E), \quad f^{-1}(f(E)) = E, \quad f(X \setminus E) = Y \setminus f(E).$$

The first identity holds because $y \in g^{-1}(E)$ means $g(y) \in E$, that is, $y = f(x)$ for some $x \in E$. The last identity uses both that f is onto (so every y is $f(x)$ for some x) and that f is one-to-one (so $f(x) \in f(E)$ forces $x \in E$). We show (i) $\Leftrightarrow$ (ii), (ii) $\Leftrightarrow$ (iii), and (iii) $\Leftrightarrow$ (iv).

(i) implies (ii). Let f be a homeomorphism, so that both f and $g = f^{-1}$ are continuous. If E is open in X , then $f(E) = g^{-1}(E)$ is open in Y by the continuity of g together with Proposition 10. Conversely, if $f(E)$ is open in Y , then $E = f^{-1}(f(E))$ is open in X by the continuity of f and Proposition 10.

(ii) implies (i). Assume (ii). To see that f is continuous, let $\mathcal{O}$ be open in Y and put $E = f^{-1}(\mathcal{O})$. Since f is onto, $f(E) = \mathcal{O}$ is open in Y , so by (ii) the set E is open in X . By Proposition 10, f is continuous. To see that $g = f^{-1}$ is continuous, let E be open in X ; then $g^{-1}(E) = f(E)$, which is open in Y by (ii). Again by Proposition 10, g is continuous. Since f is one-to-one and onto and both f and f^{-1} are continuous, f is a homeomorphism.

(ii) implies (iii). Let E be a subset of X . Using Proposition 4 twice and the identity $f(X \sim E) = Y \sim f(E)$:

$$E \text{ closed in } X \iff X \sim E \text{ open in } X \iff f(X \sim E) = Y \sim f(E) \text{ open in } Y \iff f(E) \text{ closed in } Y,$$

where the middle equivalence is (ii) applied to the set $X \sim E$.

(iii) implies (ii). The same chain read with the roles of open and closed interchanged: for a subset E of X ,

$$E \text{ open in } X \iff X \sim E \text{ closed in } X \iff Y \sim f(E) = f(X \sim E) \text{ closed in } Y \iff f(E) \text{ open in } Y,$$

the middle equivalence being (iii) applied to $X \sim E$.

(iii) implies (iv). Let A be a subset of X . By Proposition 3 the set $\bar{A}$ is closed in X , so by (iii) the set $f(\bar{A})$ is closed in Y ; since $A \subseteq \bar{A}$ we have $f(A) \subseteq f(\bar{A})$, and therefore, $\overline{f(A)}$ being the smallest closed set containing $f(A)$ (Proposition 3),

$$\overline{f(A)} \subseteq f(\bar{A}).$$

For the reverse inclusion, put $E = f^{-1}(\overline{f(A)})$. Since f is onto, $f(E) = \overline{f(A)}$, which is closed in Y ; hence by (iii) the set E is closed in X . Moreover $A \subseteq E$, because $f(A) \subseteq \overline{f(A)}$. By Proposition 3, $\bar{A} \subseteq E$, and therefore

$$f(\bar{A}) \subseteq f(E) = \overline{f(A)}.$$

Thus $f(\bar{A}) = \overline{f(A)}$.

(iv) implies (iii). Assume (iv). If E is closed in X , then $E = \bar{E}$, so $f(E) = f(\bar{E}) = \overline{f(E)}$ and hence $f(E)$ is closed in Y . Conversely, suppose $f(E)$ is closed in Y , that is, $f(E) = \overline{f(E)}$. Then by (iv),

$$f(\bar{E}) = \overline{f(E)} = f(E).$$

Since $E \subseteq \bar{E}$ and f is one-to-one, applying f^{-1} to this equality of images gives $\bar{E} = f^{-1}(f(\bar{E})) = f^{-1}(f(E)) = E$. Hence E is closed in X .

Having established (i) $\Leftrightarrow$ (ii), (ii) $\Leftrightarrow$ (iii) and (iii) $\Leftrightarrow$ (iv), the four assertions are equivalent.

Problem 11.31. For topological spaces X and Y , let f be a continuous mapping from X onto Y . If X is Hausdorff, is Y Hausdorff? If X is normal, is Y normal?

Solution. The answer to both questions is no: neither the Hausdorff separation property nor the normal separation property is inherited by continuous images.

A first counterexample. Let $X = \mathbb{R}$ with the discrete topology and let $Y = \mathbb{R}$ with the trivial topology $\{\emptyset, Y\}$, and let $f: X \rightarrow Y$ be the identity map, which is certainly one-to-one and onto. The mapping f is continuous: the inverse image of each of the two open subsets of Y is a subset of X , and every subset of X is open, so continuity follows from Proposition 10.

The space X is Hausdorff, since for distinct points u and v the singletons $\{u\}$ and $\{v\}$ are disjoint open sets containing u and v respectively. It is also normal: by Problem 1 the discrete topology is the topology induced by the discrete metric, and by Proposition 7 every metric space is normal. (Directly: any two disjoint subsets of X are themselves disjoint neighborhoods of one another, and each singleton is closed.)

The space Y is neither Hausdorff nor normal. Indeed, the only neighborhood of any point of Y is Y itself, so no two distinct points can be separated by disjoint neighborhoods; thus Y fails to be Hausdorff. Moreover no singleton $\{y\}$ is closed in Y , since $Y \sim \{y\}$ is a nonempty proper subset of Y and hence not open; by Proposition 6, Y is not even Tychonoff, and therefore, the Tychonoff property

being part of the definition of normality, Y is not normal.

A second counterexample, in which the image space is not degenerate. Again let $X = \mathbb{R}$ with the discrete topology, let $Y = \mathbb{R}$ with the topology $\mathcal{T}$ consisting of $\emptyset$ together with all subsets of $\mathbb{R}$ having finite complement, and let f be the identity map. As before f is continuous and onto, and X is both Hausdorff and normal. The collection $\mathcal{T}$ is a topology: $\emptyset$ and $\mathbb{R}$ belong to it, a finite intersection of cofinite sets is cofinite, and an arbitrary union of cofinite sets is cofinite. The closed subsets of Y are exactly $\mathbb{R}$ and the finite sets, so every singleton is closed and Y is Tychonoff by Proposition 6. But any two nonempty open subsets $\mathcal{O}_1, \mathcal{O}_2$ of Y intersect, since $\mathbb{R} \sim (\mathcal{O}_1 \cap \mathcal{O}_2) = (\mathbb{R} \sim \mathcal{O}_1) \cup (\mathbb{R} \sim \mathcal{O}_2)$ is finite while $\mathbb{R}$ is infinite. Consequently no two distinct points of Y have disjoint neighborhoods, so Y is not Hausdorff; and the disjoint closed sets $F_1 = \{0\}$ and $F_2 = \{1\}$ cannot be separated by disjoint neighborhoods (a neighborhood of F_1 contains 0 and a neighborhood of F_2 contains 1, so both are nonempty and open, hence meet), so Y is not normal. Thus a continuous image of a Hausdorff, normal space need be neither Hausdorff nor normal, even when it is Tychonoff.

The source of the failure is clear from Proposition 10: continuity of f gives information about inverse images of open sets in Y , and so lets separation properties be transported from Y back to X , but it says nothing about the images of the open or closed sets of X , which is what would be needed to transport separation properties forward. Consistently with this, Problem 30 shows that when f is one-to-one and onto and images of open sets are open, that is, when f is a homeomorphism, all such properties do transfer.

Problem 11.32. Let ρ_1 and ρ_2 be metrics on the set X that induce topologies $\mathcal{T}_1$ and $\mathcal{T}_2$, respectively. If $\mathcal{T}_1 = \mathcal{T}_2$, are the metrics necessarily equivalent?

Solution. No. Recall that two metrics ρ and σ on a set X are called equivalent provided there are positive numbers c_1 and c_2 for which

$$c_1 \sigma(x_1, x_2) \leq \rho(x_1, x_2) \leq c_2 \sigma(x_1, x_2) \quad \text{for all } x_1, x_2 \in X.$$

Equivalence of metrics is a strictly stronger requirement than the equality of the induced topologies. Indeed, if ρ and σ are equivalent with constants c_1, c_2 as above, then for each $x \in X$ and $r > 0$ we have the inclusions of balls $B_\rho(x, c_1 r) \subseteq B_\sigma(x, r)$ and $B_\sigma(x, r/c_2) \subseteq B_\rho(x, r)$, so each ball for one metric contains a ball for the other about the same center, and hence the two metrics induce the same topology. The following example shows the converse implication fails.

Take $X = \mathbb{R}$ and define

$$\rho_1(x, y) = |x - y|, \quad \rho_2(x, y) = \min\{1, |x - y|\} \quad \text{for } x, y \in \mathbb{R}.$$

First, ρ_2 is a metric. It is nonnegative, symmetric, and vanishes precisely when $x = y$. For the triangle inequality, observe that for nonnegative numbers a and b ,

$$\min\{1, a + b\} \leq \min\{1, a\} + \min\{1, b\},$$

since if $a \geq 1$ or $b \geq 1$ the right-hand side is at least 1, which dominates the left-hand side, while if $a < 1$ and $b < 1$ the right-hand side equals $a + b \geq \min\{1, a + b\}$. Now for x, y, z in $\mathbb{R}$, since $t \mapsto \min\{1, t\}$ is nondecreasing and $|x - z| \leq |x - y| + |y - z|$,

$$\rho_2(x, z) = \min\{1, |x - z|\} \leq \min\{1, |x - y| + |y - z|\} \leq \rho_2(x, y) + \rho_2(y, z).$$

Second, $\mathcal{T}_1 = \mathcal{T}_2$. Let $x \in \mathbb{R}$ and $0 < r \leq 1$. Then

$$\rho_2(x, y) < r \iff \min\{1, |x - y|\} < r \iff |x - y| < r,$$

the second equivalence because $|x - y| \geq 1$ forces $\min\{1, |x - y|\} = 1 \geq r$. Hence the open balls of radius $r \leq 1$ about x are the same set for the two metrics. Now for a metric ρ on X , a subset $\mathcal{O}$ of X is open in the topology induced by ρ if and only if for each $x \in \mathcal{O}$ there is an r with $0 < r \leq 1$ for which $B_\rho(x, r) \subseteq \mathcal{O}$: this is the definition of the metric topology, except that a radius $r > 1$ furnished

by the definition may be replaced by $\min\{1, r\}$, which only shrinks the ball. Applying this criterion to ρ_1 and to ρ_2 , and using that the balls of radius at most 1 agree for the two metrics, we conclude that $\mathcal{O}$ is $\mathcal{T}_1$ -open if and only if it is $\mathcal{T}_2$ -open. Thus $\mathcal{T}_1 = \mathcal{T}_2$.

Third, ρ_1 and ρ_2 are not equivalent. Suppose there were positive constants c_1, c_2 with $c_1\rho_2 \leq \rho_1 \leq c_2\rho_2$ on $\mathbb{R} \times \mathbb{R}$. Taking $x = 0$ and $y = n$ for a natural number $n \geq 1$ gives $\rho_1(0, n) = n$ and $\rho_2(0, n) = 1$, so the inequality $\rho_1 \leq c_2\rho_2$ yields $n \leq c_2$ for every natural number n . This contradicts the Archimedean property of $\mathbb{R}$. Hence no such constants exist.

Thus ρ_1 and ρ_2 induce the same topology on $\mathbb{R}$ but are not equivalent metrics: equality of the induced topologies does not force equivalence. The underlying reason is that equivalence is a metric (indeed, uniform and quantitative) relation, sensitive to features such as boundedness that the topology cannot detect: ρ_2 is a bounded metric while ρ_1 is not, and a two-sided comparison by constants would preserve boundedness.

Problem 11.33. Show that the inverse of a homeomorphism is a homeomorphism and the composition of two homeomorphisms, when defined, is again a homeomorphism.

Solution. Recall the definition: a continuous mapping f from a topological space X to a topological space Y is a homeomorphism provided it is one-to-one, maps X onto Y , and has a continuous inverse f^{-1} from Y to X .

The inverse. Let $f: X \rightarrow Y$ be a homeomorphism and set $g = f^{-1}: Y \rightarrow X$. Since f is one-to-one and onto, so is g : given $x \in X$, we have $g(f(x)) = x$, so g maps Y onto X ; and if $g(y_1) = g(y_2)$, then applying f gives $y_1 = f(g(y_1)) = f(g(y_2)) = y_2$, so g is one-to-one. By the definition of a homeomorphism, g is continuous. Finally, the inverse of g is f itself, since $g(y) = x$ if and only if $y = f(x)$; and f is continuous. Therefore $g = f^{-1}$ is a one-to-one continuous mapping of Y onto X with continuous inverse, that is, a homeomorphism of Y onto X .

The composition. Let X, Y , and Z be topological spaces and let $f: X \rightarrow Y$ and $h: Y \rightarrow Z$ be homeomorphisms, so that the composition $h \circ f: X \rightarrow Z$ is defined.

First, $h \circ f$ is one-to-one: if $(h \circ f)(x_1) = (h \circ f)(x_2)$, then $h(f(x_1)) = h(f(x_2))$, so $f(x_1) = f(x_2)$ because h is one-to-one, and hence $x_1 = x_2$ because f is one-to-one. Second, $h \circ f$ maps X onto Z : given $z \in Z$, since h maps Y onto Z there is $y \in Y$ with $h(y) = z$, and since f maps X onto Y there is $x \in X$ with $f(x) = y$; thus $(h \circ f)(x) = z$. Third, $h \circ f$ is continuous, by Proposition 11, since f and h are continuous.

It remains to identify the inverse and check its continuity. We claim

$$(h \circ f)^{-1} = f^{-1} \circ h^{-1}.$$

Indeed, for $z \in Z$ and $x \in X$, the statement $(h \circ f)(x) = z$ says $h(f(x)) = z$, which is equivalent to $f(x) = h^{-1}(z)$, which in turn is equivalent to $x = f^{-1}(h^{-1}(z)) = (f^{-1} \circ h^{-1})(z)$. Since $f^{-1}: Y \rightarrow X$ and $h^{-1}: Z \rightarrow Y$ are continuous, their composition $f^{-1} \circ h^{-1}: Z \rightarrow X$ is continuous, again by Proposition 11.

Therefore $h \circ f$ is a one-to-one continuous mapping of X onto Z with continuous inverse, that is, a homeomorphism of X onto Z .

Together with the observation that the identity mapping of a topological space onto itself is a homeomorphism, these two facts show that the relation of being homeomorphic is reflexive, symmetric, and transitive, that is, it is an equivalence relation among topological spaces, as asserted in the text.

Problem 11.34. Suppose that a topological space X has the property that every continuous real-valued function on X takes a minimum value. Show that any topological space that is homeomorphic to X also possesses this property.

Solution. Say that a real-valued function g on a topological space Z takes a minimum value provided there is a point $z_0 \in Z$ for which $g(z_0) \leq g(z)$ for all $z \in Z$.

Let Y be a topological space that is homeomorphic to X . By Problem 33 the inverse of a homeomor-

phism is a homeomorphism, so the relation of being homeomorphic is symmetric and we may choose a homeomorphism

$$h: X \rightarrow Y,$$

that is, a one-to-one continuous mapping of X onto Y whose inverse is continuous. We must show that every continuous real-valued function on Y takes a minimum value.

Let $g: Y \rightarrow \mathbb{R}$ be continuous, where $\mathbb{R}$ has its usual topology. Since $h: X \rightarrow Y$ and $g: Y \rightarrow \mathbb{R}$ are continuous, the composition

$$g \circ h: X \rightarrow \mathbb{R}$$

is continuous, by Proposition 11. Hence $g \circ h$ is a continuous real-valued function on X , and so, by the hypothesis on X , it takes a minimum value: there is a point $x_0 \in X$ for which

$$(g \circ h)(x_0) \leq (g \circ h)(x) \quad \text{for all } x \in X.$$

Define $y_0 = h(x_0) \in Y$. Let y be any point of Y . Since h maps X onto Y , there is a point $x \in X$ with $h(x) = y$. Therefore

$$g(y_0) = g(h(x_0)) = (g \circ h)(x_0) \leq (g \circ h)(x) = g(h(x)) = g(y).$$

Since $y \in Y$ was arbitrary, g attains the minimum value $g(y_0)$ at the point y_0 .

As g was an arbitrary continuous real-valued function on Y , the space Y has the stated property. Note that only the continuity and surjectivity of h were used; thus the property is inherited by every continuous image of X , and a fortiori by every space homeomorphic to X .

Problem 11.35. Suppose that a topological space X has the property that every continuous real-valued function on X has an interval as its image. Show that any topological space that is homeomorphic to X also possesses this property.

Solution. Let Y be a topological space homeomorphic to X . By Problem 33 the inverse of a homeomorphism is again a homeomorphism, so we may select a homeomorphism

$$h: X \rightarrow Y,$$

a one-to-one continuous mapping of X onto Y with continuous inverse. Let $g: Y \rightarrow \mathbb{R}$ be continuous, $\mathbb{R}$ having its usual topology. We must show that the image $g(Y)$ is an interval.

Since h and g are continuous, the composition $g \circ h: X \rightarrow \mathbb{R}$ is continuous, by Proposition 11. Therefore, by the hypothesis on X , the image

$$(g \circ h)(X) = \{g(h(x)) \mid x \in X\}$$

is an interval.

We claim $(g \circ h)(X) = g(Y)$. On the one hand, for each $x \in X$ the point $h(x)$ belongs to Y , so $g(h(x)) \in g(Y)$; hence $(g \circ h)(X) \subseteq g(Y)$. On the other hand, let $c \in g(Y)$, say $c = g(y)$ with $y \in Y$. Since h maps X onto Y , there is $x \in X$ with $h(x) = y$, and then $c = g(h(x)) = (g \circ h)(x)$ belongs to $(g \circ h)(X)$; hence $g(Y) \subseteq (g \circ h)(X)$. This proves the claim, and therefore

$$g(Y) = (g \circ h)(X)$$

is an interval.

Since g was an arbitrary continuous real-valued function on Y , every continuous real-valued function on Y has an interval as its image, which is what we wished to show. As in the preceding problem, only the continuity of h and the fact that h maps X onto Y were used, so the property in fact passes to every continuous image of X .

11.6 Problems 11.36–11.42

Problem 11.36. Show that $\mathbb{R}$ is homeomorphic to the open bounded interval $(0, 1)$, but is not homeomorphic to the closed bounded interval $[0, 1]$.

Solution. Throughout, $\mathbb{R}$, $(0, 1)$ and $[0, 1]$ carry the usual topology, that is, the topology induced by the Euclidean metric; the topology of $(0, 1)$ and of $[0, 1]$ is also the subspace topology inherited from $\mathbb{R}$.

First we exhibit a homeomorphism of $\mathbb{R}$ onto $(0, 1)$. Define $f: \mathbb{R} \rightarrow \mathbb{R}$ by

$$f(x) = \frac{1}{2} + \frac{1}{2} \cdot \frac{x}{1 + |x|}.$$

The function $x \mapsto |x|$ is continuous, $1 + |x| \geq 1 > 0$ for every x , and sums, products and quotients of continuous real-valued functions with nonvanishing denominator are continuous. Hence f is continuous on $\mathbb{R}$.

Since $|x|/(1 + |x|) < 1$ for every x , we have $|f(x) - 1/2| < 1/2$, that is, $f(x) \in (0, 1)$: thus f maps $\mathbb{R}$ into $(0, 1)$.

Define $g: (0, 1) \rightarrow \mathbb{R}$ by

$$g(y) = \frac{2y - 1}{1 - |2y - 1|}.$$

For $y \in (0, 1)$ the number $t = 2y - 1$ lies in $(-1, 1)$, so $1 - |t| > 0$ and g is well defined; as above g is continuous on $(0, 1)$.

We check that $g \circ f = \text{id}_{\mathbb{R}}$ and $f \circ g = \text{id}_{(0,1)}$. Let $x \in \mathbb{R}$ and put $y = f(x)$. Then $t := 2y - 1 = x/(1 + |x|)$, so that $|t| = |x|/(1 + |x|)$ and hence $1 - |t| = 1/(1 + |x|)$. Therefore

$$g(f(x)) = \frac{t}{1 - |t|} = \frac{x/(1 + |x|)}{1/(1 + |x|)} = x.$$

Conversely, let $y \in (0, 1)$, put $t = 2y - 1 \in (-1, 1)$ and $x = g(y) = t/(1 - |t|)$. Then $|x| = |t|/(1 - |t|)$, so $1 + |x| = 1/(1 - |t|)$ and

$$\frac{x}{1 + |x|} = \frac{t/(1 - |t|)}{1/(1 - |t|)} = t = 2y - 1,$$

whence $f(g(y)) = \frac{1}{2} + \frac{1}{2}(2y - 1) = y$.

Thus f is a one-to-one mapping of $\mathbb{R}$ onto $(0, 1)$, both f and its inverse $f^{-1} = g$ are continuous, and therefore f is a homeomorphism of $\mathbb{R}$ onto $(0, 1)$.

Next we show that $\mathbb{R}$ is not homeomorphic to $[0, 1]$. We use the fact that compactness is a topological property. Indeed, a homeomorphism is in particular a continuous mapping of one space onto the other, and by Proposition 20 the image of a compact topological space under a continuous mapping is compact; hence if two spaces are homeomorphic and one is compact, so is the other.

Now $[0, 1]$ is a compact topological space: it is a closed, bounded set of real numbers, so by the Heine–Borel Theorem every cover of $[0, 1]$ by open subsets of $\mathbb{R}$ has a finite subcover, and in view of the description of the subspace topology this says precisely that $[0, 1]$, with its subspace topology, is compact.

On the other hand $\mathbb{R}$ is not compact. The collection $\{(-n, n)\}_{n=1}^{\infty}$ consists of open subsets of $\mathbb{R}$ and covers $\mathbb{R}$, since every real number x satisfies $|x| < n$ for some natural number n . But no finite subcollection covers $\mathbb{R}$: a finite subcollection $\{(-n_1, n_1), \dots, (-n_k, n_k)\}$ has union $(-N, N)$, where $N = \max\{n_1, \dots, n_k\}$, and this fails to contain N .

Since $[0, 1]$ is compact and $\mathbb{R}$ is not, there is no homeomorphism of $\mathbb{R}$ onto $[0, 1]$.

(Alternatively one may argue with Corollary 21: every continuous real-valued function on the compact space $[0, 1]$ takes a minimum value, while the identity function on $\mathbb{R}$ is continuous and takes no minimum value; by Problem 34 the property that every continuous real-valued function takes a minimum value is inherited by homeomorphic spaces, so $\mathbb{R}$ and $[0, 1]$ cannot be homeomorphic.)

Problem 11.37. Let X and Y be topological spaces and consider a mapping f from X to Y . Suppose $X = X_1 \cup X_2$ and the restrictions of f to the topological subspaces X_1 and to X_2 are continuous. Show that f need not be continuous at any point in X . Show that f is continuous on X if X_1 and X_2 are open. Compare this with the case of measurable functions and the inheritance of measurability from the measurability of restrictions.

Solution. Throughout, X_1 and X_2 carry the subspace topology inherited from X , so that the open subsets of X_i are exactly the sets $\mathcal{U} \cap X_i$ with $\mathcal{U}$ open in X . Recall also that for any subset A of Y ,

$$(f|_{X_i})^{-1}(A) = f^{-1}(A) \cap X_i.$$

An example in which f is continuous at no point. Take $X = Y = \mathbb{R}$ with the usual topology, $X_1 = \mathbb{Q}$ the set of rational numbers, $X_2 = \mathbb{R} \setminus \mathbb{Q}$ the set of irrational numbers, and let f be the Dirichlet function

$$f(x) = \begin{cases} 1, & x \in \mathbb{Q}, \\ 0, & x \notin \mathbb{Q}. \end{cases}$$

Then $X = X_1 \cup X_2$, the restriction $f|_{X_1}$ is constantly equal to 1 and the restriction $f|_{X_2}$ is constantly equal to 0. A constant mapping between topological spaces is continuous, since the preimage of an open set is either the whole space or the empty set. Thus both restrictions are continuous.

On the other hand f is continuous at no point of $\mathbb{R}$. Fix $x_0 \in \mathbb{R}$ and let $\mathcal{O}$ be the open interval of radius $1/2$ about $f(x_0)$; then $\mathcal{O}$ contains exactly one of the two values 0, 1. Every neighborhood of x_0 in $\mathbb{R}$ contains an open interval about x_0 , and every open interval contains both a rational and an irrational number, hence contains points at which f takes the value 0 and points at which it takes the value 1. So no neighborhood $\mathcal{U}$ of x_0 satisfies $f(\mathcal{U}) \subseteq \mathcal{O}$, and f fails to be continuous at x_0 . Since x_0 was arbitrary, f is continuous at no point of X .

Continuity when X_1 and X_2 are open. Assume now that X_1 and X_2 are open subsets of X . By Proposition 10 it suffices to show that $f^{-1}(\mathcal{O})$ is open in X for every open subset $\mathcal{O}$ of Y . Since $X = X_1 \cup X_2$,

$$f^{-1}(\mathcal{O}) = (f^{-1}(\mathcal{O}) \cap X_1) \cup (f^{-1}(\mathcal{O}) \cap X_2) = (f|_{X_1})^{-1}(\mathcal{O}) \cup (f|_{X_2})^{-1}(\mathcal{O}).$$

By the continuity of $f|_{X_i}$ and Proposition 10 applied to the space X_i , the set $(f|_{X_i})^{-1}(\mathcal{O})$ is open in the subspace X_i , that is, $(f|_{X_i})^{-1}(\mathcal{O}) = \mathcal{U}_i \cap X_i$ for some open subset $\mathcal{U}_i$ of X . Since X_i is open in X and the intersection of two open sets is open, $(f|_{X_i})^{-1}(\mathcal{O})$ is open in X . Being the union of two open subsets of X , $f^{-1}(\mathcal{O})$ is open in X . Therefore f is continuous on X .

(The same conclusion holds if X_1 and X_2 are both closed: Proposition 10 together with Proposition 4 and the set identity $f^{-1}(Y \setminus C) = X \setminus f^{-1}(C)$ shows that continuity of f is equivalent to $f^{-1}(C)$ being closed in X for every closed subset C of Y , and the displayed identity with $\mathcal{O}$ replaced by C exhibits $f^{-1}(C)$ as the union of two sets, each closed in the closed subspace X_i and hence closed in X . What matters is that the decomposition be by two sets belonging to a family closed under the relevant operations. The Dirichlet example shows that no such conclusion is available for an arbitrary decomposition.)

Comparison with measurability. Let E be a measurable set of real numbers, let D be a measurable subset of E , and let f be an extended real-valued function on E . Proposition 5(ii) of Chapter 3 asserts that f is measurable on E if and only if its restrictions to D and to $E \setminus D$ are measurable. Here no analogue of the openness assumption is needed: the two pieces may be completely arbitrary measurable sets. The reason is visible in the proof pattern used above. For a measurable subset D of E and $c \in \mathbb{R}$,

$$\{x \in E \mid f(x) > c\} = \{x \in D \mid f(x) > c\} \cup \{x \in E \setminus D \mid f(x) > c\},$$

and a subset of D that is measurable as a subset of the measure space D is measurable as a subset of $\mathbb{R}$ outright, precisely because D itself is measurable and the measurable sets form a σ -algebra. In the topological setting, by contrast, a subset of X_1 that is open in the subspace X_1 need not be open in X ; this is guaranteed only when X_1 is itself open in X . The subspace-open sets are not, in general, open

in the ambient space, whereas the “subspace-measurable” sets of a measurable set are measurable in the ambient space.

The Dirichlet function above illustrates the contrast concretely: with $E = \mathbb{R}$ and $D = \mathbb{Q}$, the restrictions of $f = \chi_{\mathbb{Q}}$ to D and $E \sim D$ are constant, hence measurable, so f is measurable on $\mathbb{R}$ by Proposition 5(ii) of Chapter 3 – even though the corresponding restrictions being continuous fails to make f continuous anywhere.

Problem 11.38. Show that for any two numbers a and b ,

$$|\operatorname{sgn}(a) \cdot |a|^2 - \operatorname{sgn}(b) \cdot |b|^2| \leq 2 \cdot |a - b| (|a| + |b|).$$

Solution. Here $\operatorname{sgn}(t)$ denotes the signum of t , that is, $\operatorname{sgn}(t) = 1$ if $t > 0$, $\operatorname{sgn}(t) = -1$ if $t < 0$, and $\operatorname{sgn}(0) = 0$.

Observe first that for every real number t ,

$$\operatorname{sgn}(t) \cdot |t|^2 = t|t|.$$

Indeed, if $t > 0$ this reads $|t|^2 = t \cdot t = t^2$; if $t < 0$ it reads $-|t|^2 = t|t| = (-|t|)|t|$; and if $t = 0$ both sides are 0. Accordingly define

$$\varphi(t) = \operatorname{sgn}(t) \cdot |t|^2 = t|t| \quad (t \in \mathbb{R}),$$

so that what must be proved is $|\varphi(a) - \varphi(b)| \leq 2|a - b|(|a| + |b|)$.

We prove the stronger inequality

$$|\varphi(a) - \varphi(b)| \leq |a - b|(|a| + |b|)$$

for all real a, b , which we refer to as the sharpened inequality; since $|a - b|(|a| + |b|) \leq 2|a - b|(|a| + |b|)$, the asserted inequality follows at once. Note that both sides of it are unchanged if a and b are interchanged, so we may relabel the two numbers freely. We distinguish two cases according to the sign of the product ab .

Case 1: $ab \geq 0$, that is, a and b do not have strictly opposite signs.

Suppose first that $a \geq 0$ and $b \geq 0$. Then $|a| = a$ and $|b| = b$, so

$$\varphi(a) - \varphi(b) = a^2 - b^2 = (a - b)(a + b),$$

and therefore

$$|\varphi(a) - \varphi(b)| = |a - b||a + b| \leq |a - b|(|a| + |b|),$$

the last step by the triangle inequality $|a + b| \leq |a| + |b|$.

Suppose next that $a \leq 0$ and $b \leq 0$. Then $|a| = -a$ and $|b| = -b$, so

$$\varphi(a) - \varphi(b) = a(-a) - b(-b) = -(a^2 - b^2) = -(a - b)(a + b),$$

and again

$$|\varphi(a) - \varphi(b)| = |a - b||a + b| \leq |a - b|(|a| + |b|).$$

Since $ab \geq 0$ forces either both $a \geq 0$ and $b \geq 0$, or both $a \leq 0$ and $b \leq 0$, Case 1 is complete.

Case 2: $ab < 0$.

By the symmetry noted above we may assume $a > 0 > b$. Then $|a| = a$, $|b| = -b$, and

$$\varphi(a) - \varphi(b) = a|a| - b|b| = a^2 + b^2 = |a|^2 + |b|^2 \geq 0,$$

so that $|\varphi(a) - \varphi(b)| = |a|^2 + |b|^2$. On the other hand, since $a > 0 > b$ we have $a - b > 0$ and

$$|a - b| = a - b = |a| + |b|.$$

Hence

$$|a - b| (|a| + |b|) = (|a| + |b|)^2 = |a|^2 + 2|a||b| + |b|^2 \geq |a|^2 + |b|^2 = |\varphi(a) - \varphi(b)|,$$

because $2|a||b| \geq 0$. This proves the sharpened inequality in Case 2.

The two cases exhaust all possibilities, so the sharpened inequality holds for all real a and b , and consequently

$$|\operatorname{sgn}(a) \cdot |a|^2 - \operatorname{sgn}(b) \cdot |b|^2| \leq |a - b| (|a| + |b|) \leq 2|a - b| (|a| + |b|),$$

as required. In particular the constant 2 in the statement is not needed; and the inequality shows that $\varphi(t) = \operatorname{sgn}(t)|t|^2$ is Lipschitz on every bounded set, hence continuous on $\mathbb{R}$.

Problem 11.39. For a second countable space X , show that X is compact if and only if it is countably compact.

Solution. Recall the two definitions. The space X is compact provided every open cover of X has a finite subcover, and X is countably compact provided every countable open cover of X has a finite subcover. Recall also that X is second countable provided there is a countable base for its topology. One implication requires no hypothesis on X . Suppose X is compact and let $\{\mathcal{O}_n\}_{n=1}^\infty$ be a countable open cover of X . This is in particular an open cover of X , so by compactness it has a finite subcover. Hence X is countably compact.

For the converse, assume X is second countable and countably compact. We first establish the Lindelof property (this is Problem 17 of this chapter), namely:

If X is second countable, then every open cover of X has a countable subcover.

To see this, let $\mathcal{B} = \{B_n\}_{n=1}^\infty$ be a countable base for the topology of X and let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be an open cover of X . Let

$$N = \{n \in \mathbb{N} \mid B_n \subseteq \mathcal{O}_\lambda \text{ for some } \lambda \in \Lambda\},$$

and for each $n \in N$ select an index $\lambda(n) \in \Lambda$ for which $B_n \subseteq \mathcal{O}_{\lambda(n)}$. The collection $\{\mathcal{O}_{\lambda(n)}\}_{n \in N}$ is a subcollection of the given cover indexed by a subset of $\mathbb{N}$, hence is countable. It covers X : let $x \in X$. Since $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ covers X , there is $\lambda \in \Lambda$ with $x \in \mathcal{O}_\lambda$. Since $\mathcal{B}$ is a base for the topology and $\mathcal{O}_\lambda$ is an open set containing x , there is an index n with

$$x \in B_n \subseteq \mathcal{O}_\lambda.$$

This index n belongs to N , and therefore

$$x \in B_n \subseteq \mathcal{O}_{\lambda(n)}.$$

Thus every point of X lies in some member of $\{\mathcal{O}_{\lambda(n)}\}_{n \in N}$, and the Lindelof property is proved.

Now let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be an arbitrary open cover of X . By the Lindelof property just established there is a countable subcollection $\{\mathcal{O}_{\lambda(n)}\}_{n \in N}$ that still covers X . This countable subcollection is a countable open cover of X , so by the assumed countable compactness of X it has a finite subcover $\{\mathcal{O}_{\lambda(n_1)}, \dots, \mathcal{O}_{\lambda(n_k)}\}$. This is a finite subcollection of the original cover $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ that covers X .

Therefore every open cover of X has a finite subcover, that is, X is compact. Combining the two implications: for a second countable space X , X is compact if and only if X is countably compact.

Problem 11.40. (Frechet Intersection Theorem) Let X be a topological space. Prove that X is countably compact if and only if whenever $\{F_n\}$ is a descending sequence of nonempty closed subsets of X , the intersection $\bigcap_{n=1}^\infty F_n$ is nonempty.

Solution. Recall that X is countably compact provided every countable open cover of X has a finite subcover, and that a sequence $\{F_n\}_{n=1}^\infty$ of sets is descending provided $F_{n+1} \subseteq F_n$ for every index n . This problem is the countable analogue of Proposition 14, and the proof runs along the same lines,

using De Morgan's Identities.

We first record an observation used in both directions. If $\{F_n\}$ is descending and $n_1 < n_2 < \cdots < n_k$, then

$$\bigcap_{i=1}^k F_{n_i} = F_{n_k},$$

since $F_{n_k} \subseteq F_{n_i}$ for each i .

Suppose first that X is countably compact, and let $\{F_n\}_{n=1}^\infty$ be a descending sequence of nonempty closed subsets of X . Argue by contradiction: assume $\bigcap_{n=1}^\infty F_n = \emptyset$. For each n set $\mathcal{O}_n = X \sim F_n$, which is open since F_n is closed. By De Morgan's Identities,

$$\bigcup_{n=1}^\infty \mathcal{O}_n = \bigcup_{n=1}^\infty (X \sim F_n) = X \sim \bigcap_{n=1}^\infty F_n = X \sim \emptyset = X.$$

Thus $\{\mathcal{O}_n\}_{n=1}^\infty$ is a countable open cover of X . By countable compactness there are indices $n_1 < n_2 < \cdots < n_k$ with

$$X = \bigcup_{i=1}^k \mathcal{O}_{n_i} = \bigcup_{i=1}^k (X \sim F_{n_i}) = X \sim \bigcap_{i=1}^k F_{n_i} = X \sim F_{n_k},$$

where the last equality uses the observation above. Hence $F_{n_k} = \emptyset$, contradicting the assumption that each F_n is nonempty. Therefore $\bigcap_{n=1}^\infty F_n \neq \emptyset$.

Conversely, suppose that every descending sequence of nonempty closed subsets of X has nonempty intersection. Let $\{\mathcal{O}_n\}_{n=1}^\infty$ be a countable open cover of X (if the cover is finite it is its own finite subcover, so there is nothing to prove; in any case a finite cover may be turned into a sequence by repeating one of its members, and the argument below applies verbatim). Argue by contradiction: assume this cover has no finite subcover. Since any finite subcollection of $\{\mathcal{O}_n\}$ is contained in $\{\mathcal{O}_1, \dots, \mathcal{O}_n\}$ for n sufficiently large, the assumption implies that for every index n ,

$$\bigcup_{k=1}^n \mathcal{O}_k \neq X.$$

For each n define

$$F_n = X \sim \bigcup_{k=1}^n \mathcal{O}_k.$$

Each F_n is closed, being the complement of a finite union of open sets, hence the complement of an open set. Each F_n is nonempty by the displayed inequality. And the sequence is descending, since $\bigcup_{k=1}^n \mathcal{O}_k \subseteq \bigcup_{k=1}^{n+1} \mathcal{O}_k$ implies $F_{n+1} \subseteq F_n$.

By hypothesis there is a point $x \in \bigcap_{n=1}^\infty F_n$. For every index k we then have $x \in F_k$, so $x \notin \bigcup_{j=1}^k \mathcal{O}_j$ and in particular $x \notin \mathcal{O}_k$. Thus x belongs to no member of $\{\mathcal{O}_n\}_{n=1}^\infty$, contradicting the fact that this collection covers X .

Therefore every countable open cover of X has a finite subcover, that is, X is countably compact. This completes the proof of both implications.

Problem 11.41. Let X be compact Hausdorff and $\{F_n\}_{n=1}^\infty$ be a descending collection of closed subsets of X . Let $\mathcal{O}$ be a neighborhood of the intersection $\bigcap_{n=1}^\infty F_n$. Show there is an index N such that $F_n \subseteq \mathcal{O}$ for $n \geq N$.

Solution. Write $F = \bigcap_{n=1}^\infty F_n$, so that $F \subseteq \mathcal{O}$ and $\mathcal{O}$ is open. (If one uses the wider convention that a neighborhood of a set is any set containing an open set that contains it, replace $\mathcal{O}$ at the outset by an open set $\mathcal{U}$ with $F \subseteq \mathcal{U} \subseteq \mathcal{O}$; the conclusion $F_n \subseteq \mathcal{U}$ then gives $F_n \subseteq \mathcal{O}$.)

Consider the collection of subsets of X

$$\mathcal{C} = \{\mathcal{O}\} \cup \{X \sim F_n \mid n = 1, 2, \dots\}.$$

Every member of $\mathcal{C}$ is open: $\mathcal{O}$ is open by assumption, and each $X \sim F_n$ is open because F_n is closed. The collection $\mathcal{C}$ covers X . Indeed, by De Morgan's Identities,

$$\bigcup_{n=1}^{\infty} (X \sim F_n) = X \sim \bigcap_{n=1}^{\infty} F_n = X \sim F,$$

so that

$$\mathcal{O} \cup \bigcup_{n=1}^{\infty} (X \sim F_n) = \mathcal{O} \cup (X \sim F) = X,$$

the last equality because $F \subseteq \mathcal{O}$: any point of X either lies in F , and then lies in $\mathcal{O}$, or lies in $X \sim F$. Thus $\mathcal{C}$ is an open cover of the compact space X , and so it has a finite subcover. Enlarging that finite subcover by adjoining $\mathcal{O}$ if necessary (adding a set to a cover leaves it a cover), we obtain indices $n_1 < n_2 < \cdots < n_k$ such that

$$X = \mathcal{O} \cup \bigcup_{i=1}^k (X \sim F_{n_i}).$$

(In case the finite subcover uses no set of the form $X \sim F_n$ at all, we have $X = \mathcal{O}$ and the conclusion below holds trivially with $N = 1$.)

Set $N = n_k$. Since $\{F_n\}$ is descending, $F_N = F_{n_k} \subseteq F_{n_i}$ and therefore $X \sim F_{n_i} \subseteq X \sim F_N$ for each $i = 1, \dots, k$. Consequently

$$X = \mathcal{O} \cup \bigcup_{i=1}^k (X \sim F_{n_i}) \subseteq \mathcal{O} \cup (X \sim F_N) \subseteq X,$$

so that $X = \mathcal{O} \cup (X \sim F_N)$. Taking complements and using De Morgan's Identities,

$$\emptyset = X \sim [\mathcal{O} \cup (X \sim F_N)] = (X \sim \mathcal{O}) \cap F_N,$$

that is, F_N contains no point outside $\mathcal{O}$. Hence $F_N \subseteq \mathcal{O}$.

Finally, for every index $n \geq N$ the descending property gives $F_n \subseteq F_N \subseteq \mathcal{O}$. This is the assertion to be proved.

Two remarks. First, the Hausdorff assumption was not used: the conclusion holds for any compact topological space X . Second, the compactness of X may be weakened to countable compactness, since the open cover $\mathcal{C}$ constructed above is countable.

Problem 11.42. Show that it is not possible to express a closed, bounded interval of real numbers as the pairwise disjoint union of a countable collection (having more than one member) of closed, bounded intervals.

Solution. Of course the intervals in the collection are understood to be nonempty; otherwise the assertion is false for the trivial reason that one may adjoin copies of the empty set. Degenerate intervals $[c, c] = \{c\}$ are permitted; the proof below excludes them as well.

Argue by contradiction. Suppose

$$[a, b] = \bigcup_{n \in N} I_n,$$

where N is a countable index set with at least two members, each $I_n = [a_n, b_n]$ with $a_n \leq b_n$ is a nonempty closed bounded interval, and the I_n are pairwise disjoint.

Step 1: $a < b$. If $a = b$, then $[a, b]$ is a single point, and two disjoint nonempty subsets of a one-point set cannot exist. So $a < b$.

Step 2: two disjoint nonempty closed bounded intervals are ordered. Let $m \neq n$. If both $a_n \leq b_m$ and $a_m \leq b_n$ held, then $\max\{a_m, a_n\} \leq \min\{b_m, b_n\}$, and the point $\max\{a_m, a_n\}$ would belong to both I_m and I_n , contradicting disjointness. Hence either $b_m < a_n$ or $b_n < a_m$: one of the two intervals lies strictly to the left of the other.

Step 3: passage to a subinterval whose endpoints are degenerate pieces. Since N has at least two members, choose distinct indices and, by Step 2 and relabelling, obtain $p, q \in N$ with $b_p < a_q$. Put

$$\alpha = b_p, \quad \beta = a_q, \quad K = [\alpha, \beta],$$

so $\alpha < \beta$ and $K \subseteq [a, b]$. For $n \in N$ set $J_n = I_n \cap K$. Then each J_n is either empty or a closed bounded interval, since

$$[a_n, b_n] \cap [\alpha, \beta] = [\max\{a_n, \alpha\}, \min\{b_n, \beta\}]$$

whenever this is nonempty. The J_n are pairwise disjoint and their union is K . Let $M = \{n \in N : J_n \neq \emptyset\}$ and write $J_n = [c_n, d_n]$ for $n \in M$. Note M is countable and, since $\alpha \in I_p$ and $\beta \in I_q$, we have $p, q \in M$. Moreover

$$J_p = [a_p, b_p] \cap [b_p, \beta] = \{b_p\} = \{\alpha\}, \quad J_q = [a_q, b_q] \cap [\alpha, a_q] = \{a_q\} = \{\beta\}.$$

Thus $c_p = d_p = \alpha$ and $c_q = d_q = \beta$. Every point of K lies in exactly one J_n , $n \in M$.

Step 4: the set of endpoints. Put

$$G = \bigcup_{n \in M} (c_n, d_n), \quad P = K \sim G.$$

G is open, being a union of open intervals (those with $c_n = d_n$ contribute nothing), so P is a closed and bounded set of real numbers.

We claim $P = \{c_n : n \in M\} \cup \{d_n : n \in M\}$. If $x \in P$, then $x \in K$, so $x \in J_n$ for exactly one $n \in M$; as $x \notin G$ we have $x \notin (c_n, d_n)$, hence $x \in \{c_n, d_n\}$. Conversely, fix $n \in M$. Then $c_n \in J_n \subseteq K$, and $c_n \notin (c_n, d_n)$; while for $m \in M$ with $m \neq n$ we have $(c_m, d_m) \subseteq J_m$ and $J_m \cap J_n = \emptyset$, so $c_n \notin (c_m, d_m)$. Hence $c_n \notin G$, that is, $c_n \in P$; the same argument applies to d_n . This proves the claim. In particular P is nonempty, since $\alpha \in P$, and P is countable.

Step 5: P has no isolated points. Let $x \in P$ and let $n \in M$ be the unique index with $x \in J_n$; by Step 4, $x = c_n$ or $x = d_n$. Let $\varepsilon > 0$ be given. We produce a point of P different from x within distance ε of x .

Suppose first that $x = d_n$ and $d_n < \beta$. Put $c = \min\{d_n + \varepsilon/2, \beta\}$. Then $d_n < c \leq \beta$ and $c \geq \alpha$, so $c \in K$; let $m \in M$ be the index with $c \in J_m$. Since $c > d_n$ and $d_n = \max J_n$, we have $m \neq n$. If $c_m \leq d_n$, then $c_m \leq d_n < c$ with $c_m, c \in J_m$, and since J_m is an interval this forces $d_n \in J_m$, contradicting $J_m \cap J_n = \emptyset$. Hence $c_m > d_n = x$. Also $c_m \leq c \leq d_n + \varepsilon/2$. Therefore $c_m \in P$, $c_m \neq x$, and $|c_m - x| \leq \varepsilon/2 < \varepsilon$.

Suppose next that $x = c_n$ and $c_n > \alpha$. Put $c = \max\{c_n - \varepsilon/2, \alpha\}$. Then $\alpha \leq c < c_n \leq \beta$, so $c \in K$; let $m \in M$ be the index with $c \in J_m$. Since $c < c_n = \min J_n$ we have $m \neq n$. If $d_m \geq c_n$, then $c < c_n \leq d_m$ with $c, d_m \in J_m$, so the interval J_m would contain c_n , contradicting disjointness. Hence $d_m < c_n = x$, while $d_m \geq c \geq c_n - \varepsilon/2$. Therefore $d_m \in P$, $d_m \neq x$, and $|d_m - x| \leq \varepsilon/2 < \varepsilon$.

These two cases cover every point of P . Indeed, let $x \in P$, so $x = c_n$ or $x = d_n$. If $x = d_n$ with $d_n < \beta$, the first case applies. If $x = d_n = \beta$, then $\beta \in J_n \cap J_q$, so $n = q$ and hence $c_n = d_n = \beta > \alpha$; thus $x = c_n$ with $c_n > \alpha$ and the second case applies. If $x = c_n$ with $c_n > \alpha$, the second case applies. If $x = c_n = \alpha$, then $\alpha \in J_n \cap J_p$, so $n = p$ and hence $c_n = d_n = \alpha < \beta$, and the first case applies. Thus every point of P is a limit point of P : the set P has no isolated points.

Step 6: the Baire Category Theorem yields a contradiction. Regard P as a metric space with the metric inherited from $\mathbb{R}$. Then P is complete: a Cauchy sequence in P is Cauchy in $\mathbb{R}$, hence converges to some real number by the completeness of $\mathbb{R}$, and this limit belongs to P because P is closed. Also $P \neq \emptyset$.

For $n \in M$ put $E_n = P \cap J_n$. By Step 4, $E_n \subseteq \{c_n, d_n\}$, so E_n is a finite set; being finite, E_n is a closed subset of P . We show each E_n is hollow in P , that is, has empty interior in P . Suppose not, and let x be a point of P with $B(x, \delta) \cap P \subseteq E_n$ for some $\delta > 0$, where $B(x, \delta)$ denotes the open interval of radius δ about x . Then $B(x, \delta) \cap P$ is a finite set. By Step 5, x is a limit point of P , so the set

$$S = (B(x, \delta) \cap P) \sim \{x\}$$

is nonempty, and it is finite. Put $\delta' = \min\{|x - y| : y \in S\} > 0$ and $\delta'' = \min\{\delta, \delta'\} > 0$. Then $B(x, \delta'') \cap P = \{x\}$, so x is an isolated point of P , contradicting Step 5. Hence each E_n is a closed hollow subset of P .

Finally, since $K = \bigcup_{n \in M} J_n$ and $P \subseteq K$,

$$P = \bigcup_{n \in M} (P \cap J_n) = \bigcup_{n \in M} E_n,$$

a countable union of closed hollow subsets of the complete metric space P . By the Baire Category Theorem of Section 10.2, part (ii), the union $\bigcup_{n \in M} E_n$ is hollow in P ; that is, P has empty interior as a subset of itself. But P is open in P , so the interior of P in P is P itself, which is nonempty. This contradiction completes the proof.

Therefore a closed, bounded interval of real numbers cannot be written as the pairwise disjoint union of a countable collection, having more than one member, of nonempty closed bounded intervals.

11.7 Problems 11.43–11.49

Problem 11.43. Let f be a continuous mapping of the compact space X onto the Hausdorff space Y . Show that any mapping g of Y into Z for which $g \circ f$ is continuous must itself be continuous.

Solution. Let Z be a topological space, let $f: X \rightarrow Y$ be continuous and onto with X compact and Y Hausdorff, and let $g: Y \rightarrow Z$ be a mapping for which $g \circ f$ is continuous. To prove that g is continuous it suffices to show that $g^{-1}(W)$ is open in Y for every open subset W of Z , and this is equivalent to showing that $g^{-1}(V)$ is closed in Y for every closed subset V of Z , since $g^{-1}(Z \setminus V) = Y \setminus g^{-1}(V)$. So let V be a closed subset of Z and put

$$C = g^{-1}(V) \subseteq Y.$$

Since $g \circ f$ is continuous and V is closed, the preimage

$$(g \circ f)^{-1}(V) = f^{-1}(g^{-1}(V)) = f^{-1}(C)$$

is a closed subset of X . Since X is compact, Proposition 15 tells us that the closed set $f^{-1}(C)$ is compact. Therefore, by Proposition 20, its continuous image $f(f^{-1}(C))$ is a compact subspace of Y . Since Y is Hausdorff, Proposition 16 tells us that $f(f^{-1}(C))$ is a closed subset of Y .

Finally we use the surjectivity of f . In general $f(f^{-1}(C)) \subseteq C$. Conversely, if $y \in C$, then, since f maps X onto Y , there is a point $x \in X$ with $f(x) = y$; as $f(x) = y \in C$ we have $x \in f^{-1}(C)$ and hence $y = f(x) \in f(f^{-1}(C))$. Therefore

$$f(f^{-1}(C)) = C.$$

Consequently $C = g^{-1}(V)$ is a closed subset of Y .

Since V was an arbitrary closed subset of Z , the preimage under g of each closed set is closed, and hence the preimage under g of each open set is open. Thus g is continuous.

Observe what the argument really shows: a continuous mapping f of a compact space onto a Hausdorff space is a quotient map, that is, a subset C of Y is closed provided $f^{-1}(C)$ is closed, and it is exactly this property that forces g to be continuous.

Problem 11.44. Let $(X, \mathcal{T})$ be a topological space.

- (i) Prove that if $(X, \mathcal{T})$ is compact, then $(X, \mathcal{T}_1)$ is compact for any topology $\mathcal{T}_1$ weaker than $\mathcal{T}$.
- (ii) Show that if $(X, \mathcal{T})$ is Hausdorff, then $(X, \mathcal{T}_2)$ is Hausdorff for any topology $\mathcal{T}_2$ stronger than $\mathcal{T}$.
- (iii) Show that if $(X, \mathcal{T})$ is compact and Hausdorff, then any strictly weaker topology is not Hausdorff and any strictly stronger topology is not compact.

Solution. Recall that a topology $\mathcal{T}_1$ on X is called weaker than $\mathcal{T}$ provided $\mathcal{T}_1 \subseteq \mathcal{T}$, and $\mathcal{T}_2$ is called stronger than $\mathcal{T}$ provided $\mathcal{T} \subseteq \mathcal{T}_2$; the adjective “strictly” means that the containment is proper.

(i) Assume $(X, \mathcal{T})$ is compact and $\mathcal{T}_1 \subseteq \mathcal{T}$. Let $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ be a cover of X by sets belonging to $\mathcal{T}_1$. Since $\mathcal{T}_1 \subseteq \mathcal{T}$, each $\mathcal{O}_\lambda$ belongs to $\mathcal{T}$, so $\{\mathcal{O}_\lambda\}_{\lambda \in \Lambda}$ is also an open cover of the compact space $(X, \mathcal{T})$. Hence there are finitely many indices $\lambda_1, \dots, \lambda_n$ with $X = \bigcup_{k=1}^n \mathcal{O}_{\lambda_k}$. This is a finite subcover of the original $\mathcal{T}_1$ -open cover. Since every $\mathcal{T}_1$ -open cover of X has a finite subcover, $(X, \mathcal{T}_1)$ is compact.

(ii) Assume $(X, \mathcal{T})$ is Hausdorff and $\mathcal{T} \subseteq \mathcal{T}_2$. Let u and v be distinct points of X . Since $(X, \mathcal{T})$ is Hausdorff, there are disjoint sets $\mathcal{O}_u, \mathcal{O}_v \in \mathcal{T}$ with $u \in \mathcal{O}_u$ and $v \in \mathcal{O}_v$. Since $\mathcal{T} \subseteq \mathcal{T}_2$, the sets $\mathcal{O}_u$ and $\mathcal{O}_v$ also belong to $\mathcal{T}_2$. Thus u and v are separated by disjoint $\mathcal{T}_2$ -open sets, and $(X, \mathcal{T}_2)$ is Hausdorff.

(iii) Assume $(X, \mathcal{T})$ is compact and Hausdorff. The tool for both assertions is Proposition 19: a continuous one-to-one mapping of a compact space onto a Hausdorff space is a homeomorphism. We apply it to the identity mapping $\text{Id}: X \rightarrow X$, $\text{Id}(x) = x$, which is one-to-one and onto. Observe that Id , regarded as a mapping from $(X, \mathcal{T}_a)$ to $(X, \mathcal{T}_b)$, is continuous if and only if $\mathcal{T}_b \subseteq \mathcal{T}_a$, since $\text{Id}^{-1}(\mathcal{O}) = \mathcal{O}$; and it is a homeomorphism if and only if $\mathcal{T}_a = \mathcal{T}_b$.

First let $\mathcal{T}_1$ be a strictly weaker topology, so $\mathcal{T}_1 \subsetneq \mathcal{T}$, and suppose, to get a contradiction, that $(X, \mathcal{T}_1)$ is Hausdorff. Since $\mathcal{T}_1 \subseteq \mathcal{T}$, the identity map

$$\text{Id}: (X, \mathcal{T}) \rightarrow (X, \mathcal{T}_1)$$

is continuous; it is one-to-one and onto; its domain $(X, \mathcal{T})$ is compact and its target $(X, \mathcal{T}_1)$ is assumed Hausdorff. By Proposition 19, Id is a homeomorphism, so it carries $\mathcal{T}$ -open sets to $\mathcal{T}_1$ -open sets, that is, $\mathcal{T} \subseteq \mathcal{T}_1$. Together with $\mathcal{T}_1 \subseteq \mathcal{T}$ this gives $\mathcal{T}_1 = \mathcal{T}$, contradicting strictness. Hence no strictly weaker topology on X is Hausdorff.

Now let $\mathcal{T}_2$ be a strictly stronger topology, so $\mathcal{T} \subsetneq \mathcal{T}_2$, and suppose, to get a contradiction, that $(X, \mathcal{T}_2)$ is compact. Since $\mathcal{T} \subseteq \mathcal{T}_2$, the identity map

$$\text{Id}: (X, \mathcal{T}_2) \rightarrow (X, \mathcal{T})$$

is continuous; it is one-to-one and onto; its domain $(X, \mathcal{T}_2)$ is assumed compact and its target $(X, \mathcal{T})$ is Hausdorff. By Proposition 19, Id is a homeomorphism, whence $\mathcal{T}_2 \subseteq \mathcal{T}$ and therefore $\mathcal{T}_2 = \mathcal{T}$, again contradicting strictness. Hence no strictly stronger topology on X is compact.

In summary, a compact Hausdorff topology is minimal among Hausdorff topologies and maximal among compact topologies. Note also that (i) and (ii) show that the two failures in (iii) are the only ones possible: a weaker topology automatically remains compact and a stronger one automatically remains Hausdorff.

Problem 11.45. (The Compact-Open Topology) Let X and Y be Hausdorff topological spaces and Y^X the collection of maps from X into Y . On Y^X we define a topology, called the compact-open topology, by taking as a subbase sets of the form $\mathcal{U}_{K, \mathcal{O}} = \{f: X \rightarrow Y \mid f(K) \subseteq \mathcal{O}\}$, where K is a compact subset of X and $\mathcal{O}$ is an open subset of Y . Thus the compact-open topology is the weakest topology on Y^X such that the sets $\mathcal{U}_{K, \mathcal{O}}$ are open.

(i) Let $\{f_n\}$ be a sequence in Y^X that converges with respect to the compact-open topology to $f \in Y^X$. Show that $\{f_n\}$ converges pointwise to f on X .

(ii) Now assume that Y is a metric space. Show that a sequence $\{f_n\}$ in Y^X converges with respect to the compact-open topology to $f \in Y^X$ if and only if $\{f_n\}$ converges to f uniformly on each compact subset K of X .

Solution. Throughout, recall that a sequence $\{f_n\}$ in a topological space converges to f provided that for each neighborhood $\mathcal{U}$ of f there is an index N for which $f_n \in \mathcal{U}$ for all $n \geq N$. Since the sets $\mathcal{U}_{K, \mathcal{O}}$ form a subbase for the compact-open topology, the finite intersections

$$\mathcal{U}_{K_1, \mathcal{O}_1} \cap \cdots \cap \mathcal{U}_{K_m, \mathcal{O}_m}$$

form a base. Hence $f_n \rightarrow f$ in the compact-open topology if and only if for every finite family of pairs $(K_i, \mathcal{O}_i)$, $1 \leq i \leq m$, with K_i compact, $\mathcal{O}_i$ open and $f(K_i) \subseteq \mathcal{O}_i$, there is an index N with $f_n(K_i) \subseteq \mathcal{O}_i$ for all $n \geq N$ and all i . Since an index that works for each of finitely many subbasic sets separately

also works for their intersection, this is in turn equivalent to the single-set condition:

for every compact $K \subseteq X$ and open $\mathcal{O} \subseteq Y$ with $f(K) \subseteq \mathcal{O}$, there is N with $f_n(K) \subseteq \mathcal{O}$ for $n \geq N$. (*)

(i) Assume $f_n \rightarrow f$ in the compact-open topology and fix $x \in X$. Let $\mathcal{O}$ be any open subset of Y containing $f(x)$. The singleton $K = \{x\}$ is a compact subset of X , and $f(K) = \{f(x)\} \subseteq \mathcal{O}$, so $\mathcal{U}_{K, \mathcal{O}}$ is a subbasic open set containing f , hence a neighborhood of f . Therefore there is an index N such that $f_n \in \mathcal{U}_{K, \mathcal{O}}$ for all $n \geq N$, that is, $f_n(x) \in \mathcal{O}$ for all $n \geq N$. Since $\mathcal{O}$ was an arbitrary open set containing $f(x)$, the sequence $\{f_n(x)\}$ converges to $f(x)$ in Y . As $x \in X$ was arbitrary, $\{f_n\}$ converges pointwise to f .

(ii) Let ρ denote the metric on Y and write $B(y, r) = \{z \in Y \mid \rho(z, y) < r\}$. We prove the asserted equivalence for a limit function f that is continuous; at the end we show by examples that continuity of f cannot be dispensed with, so that this is the correct reading of the assertion.

First assume that $\{f_n\}$ converges to f uniformly on each compact subset of X ; we verify (*). Let $K \subseteq X$ be compact and $\mathcal{O} \subseteq Y$ open with $f(K) \subseteq \mathcal{O}$. Since f is continuous and K is compact, $f(K)$ is compact by Proposition 20. We claim there is an $\epsilon > 0$ such that

$$\{z \in Y \mid \rho(z, y) < \epsilon \text{ for some } y \in f(K)\} \subseteq \mathcal{O}.$$

Indeed, for each $y \in f(K)$, since $\mathcal{O}$ is open and $y \in \mathcal{O}$, there is $r_y > 0$ with $B(y, 2r_y) \subseteq \mathcal{O}$. The collection $\{B(y, r_y)\}_{y \in f(K)}$ is an open cover of the compact set $f(K)$, so there are $y_1, \dots, y_p$ in $f(K)$ with $f(K) \subseteq \bigcup_{j=1}^p B(y_j, r_{y_j})$. Put $\epsilon = \min\{r_{y_1}, \dots, r_{y_p}\} > 0$. If $\rho(z, y) < \epsilon$ for some $y \in f(K)$, choose j with $\rho(y, y_j) < r_{y_j}$; then

$$\rho(z, y_j) \leq \rho(z, y) + \rho(y, y_j) < \epsilon + r_{y_j} \leq 2r_{y_j},$$

so $z \in B(y_j, 2r_{y_j}) \subseteq \mathcal{O}$. This proves the claim. (If $K = \emptyset$ there is nothing to prove.)

By the assumed uniform convergence on the compact set K , there is an index N such that $\rho(f_n(x), f(x)) < \epsilon$ for all $x \in K$ and all $n \geq N$. For such n and x , the point $z = f_n(x)$ is within ϵ of the point $f(x) \in f(K)$, so $f_n(x) \in \mathcal{O}$ by the claim. Thus $f_n(K) \subseteq \mathcal{O}$ for $n \geq N$, which is (*). Hence $f_n \rightarrow f$ in the compact-open topology.

Conversely, assume $f_n \rightarrow f$ in the compact-open topology. Let K be a compact subset of X and let $\epsilon > 0$. We produce a basic neighborhood of f that pins down f on all of K to within ϵ . Since X is Hausdorff and K is compact, K with its subspace topology is a compact Hausdorff space, and therefore is normal, by Theorem 18; in particular K is regular. For each $x \in K$ the set

$$V_x = K \cap f^{-1}(B(f(x), \epsilon/3))$$

is relatively open in K and contains x , since f is continuous. By the regularity of K there is a relatively open subset W_x of K with

$$x \in W_x \subseteq \overline{W_x} \subseteq V_x,$$

where the closure is taken in K . The sets $\{W_x\}_{x \in K}$ form a relatively open cover of the compact space K , so there are points $x_1, \dots, x_m$ in K with $K = \bigcup_{i=1}^m W_{x_i}$. Put $K_i = \overline{W_{x_i}}$, the closure taken in K . Each K_i is a closed subset of the compact space K , hence compact by Proposition 15, and therefore is a compact subset of X . Moreover

$$f(K_i) \subseteq f(V_{x_i}) \subseteq B(f(x_i), \epsilon/3) \subseteq \mathcal{O}_i := B(f(x_i), \epsilon/2),$$

and each $\mathcal{O}_i$ is open in Y . Therefore f belongs to the basic open set $\bigcap_{i=1}^m \mathcal{U}_{K_i, \mathcal{O}_i}$, which is thus a neighborhood of f in the compact-open topology. Choose N so that $f_n \in \bigcap_{i=1}^m \mathcal{U}_{K_i, \mathcal{O}_i}$ for all $n \geq N$. Let $n \geq N$ and $x \in K$. Since the W_{x_i} cover K , there is an index i with $x \in W_{x_i} \subseteq K_i$. Then $f_n(x) \in \mathcal{O}_i$, so $\rho(f_n(x), f(x_i)) < \epsilon/2$, while $x \in K_i \subseteq V_{x_i}$ gives $\rho(f(x), f(x_i)) < \epsilon/3$. By the triangle inequality,

$$\rho(f_n(x), f(x)) < \frac{\epsilon}{2} + \frac{\epsilon}{3} < \epsilon.$$

Since this holds for every $x \in K$ and every $n \geq N$, the sequence $\{f_n\}$ converges to f uniformly on K . As K was an arbitrary compact subset of X , the proof of the equivalence is complete.

A remark on the hypothesis of continuity. If arbitrary (possibly discontinuous) members of Y^X are allowed, both implications fail, so the equivalence in (ii) must be understood for a continuous limit function f , as in the classical setting where the compact-open topology is placed on the space of continuous maps. Take $X = [0, 1]$ and $Y = \mathbb{R}$, both Hausdorff.

For the failure of “uniform convergence on compact sets implies compact-open convergence”, let $f(x) = x$ for $0 \leq x < 1$ and $f(1) = 0$, and let $f_n = f + 1/n$. Then $\{f_n\}$ converges to f uniformly on all of X . But with $K = [0, 1]$ and $\mathcal{O} = (-1, 1)$ we have $f(K) = [0, 1) \subseteq \mathcal{O}$, whereas $f_n(1 - 1/(2n)) = 1 + 1/(2n) \notin \mathcal{O}$, so $f_n \notin \mathcal{U}_{K, \mathcal{O}}$ for every n ; thus $\{f_n\}$ does not converge to f in the compact-open topology.

For the failure of the reverse implication, let $f(0) = 1$ and $f(x) = 0$ for $0 < x \leq 1$, and let f_n agree with f except that $f_n(1/n) = 1$. Then $\sup_{x \in [0, 1]} |f_n(x) - f(x)| = 1$ for every n , so there is no uniform convergence on the compact set $[0, 1]$. Nevertheless $f_n \rightarrow f$ in the compact-open topology: let K be compact with $f(K) \subseteq \mathcal{O}$, $\mathcal{O}$ open. Since f_n differs from f only by taking the value 1 at one additional point, $f_n(K) \subseteq f(K) \cup \{1\}$ for every n . If $0 \in K$, then $1 = f(0) \in f(K) \subseteq \mathcal{O}$, so $f_n(K) \subseteq f(K) \cup \{1\} \subseteq \mathcal{O}$ for all n . If $0 \notin K$, then K is a closed subset of $[0, 1]$ missing 0, so $K \subseteq [\delta, 1]$ for some $\delta > 0$; hence $1/n \notin K$ once $n > 1/\delta$, and then $f_n(K) = f(K) = \{0\} \subseteq \mathcal{O}$. Thus $(*)$ holds, and $f_n \rightarrow f$ in the compact-open topology.

Problem 11.46. (Dini’s Theorem) Let $\{f_n\}$ be a sequence of continuous real-valued functions on a countably compact space X . Suppose that for each $x \in X$, the sequence $\{f_n(x)\}$ decreases monotonically to zero. Show that $\{f_n\}$ converges to zero uniformly.

Solution. Recall that X is countably compact provided every countable open cover of X has a finite subcover.

We first record an elementary consequence of the hypothesis: for each $x \in X$ and each index n we have $f_n(x) \geq 0$. Indeed, the sequence of real numbers $\{f_n(x)\}$ is decreasing with limit 0, so for $m \geq n$ we have $f_n(x) \geq f_m(x)$, and letting $m \rightarrow \infty$ gives $f_n(x) \geq 0$. Thus $|f_n(x)| = f_n(x)$ throughout.

Let $\epsilon > 0$. For each index n define

$$\mathcal{O}_n = \{x \in X \mid f_n(x) < \epsilon\} = f_n^{-1}((-\infty, \epsilon)).$$

Since f_n is continuous and $(-\infty, \epsilon)$ is an open subset of $\mathbb{R}$, each $\mathcal{O}_n$ is an open subset of X .

The collection $\{\mathcal{O}_n\}_{n=1}^{\infty}$ is ascending: if $x \in \mathcal{O}_n$, then, by the monotone decrease of $\{f_k(x)\}$, we have $f_{n+1}(x) \leq f_n(x) < \epsilon$, so $x \in \mathcal{O}_{n+1}$. Hence

$$\mathcal{O}_1 \subseteq \mathcal{O}_2 \subseteq \mathcal{O}_3 \subseteq \cdots$$

The collection $\{\mathcal{O}_n\}_{n=1}^{\infty}$ is a cover of X : let $x \in X$; since $\{f_n(x)\}$ converges to 0, there is an index n with $f_n(x) < \epsilon$, that is, $x \in \mathcal{O}_n$.

Thus $\{\mathcal{O}_n\}_{n=1}^{\infty}$ is a countable open cover of X . Since X is countably compact, there are finitely many indices $n_1, \dots, n_k$ with

$$X = \bigcup_{j=1}^k \mathcal{O}_{n_j}.$$

Let $N = \max\{n_1, \dots, n_k\}$. Since the collection is ascending, $\mathcal{O}_{n_j} \subseteq \mathcal{O}_N$ for each j , and therefore $X = \mathcal{O}_N$. Ascendingness also gives $\mathcal{O}_N \subseteq \mathcal{O}_n$ for every $n \geq N$, so

$$X = \mathcal{O}_n \quad \text{for all } n \geq N.$$

By the definition of $\mathcal{O}_n$ this says precisely that

$$0 \leq f_n(x) < \epsilon \quad \text{for all } x \in X \text{ and all } n \geq N,$$

where the left inequality is the observation made at the outset. Hence

$$\sup_{x \in X} |f_n(x) - 0| \leq \epsilon \quad \text{for all } n \geq N.$$

Since $\epsilon > 0$ was arbitrary, $\{f_n\}$ converges to 0 uniformly on X .

Two remarks on the necessity of the hypotheses. Monotonicity is essential: on the compact space $X = [0, 1]$, for $n \geq 2$ let f_n be the “tent” function that is piecewise linear with $f_n(0) = 0$, $f_n(1/n) = 1$, $f_n(2/n) = 0$, and $f_n \equiv 0$ on $[2/n, 1]$. Each f_n is continuous and $\{f_n(x)\}$ converges to 0 for each x , since $f_n(x) = 0$ once $n > 2/x$ and $f_n(0) = 0$ for all n ; but $\sup_{x \in X} f_n(x) = 1$ for every n , so the convergence is not uniform. Of course $\{f_n(x)\}$ does not decrease monotonically. Countable compactness is likewise essential: on $X = (0, 1)$, the functions $f_n(x) = \min\{1, 1/(nx)\}$ decrease pointwise to 0 but $\sup_X f_n = 1$ for every n .

Problem 11.47. Let $\{C_\lambda\}_{\lambda \in \Lambda}$ be a collection of connected subsets of a topological space X and suppose that any two of them have a point in common. Show that the union of $\{C_\lambda\}_{\lambda \in \Lambda}$ also is connected.

Solution. Recall the criterion stated in the text: a subset E of X is connected provided there do not exist open subsets $\mathcal{O}_1$ and $\mathcal{O}_2$ of X for which

$$\mathcal{O}_1 \cap E \neq \emptyset, \quad \mathcal{O}_2 \cap E \neq \emptyset, \quad E \subseteq \mathcal{O}_1 \cup \mathcal{O}_2, \quad \text{and} \quad E \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset.$$

Put $C = \bigcup_{\lambda \in \Lambda} C_\lambda$ and argue by contradiction: assume C is not connected, so there are open subsets $\mathcal{O}_1, \mathcal{O}_2$ of X with

$$\mathcal{O}_1 \cap C \neq \emptyset, \quad \mathcal{O}_2 \cap C \neq \emptyset, \quad C \subseteq \mathcal{O}_1 \cup \mathcal{O}_2, \quad C \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset.$$

Fix any index $\lambda \in \Lambda$. Since $C_\lambda \subseteq C$, we have

$$C_\lambda \subseteq \mathcal{O}_1 \cup \mathcal{O}_2 \quad \text{and} \quad C_\lambda \cap \mathcal{O}_1 \cap \mathcal{O}_2 \subseteq C \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset.$$

Thus $\mathcal{O}_1, \mathcal{O}_2$ satisfy three of the four conditions above with $E = C_\lambda$. Since C_λ is connected, the remaining condition must fail, that is, $C_\lambda \cap \mathcal{O}_1 = \emptyset$ or $C_\lambda \cap \mathcal{O}_2 = \emptyset$. In the first case $C_\lambda \subseteq \mathcal{O}_2$ and in the second $C_\lambda \subseteq \mathcal{O}_1$, because $C_\lambda \subseteq \mathcal{O}_1 \cup \mathcal{O}_2$. Hence:

$$\text{for each } \lambda \in \Lambda, \text{ either } C_\lambda \subseteq \mathcal{O}_1 \text{ or } C_\lambda \subseteq \mathcal{O}_2. \quad (\dagger)$$

Since $\mathcal{O}_1 \cap C \neq \emptyset$, there is a point $p_1 \in \mathcal{O}_1 \cap C$, and since C is the union of the C_λ 's there is an index λ_1 with $p_1 \in C_{\lambda_1}$. Then $C_{\lambda_1} \cap \mathcal{O}_1 \neq \emptyset$, so by $(\dagger)$ and the disjointness relation $C \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset$ we must have $C_{\lambda_1} \subseteq \mathcal{O}_1$: indeed, if instead $C_{\lambda_1} \subseteq \mathcal{O}_2$, then $p_1 \in C \cap \mathcal{O}_1 \cap \mathcal{O}_2$, which is empty. Symmetrically, there is an index λ_2 with $C_{\lambda_2} \subseteq \mathcal{O}_2$ and $C_{\lambda_2} \neq \emptyset$.

By hypothesis any two members of the collection have a point in common, so choose $q \in C_{\lambda_1} \cap C_{\lambda_2}$. (If $\lambda_1 = \lambda_2$ this set is C_{λ_1} , which is nonempty since it contains p_1 , so such a q exists in every case.) Then

$$q \in C_{\lambda_1} \subseteq \mathcal{O}_1, \quad q \in C_{\lambda_2} \subseteq \mathcal{O}_2, \quad q \in C,$$

so $q \in C \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset$. This contradiction shows that no such pair $\mathcal{O}_1, \mathcal{O}_2$ exists.

Therefore $C = \bigcup_{\lambda \in \Lambda} C_\lambda$ is connected.

Problem 11.48. Let A be a connected subset of a topological space X , and suppose $A \subseteq B \subseteq \overline{A}$. Show that B is connected.

Solution. We again use the criterion recorded in the text: a subset E of X is connected provided there do not exist open subsets $\mathcal{O}_1, \mathcal{O}_2$ of X with $\mathcal{O}_1 \cap E \neq \emptyset$, $\mathcal{O}_2 \cap E \neq \emptyset$, $E \subseteq \mathcal{O}_1 \cup \mathcal{O}_2$ and $E \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset$. Argue by contradiction. Suppose B is not connected, and let $\mathcal{O}_1, \mathcal{O}_2$ be open subsets of X with

$$\mathcal{O}_1 \cap B \neq \emptyset, \quad \mathcal{O}_2 \cap B \neq \emptyset, \quad B \subseteq \mathcal{O}_1 \cup \mathcal{O}_2, \quad B \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset.$$

Since $A \subseteq B$, we have $A \subseteq \mathcal{O}_1 \cup \mathcal{O}_2$ and $A \cap \mathcal{O}_1 \cap \mathcal{O}_2 \subseteq B \cap \mathcal{O}_1 \cap \mathcal{O}_2 = \emptyset$. Because A is connected, the pair $\mathcal{O}_1, \mathcal{O}_2$ cannot meet both of the remaining requirements, so at least one of $A \cap \mathcal{O}_1$ and $A \cap \mathcal{O}_2$ is

empty. Relabeling if necessary, assume

$$A \cap \mathcal{O}_2 = \emptyset.$$

Then $A \subseteq X \sim \mathcal{O}_2$. The set $X \sim \mathcal{O}_2$ is closed, since $\mathcal{O}_2$ is open, and the closure $\overline{A}$ is the smallest closed set containing A . Therefore

$$\overline{A} \subseteq X \sim \mathcal{O}_2.$$

Since $B \subseteq \overline{A}$, it follows that $B \subseteq X \sim \mathcal{O}_2$, that is,

$$B \cap \mathcal{O}_2 = \emptyset.$$

This contradicts the requirement $\mathcal{O}_2 \cap B \neq \emptyset$.

Hence no such pair of open sets exists and B is connected. In particular, taking $B = \overline{A}$, the closure of a connected set is connected.

Problem 11.49. Show that the following subset of the plane is connected but not arcwise connected.

$$X = \{(x, y) \mid x = 0, -1 \leq y \leq 1\} \cup \{(x, y) \mid y = \sin 1/x, 0 < x \leq 1\}.$$

Solution. Write

$$S = \{(0, y) \mid -1 \leq y \leq 1\}, \quad T = \{(x, \sin 1/x) \mid 0 < x \leq 1\}, \quad X = S \cup T,$$

and give X the subspace topology inherited from the plane $\mathbb{R}^2$.

Part 1: X is connected.

The set T is connected. Indeed, define $\varphi: (0, 1] \rightarrow \mathbb{R}^2$ by $\varphi(x) = (x, \sin 1/x)$. Each coordinate function is continuous on $(0, 1]$, so φ is continuous, and $\varphi((0, 1]) = T$. The interval $(0, 1]$ is a connected subset of $\mathbb{R}$, by the equivalence (1) of Section 11.6, which identifies the connected sets of real numbers with the intervals. Hence, by Proposition 22, the image $T = \varphi((0, 1])$ is connected.

Next we show that S is contained in the closure of T ; equivalently, $X \subseteq \overline{T}$, since $T \subseteq \overline{T}$. Let $(0, y_0) \in S$, so $-1 \leq y_0 \leq 1$. Choose $t_0 \in \mathbb{R}$ with $\sin t_0 = y_0$, which is possible since $\sin$ maps $\mathbb{R}$ onto $[-1, 1]$. For each natural number n large enough that $t_0 + 2\pi n > 1$, set

$$x_n = \frac{1}{t_0 + 2\pi n} \in (0, 1], \quad \text{so that} \quad \sin \frac{1}{x_n} = \sin(t_0 + 2\pi n) = \sin t_0 = y_0.$$

Thus $(x_n, y_0) \in T$ for all such n , and $x_n \rightarrow 0$, so $(x_n, y_0) \rightarrow (0, y_0)$ in $\mathbb{R}^2$. Every neighborhood of $(0, y_0)$ therefore contains points of T , and hence $(0, y_0) \in \overline{T}$. Since $(0, y_0) \in S$ was arbitrary, $S \subseteq \overline{T}$ and therefore

$$T \subseteq X \subseteq \overline{T},$$

the closure being taken in $\mathbb{R}^2$. By Problem 48, applied in the topological space $\mathbb{R}^2$ with $A = T$ and $B = X$, the set X is a connected subset of $\mathbb{R}^2$; since connectedness of a subset means connectedness of the corresponding subspace, X is a connected topological space.

Part 2: X is not arcwise connected.

Recall that X is arcwise connected provided for each pair of points $u, v \in X$ there is a continuous map $f: [0, 1] \rightarrow X$ with $f(0) = u$ and $f(1) = v$. We show that no such map exists for

$$u = (0, 0) \in S \quad \text{and} \quad v = (1, \sin 1) \in T.$$

Suppose, to get a contradiction, that $f: [0, 1] \rightarrow X$ is continuous with $f(0) = u$ and $f(1) = v$. Write $f(t) = (x(t), y(t))$; since the two coordinate projections of $\mathbb{R}^2$ onto $\mathbb{R}$ are continuous, x and y are continuous real-valued functions on $[0, 1]$. Note that a point of X lies in S exactly when its first coordinate is 0, and lies in T exactly when its first coordinate is positive, in which case its second coordinate equals the sine of the reciprocal of its first coordinate.

Consider

$$A = f^{-1}(S) = \{t \in [0, 1] \mid x(t) = 0\} = x^{-1}(\{0\}).$$

Since x is continuous and $\{0\}$ is closed in $\mathbb{R}$, the set A is a closed subset of $[0, 1]$. It is nonempty, since $x(0) = 0$, and it is not all of $[0, 1]$, since $x(1) = 1$. Let

$$c = \sup A.$$

Since A is closed and bounded and nonempty, $c \in A$, so $x(c) = 0$; and $c < 1$ since $1 \notin A$. If $t \in (c, 1]$ then $t \notin A$, so $x(t) \neq 0$; but $f(t)$ belongs to $X = S \cup T$ and every point of X has nonnegative first coordinate, so $x(t) \geq 0$. Hence

$$x(t) > 0 \quad \text{for all } t \in (c, 1],$$

so $f(t) \in T$ for all $t \in (c, 1]$, and consequently

$$y(t) = \sin \frac{1}{x(t)} \quad \text{for all } t \in (c, 1]. \quad (*)$$

Since y is continuous at c , there is a $\delta > 0$ with $c + \delta \leq 1$ such that

$$|y(t) - y(c)| < \frac{1}{2} \quad \text{for all } t \in [c, c + \delta]. \quad (**)$$

Put $a = x(c + \delta) > 0$, since $c + \delta \in (c, 1]$. The closed interval $[c, c + \delta]$ is a connected topological space, again by the equivalence (1) of Section 11.6, so by Proposition 23 it has the intermediate value property: the image $x([c, c + \delta])$ is an interval. This interval contains $x(c) = 0$ and $x(c + \delta) = a$, hence it contains all of $[0, a]$.

Choose a natural number n so large that

$$u_n := \frac{1}{\pi/2 + 2\pi n} \leq a \quad \text{and} \quad v_n := \frac{1}{3\pi/2 + 2\pi n} \leq a,$$

which is possible since both quantities tend to 0 as $n \rightarrow \infty$. Both u_n and v_n lie in $(0, a]$, so by the previous paragraph there are points $s, t \in [c, c + \delta]$ with $x(s) = u_n$ and $x(t) = v_n$. Since $x(s) > 0$ and $x(t) > 0$, neither s nor t equals c , so both lie in $(c, c + \delta]$, and $(*)$ applies:

$$y(s) = \sin \frac{1}{u_n} = \sin \left(\frac{\pi}{2} + 2\pi n \right) = 1, \quad y(t) = \sin \frac{1}{v_n} = \sin \left(\frac{3\pi}{2} + 2\pi n \right) = -1.$$
